PROGRAMMABLE CONTROLLER INTERFACE

The Chrysler **programmable controller interface (PCI)** is a one-wire communication protocol that connects at the OBD-II DLC at terminal 2. The PCI BUS is connected to all modules on the BUS in a star configuration and operates at a baud rate of 10,200 bps. The voltage signal toggles between 7.5 and 0 V. If this voltage is checked at terminal 2 of the OBD-II DLC, a voltage of about 1 V indicates the average voltage and means that the BUS is functioning and is not shorted-to-ground. PCI and CCD are often used in the same vehicle. ● **SEE FIGURE 49–18.**

SERIAL COMMUNICATIONS INTERFACE

Chrysler used **serial communications interface (SCI)** for most scan tool and flash reprogramming functions until it was replaced with CAN. SCI is connected at the OBD-II diagnostic link connector (DLC) at terminals 6 (SCI receive) and 7 (SCI transmit). A scan tool must be connected to test the circuit.

CONTROLLER AREA NETWORK

BACKGROUND

Robert Bosch Corporation developed the CAN protocol, which was called CAN 1.2, in 1993. The CAN protocol was approved by the Environmental Protection Agency (EPA) for 2003 and newer vehicle diagnostics, and a legal requirement for all vehicles by 2008. The CAN diagnostic systems use pins 6 and 14 in the standard 16 pin OBD-II (J-1962) connector. Before CAN, the scan tool protocol had been manufacturer specific.

CAN FEATURES

The CAN protocol offers the following features.

- Faster than other BUS communication protocols
- Cost effective because it is an easier system than others to use

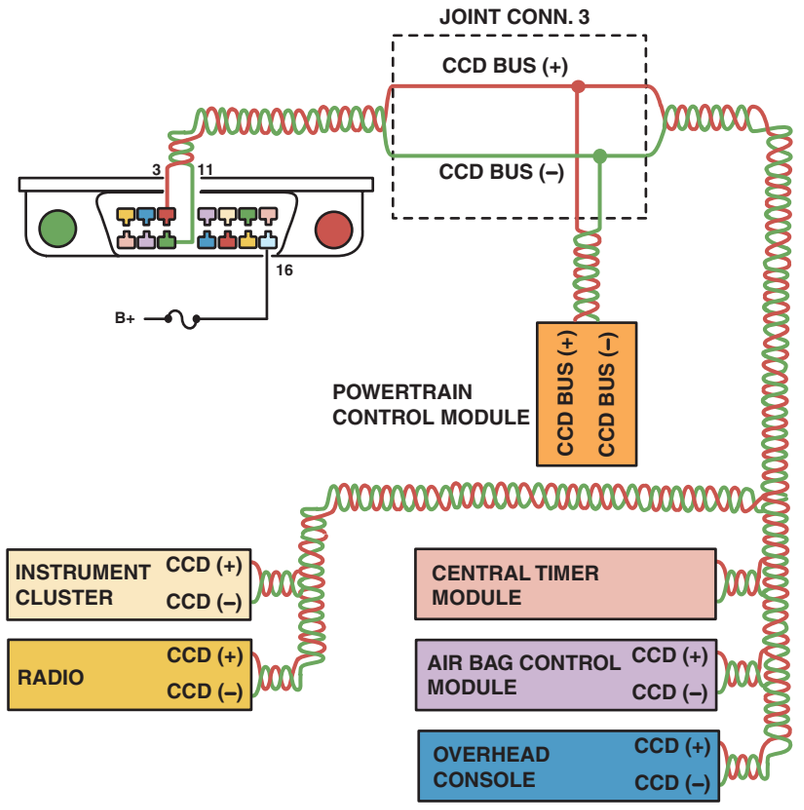

FIGURE 49–16 CCD signals are labeled plus and minus and use a twisted pair of wires. Notice that terminals 3 and 11 of the data link connector are used to access the CCD BUS from a scan tool. Pin 16 is used to supply 12 volts to the scan tool.

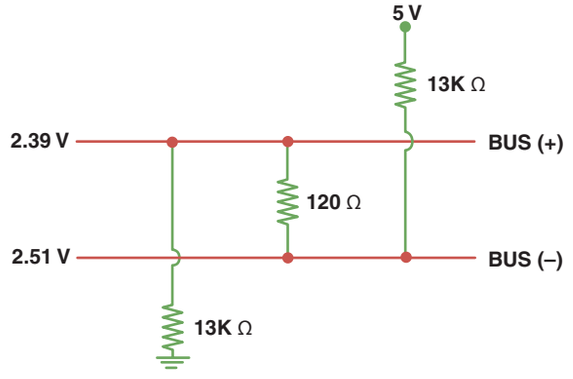

FIGURE 49–17 The differential voltage for the CCD BUS is created by using resistors in a module.

- Less effected by electromagnetic interference (Data is transferred on two wires that are twisted together, called twisted pair, to help reduce EMI interference.)
- Message based rather than address based which makes it easier to expand
- No wakeup needed because it is a two-wire system
- Supports up to15 modules plus a scan tool
- Uses a 120 ohm resistor at the ends of each pair to reduce electrical noise
- Applies 2.5 volts on both wires:
  H (high) goes to 3.5 volts when active
  L (low) goes to 1.5 volts when active
  ● **SEE FIGURE 49–19.**

CAN CLASS A, B, AND C There are three classes of CAN and they operate at different speeds. The CAN A, B, and C networks can all be linked using a gateway within the same vehicle. The gateway is usually one of the many modules in the vehicle.

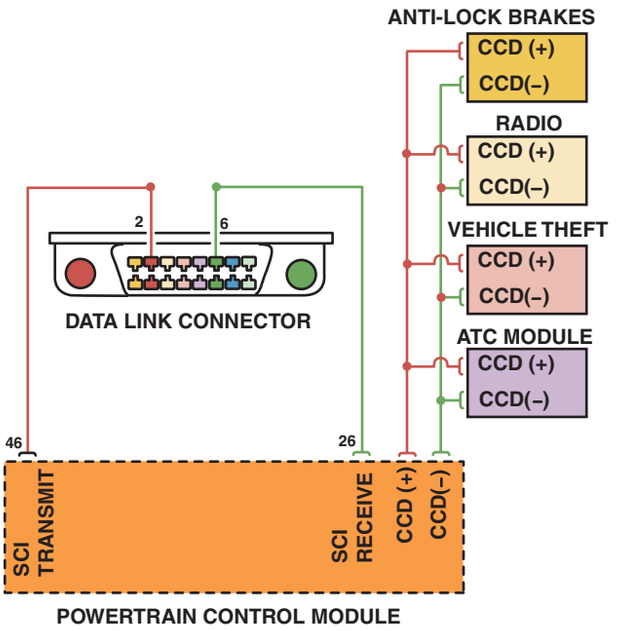

FIGURE 49–18 Many Chrysler vehicles use both SCI and CCD for module communication.

- **CAN A.** This class operates on only one wire at slow speeds and is therefore less expensive to build. CAN A operates a data transfer rate of 33.33 Kbs in normal mode and up to 83.33 Kbs during reprogramming mode. CAN A uses the vehicle ground as the signal return circuit.
- **CAN B.** This class operates on a two-wire network and does not use the vehicle ground as the signal return circuit. CAN B

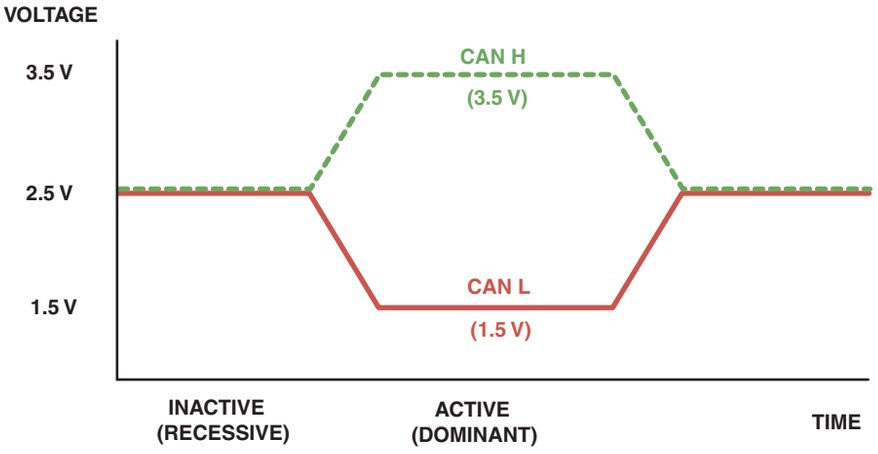

FIGURE 49–19 CAN uses a differential type of module communication where the voltage on one wire is the equal but opposite voltage on the other wire. When no communication is occurring, both wires have 2.5 volts applied. When communication is occurring, CAN H (high) goes up 1 volt to 3.5 volts and CAN L (low) goes down 1 volt to 1.5 volts.

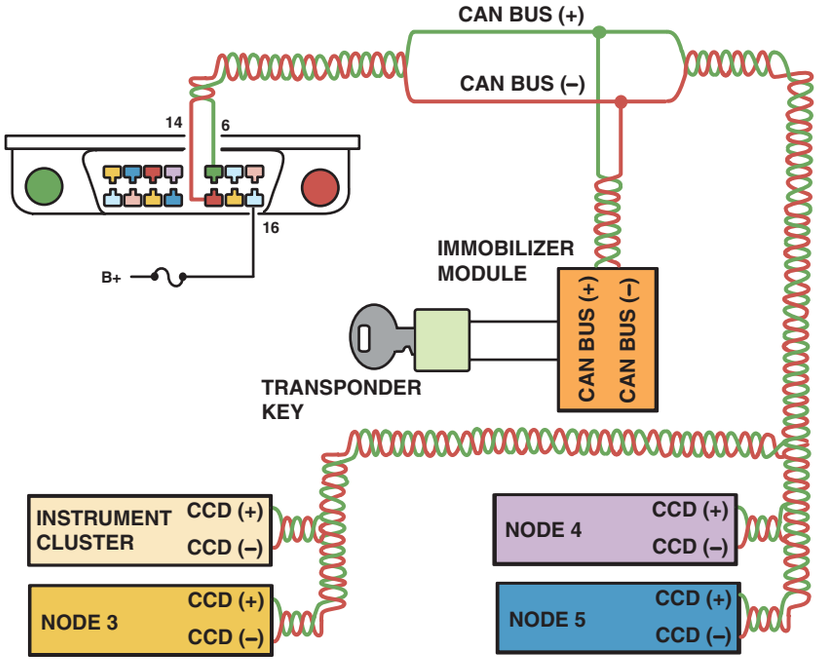

FIGURE 49–20 A typical (generic) system showing how the CAN BUS is connected to various electrical accessories and systems in the vehicle.

uses a data transfer rate of 95.2 Kbs. Instead, CAN B (and CAN C) uses two network wires for differential signaling. This means that the two data signal voltages are opposite to each other and used for error detection by constantly being compared. In this case, when the signal voltage at one of the CAN data wires goes high (CAN H), the other one goes low (CAN L), hence the name *differential signaling.* Differential signaling is also used for redundancy, in case one of the signal wires shorts out.

- **CAN C.** This class is the highest speed CAN protocol with speeds up to 500 Kbs. Beginning with 2008 models, all vehicles sold in the United States must use CAN BUS for scan tool communications. Most vehicle manufacturers started using CAN in older models; and it is easy to determine if a vehicle is equipped with CAN. The CAN BUS communicates to the scan tool through terminals 6 and 14 of the DLC indicating that the vehicle is equipped with CAN. ● **SEE FIGURE 49–20.**

The total voltage remains constant at all times and the electromagnetic field effects of the two data BUS lines cancel each other out. The data BUS line is protected against received radiation and is virtually neutral in sending radiation.

HONDA/TOYOTA COMMUNICATIONS

The primary BUS communications on pre-CAN-equipped vehicles is ISO 9141-2 using terminals 7 and 15 at the OBD-II DLC. ● **SEE FIGURE 49–21.**

A factory scan tool or an aftermarket scan tool equipped with enhanced original equipment (OE) software is needed to access many of the BUS messages. ● **SEE FIGURE 49–22.**

EUROPEAN BUS COMMUNICATIONS

UNIQUE DIAGNOSTIC CONNECTOR Many different types of module communications protocols are used on European vehicles such as Mercedes and BMW.

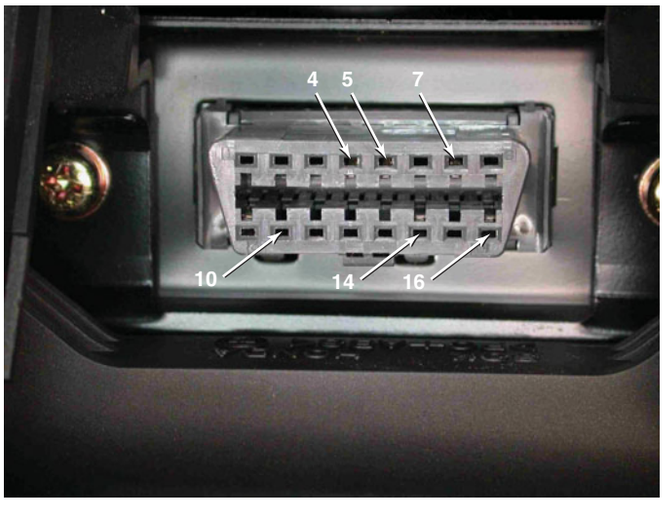

FIGURE 49–21 A DLC from a pre-CAN Acura. It shows terminals in cavities 4, 5 (grounds), 7, 10, 14, and 16 (B+).

FIGURE 49–22 A Honda scan display showing a B and two U codes, all indicating a BUS-related problem(s).

Most of these communication BUS messages cannot be accessed through the data link connector (DLC). To check the operation of the individual modules, a scan tool equipped with factory-type software will be needed to communicate with the module through the gateway module. ● **SEE FIGURE 49–23** for an alternative access method to the modules.

MEDIA ORIENTED SYSTEM TRANSPORT BUS The media oriented system transport (MOST) BUS uses fiber optics for module-to-module communications in a ring or star configuration. This BUS system is currently being used for entertainment equipment data communications for videos, CDs, and other media systems in the vehicle.

MOTOROLA INTERCONNECT BUS Motorola interconnect (MI) is a single-wire serial communications protocol, using one master control module and many slave modules. Typical application of the MI BUS protocol is with power and memory mirrors, seats, windows, and headlight levelers.

DISTRIBUTED SYSTEM INTERFACE BUS Distributed system interface (DSI) BUS protocol was developed by Motorola and uses a two-wire serial BUS. This BUS protocol is currently being used for safety-related sensors and components.

FIGURE 49–23 A typical 38-cavity diagnostic connector as found on many BMW and Mercedes vehicles under the hood. The use of a breakout box (BOB) connected to this connector can often be used to gain access to module BUS information.

FREQUENTLY ASKED QUESTION

How Do You Know What System Is Used?

Use service information to determine which network communication protocol is used. However, due to the various systems on some vehicles, it may be easier to look at the data link connection to determine the system. All OBD-II vehicles have terminals in the following cavities.

Terminal 4: chassis ground

Terminal 5: computer (signal) ground

Terminal 16: 12 V positive

The terminals in cavities 6 and 14 mean that this vehicle is equipped with CAN as the only module communication protocol available at the DLC. To perform a test of the BUS, use a **breakout box (BOB)** to gain access to the terminals while connecting to the vehicle, using a scan tool. ● **SEE FIGURE 49–24** for a typical OBD-II connector breakout box.

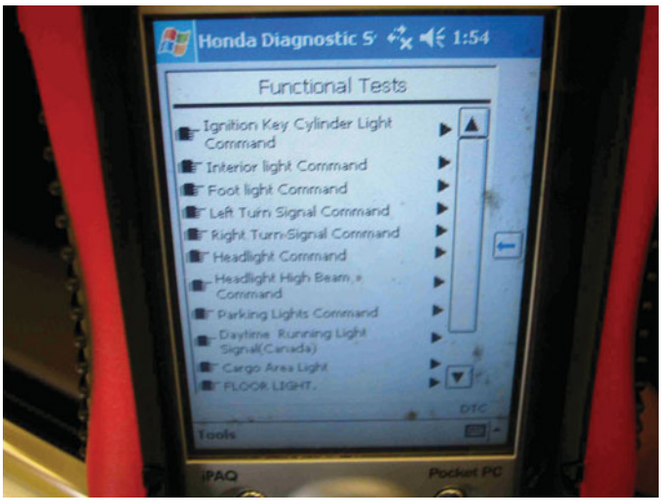

FIGURE 49–25 This Honda scan tool allows the technician to turn on individual lights and operate individual power windows and other accessories that are connected to the BUS system.

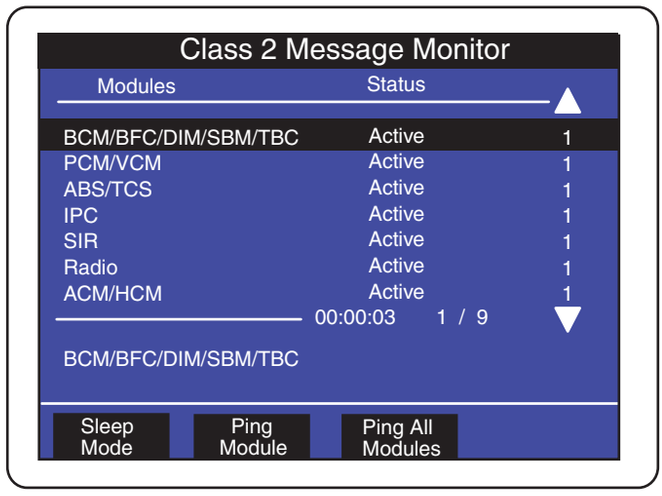

FIGURE 49–26 Modules used in a General Motors vehicle can be "pinged" using a Tech 2 scan tool.

BOSCH-SIEMANS-TEMIC BUS The Bosch-Siemans-Temic (BST) BUS is another system that is used for safety-related components and sensors in a vehicle, such as airbags. The BST BUS is a two-wire system and operates up to 250,000 bps.

BYTEFLIGHT BUS The byteflight BUS is used in safety critical systems, such as airbags, and uses the time division multiple access (TDMA) protocol, which operates at 10 million bps using a **plastic optical fiber (POF).**

FLEXRAY BUS FlexRay BUS is a version of byteflight, and is a high-speed serial communication system for in-vehicle networks. FlexRay is commonly used for steer-by-wire and brake-by-wire systems.

DOMESTIC DIGITAL BUS The domestic digital BUS, commonly designated D2B, is an optical BUS system connecting audio, video, computer, and telephone components in a single-ring structure with a speed of up to 5,600,000 bps.

LOCAL INTERCONNECT NETWORK BUS Local interconnect network (LIN) is a BUS protocol used between intelligent sensors and actuators, and has a BUS speed of 19,200 bps.

NETWORK COMMUNICATIONS DIAGNOSIS

STEPS TO FINDING A FAULT When a network communications fault is suspected, perform the following steps.

STEP 1 **Check everything that does and does not work.** Often accessories that do not seem to be connected can help identify which module or BUS circuit is at fault.

STEP 2 **Perform module status test.** Use a factory level scan tool or an aftermarket scan tool equipped with enhanced software that allows OE-like functions. Check if the components or systems can be operated through the scan tool. ● **SEE FIGURE 49–25.**

- **Ping modules.** Start the Class 2 diagnosis by using a scan tool and select *diagnostic circuit check.* If no diagnostic trouble codes (DTCs) are shown, there could be a communication problem. Select *message monitor,* which will display the status of all of the modules on the Class 2 BUS circuit. The modules that are awake will be shown as active and the scan tool can be used to ping individual modules or command all modules. The ping command should change the status from "active" to "inactive." ● **SEE FIGURE 49–26.**

  NOTE: If an excessive parasitic draw is being diagnosed, use a scan tool to ping the modules in one way to determine if one of the modules is not going to sleep and causing the excessive battery drain.

- **Check state of health.** All modules on the Class 2 BUS circuit have at least one other module responsible for reporting **state of health (SOH).** If a module fails to send a state of health message within five seconds, the companion module will set a diagnostic trouble code for the module that did not respond. The defective module is not capable of sending this message.

STEP 3 **Check the resistance of the terminating resistors.** Most high-speed BUS systems use resistors at each end, called **terminating resistors.** These resistors are used to help reduce interference into other systems in the vehicle. Usually two 120 ohm resistors are installed at each end and are therefore connected electrically in parallel. Two 120 ohm resistors connected in parallel would measure 60 ohms if being tested using an ohmmeter. ● **SEE FIGURE 49–27.**

STEP 4 **Check data BUS for voltages.** Use a digital multimeter set to DC volts, to monitor communications and check the BUS for proper operation. Some BUS conditions and possible causes include:

- **Signal is zero volt all of the time.** Check for short-to-ground by unplugging modules one at a time to check if one module is causing the problem.
- **Signal is high or 12 volts all of the time.** The BUS circuit could be shorted to 12 V. Check with the customer to see if any service or body repair work was done recently. Try unplugging each module one at a time to pin down which module is causing the communications problem.

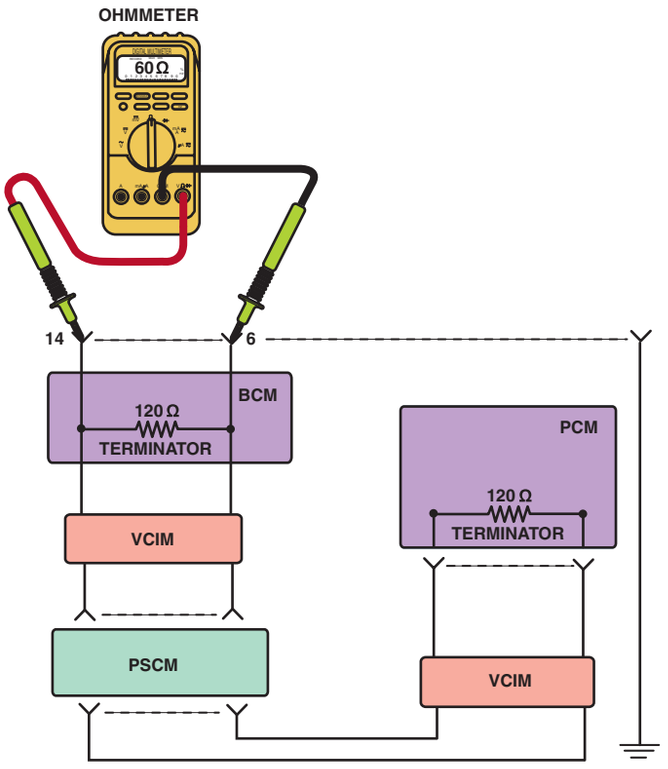

FIGURE 49–27 Checking the terminating resistors using an ohmmeter at the DLC.

FIGURE 49–28 Use front-probe terminals to access the data link connector. Always follow the specified back-probe and front-probe procedures as found in service information.

- **A variable voltage usually indicates that messages are being sent and received.** CAN and Class 2 can be identified by looking at the data link connector (DLC) for a terminal in cavity number 2. Class 2 is active all of the time the ignition is on, and therefore voltage variation between 0 and 7 V can be measured using a DMM set to read DC volts. ● **SEE FIGURE 49–28.**

STEP 5 **Use a digital storage oscilloscope to monitor the waveforms of the BUS circuit.** Using a scope on the data line terminals can show if communication is being transmitted. Typical faults and their causes include:

- **Normal operation.** Normal operation shows variable voltage signals on the data lines. It is impossible to know what information is being transmitted, but if there is activity with short sections of inactivity, this indicates normal data line transmission activity. ● **SEE FIGURE 49–29.**
- **High voltage.** If there is a constant high-voltage signal without any change, this indicates that the data line is shorted to voltage.
- **Zero or low voltage.** If the data line voltage is zero or almost zero and not showing any higher voltage signals, then the data line is short-to-ground.

TECH TIP

No Communication? Try Bypass Mode.

If a Tech 2 scan tool shows "no communication," try using the bypass mode to see what should be on the data display. To enter bypass mode, perform the following steps.

STEP 1 Select tool option (F3).

STEP 2 Set communications to bypass (F5).

STEP 3 Select enable.

STEP 4 Input make/model and year of vehicle.

STEP 5 Note all parameters that should be included, as shown. The values will not be shown.

REAL WORLD FIX

The Radio Caused No-Start Story

A 2005 Chevrolet Cobalt did not start. A technician checked with a subscription-based helpline service and discovered that a fault with the Class 2 data circuit could prevent the engine from starting. The advisor suggested that a module should be disconnected one at a time to see if one of them was taking the data line to ground. The two most common components on the Class 2 serial data line that have been known to cause a lack of communication and become shorted-to-ground are the radio and electronic brake control module (EBCM). The first one the technician disconnected was the radio. The engine started and ran. Apparently the Class 2 serial data line was shorted-to-ground inside the radio, which took the entire BUS down. When BUS communication is lost, the PCM is not able to energize the fuel pump, ignition, or fuel injectors so the engine would not start. The radio was replaced to solve the no-start condition.

FREQUENTLY ASKED QUESTION

Which Module Is the Gateway Module?

The gateway module is responsible for communicating with other modules and acts as the main communications module for scan tool data. Most General Motors vehicles use the body control module (BCM) or the instrument panel control (IPC) module as the gateway. To verify which module is the gateway, check the schematic and look for one that has voltage applied during all of the following conditions.

- Key on, engine off
- Engine cranking
- Engine running

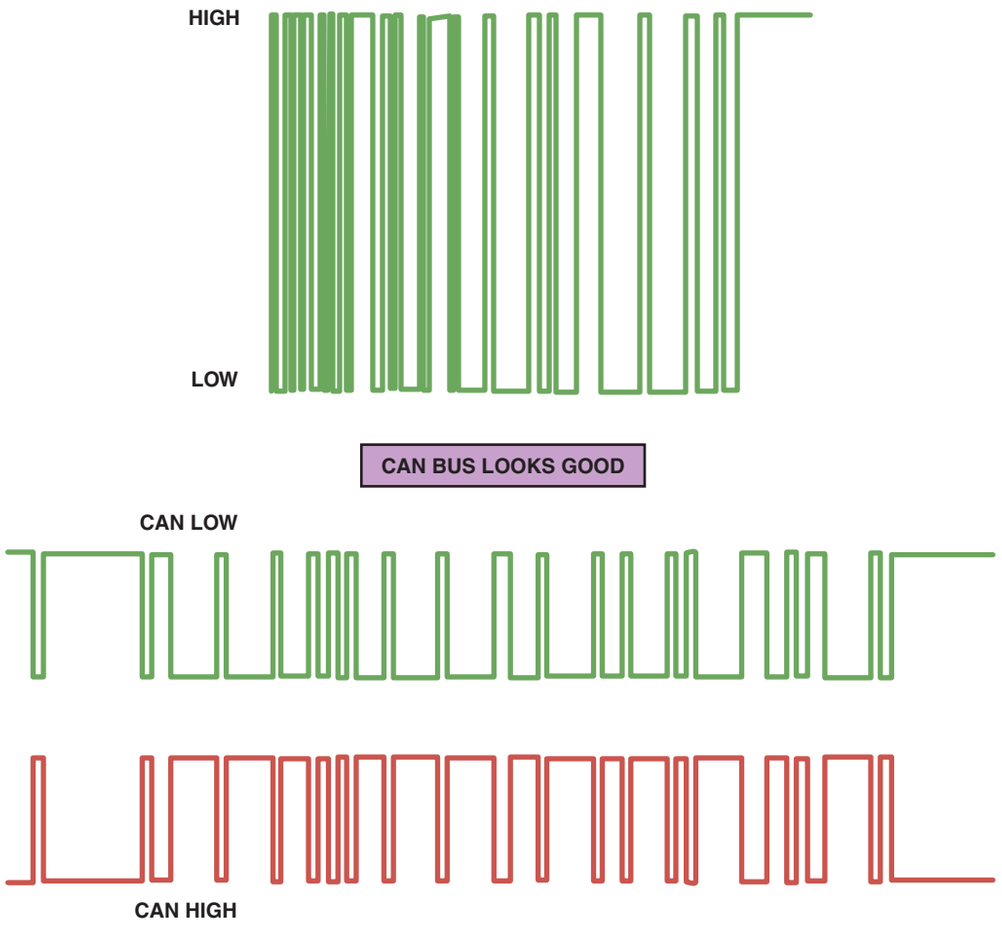

FIGURE 49–29 (a) Data is sent in packets, so it is normal to see activity then a flat line between messages. (b) A CAN BUS should show voltages that are opposite when there is normal communications. CAN H (high) circuit should go from 2.5 volts at rest to 3.5 volts when active. The CAN L (low) circuit goes from 2.5 volts at rest to 1.5 volts when active.

STEP 6 **Follow factory service information instructions to isolate the cause of the fault.** This step often involves disconnecting one module at a time to see if it is the cause of a short-to-ground or an open in the BUS circuit.

INTRODUCTION

PURPOSE AND FUNCTION

Everything electrical in a vehicle is supplied current from the battery. The battery is one of the most important parts of a vehicle because it is the heart or foundation of the electrical system. The primary purpose of an automotive battery is to provide a source of electrical power for starting and for electrical demands that exceed alternator output.

WHY BATTERIES ARE IMPORTANT

The battery also acts as a stabilizer to the voltage for the entire electrical system. The battery is a voltage stabilizer because it acts as a reservoir where large amounts of current (amperes) can be removed quickly during starting and replaced gradually by the alternator during charging.

- The battery *must* be in good (serviceable) condition before the charging system and the cranking system can be tested. For example, if a battery is discharged, the cranking circuit (starter motor) could test as being defective because the battery voltage might drop below specifications.
- The charging circuit could also test as being defective because of a weak or discharged battery. It is important to test the vehicle battery before further testing of the cranking or charging system.

BATTERY CONSTRUCTION

CASE

Most automotive battery cases (container or covers) are constructed of polypropylene, a thin (approximately 0.08 in., or 0.02 mm, thick), strong, and lightweight plastic. In contrast, containers for industrial batteries and some truck batteries are constructed of a hard, thick rubber material.

Inside the case are six cells (for a 12 volt battery). ● **SEE FIGURE 50–1.** Each cell has positive and negative plates. Built into the bottom of many batteries are ribs that support the lead-alloy plates and provide a space for sediment to settle, called the **sediment chamber.** This space prevents spent active material from causing a short circuit between the plates at the bottom of the battery.

A **maintenance-free battery** uses little water during normal service because of the alloy material used to construct the battery plate grids. Maintenance-free batteries are also called **low-water-loss batteries.**

GRIDS

Each positive and negative plate in a battery is constructed on a framework, or **grid,** made primarily of lead. Lead is a

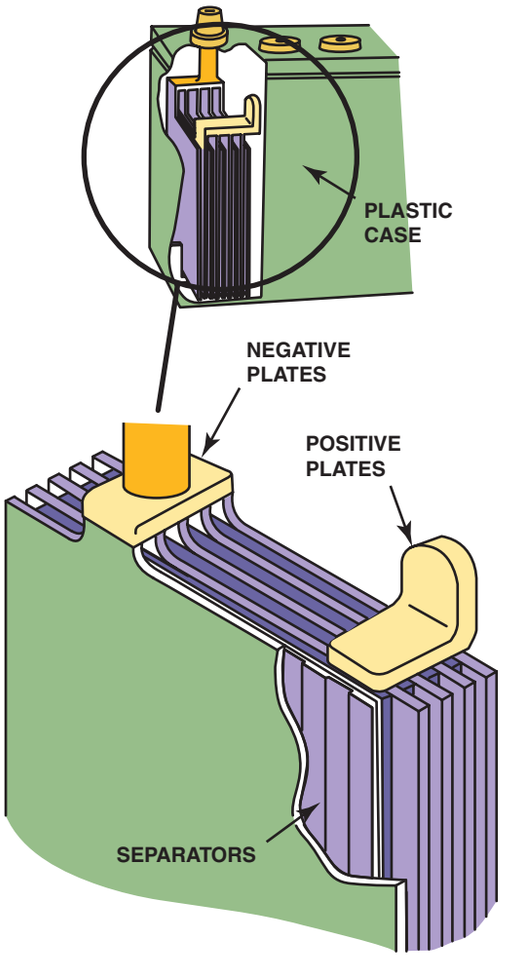

FIGURE 50–1 Batteries are constructed of plates grouped into cells and installed in a plastic case.

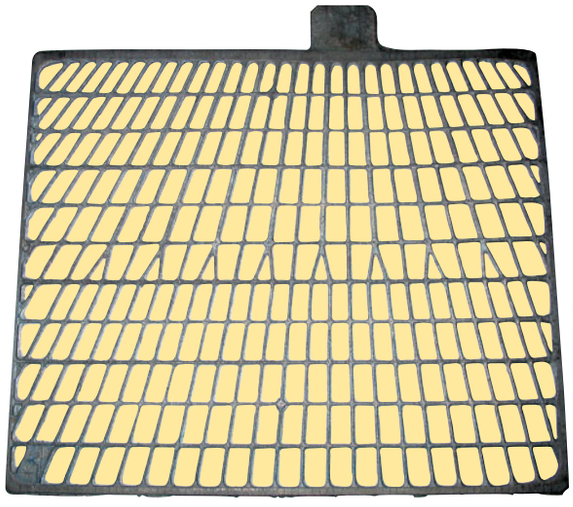

FIGURE 50–2 A grid from a battery used in both positive and negative plates.

soft material and must be strengthened for use in an automotive battery grid. Adding antimony or calcium to the pure lead adds strength to the lead grids. ● **SEE FIGURE 50–2.**

Battery grids hold the active material and provide the electrical pathways for the current created in the plate.

Maintenance-free batteries use calcium instead of antimony, because 0.2% calcium has the same strength as 6% antimony. A typical lead-calcium grid uses only 0.09% to 0.12% calcium. Using low amounts of calcium instead of higher amounts of antimony reduces **gassing.** Gassing is the release of hydrogen and oxygen from the battery that occurs during charging and results in water usage.

? **FREQUENTLY ASKED QUESTION**

What Is an SLI Battery?

Sometimes the term *SLI* is used to describe a type of battery. **SLI** means starting, lighting, and ignition, and describes the use of a typical automotive battery. Other types of batteries used in industry are usually batteries designed to be deep cycled and are usually not as suitable for automotive needs.

Low-maintenance batteries use a low percentage of antimony (about 2% to 3%), or use antimony only in the positive grids and calcium for the negative grids. *The percentages that make up the alloy of the plate grids constitute the major difference between standard and maintenance-free batteries.* The chemical reactions that occur inside each battery are identical regardless of the type of material used to construct the grid plates.

POSITIVE PLATES The positive plates have *lead dioxide (peroxides),* in paste form placed onto the grid framework. This process is called *pasting.* This active material can react with the sulfuric acid of the battery and is dark brown in color.

NEGATIVE PLATES The negative plates are pasted to the grid with a pure **porous lead,** called **sponge lead,** and are gray in color.

SEPARATORS The positive and the negative plates must be installed alternately next to each other without touching. Nonconducting *separators* are used, which allow room for the reaction of the acid with both plate materials, yet insulate the plates to prevent shorts. These separators are porous (with many small holes) and have ribs facing the positive plate. Separators can be made from resin-coated paper, porous rubber, fiberglass, or expanded plastic. Many batteries use envelope-type separators that encase the entire plate and help prevent any material that may shed from the plates from causing a short circuit between plates at the bottom of the battery.

CELLS **Cells** are constructed of positive and negative plates with insulating separators between each plate. Most batteries use one more negative plate than positive plate in each cell; however, many newer batteries use the same number of positive and negative plates. A cell is also called an **element.** Each cell is actually a 2.1 volt battery, regardless of the number of positive or negative plates used. The greater the number of plates used in each cell, the greater the amount of *current* that can be produced. Typical batteries contain four positive plates and five negative plates per cell. A 12 volt battery contains six cells connected in series, which produce 12.6 volts ($6 \times 2.1 = 12.6$) and contain 54 plates (9 plates per cell $\times$ 6 cells). If the same 12 volt battery had five positive plates and six negative plates, for a total of 11 plates per cell ($5 + 6$), or 66 plates (11 plates $\times$ 6 cells), then it would have the same voltage, but the amount of current that the battery could produce would be increased. ● **SEE FIGURE 50–3.**

The amperage capacity of a battery is determined by the amount of active plate material in the battery and the area of the plate material exposed to the electrolyte in the battery.

PARTITIONS Each cell is separated from the other cells by **partitions,** which are made of the same material as that used for the outside case of the battery. Electrical connections between cells are provided by lead connectors that loop over the top of the partition and connect the plates of the cells together. Many batteries connect the

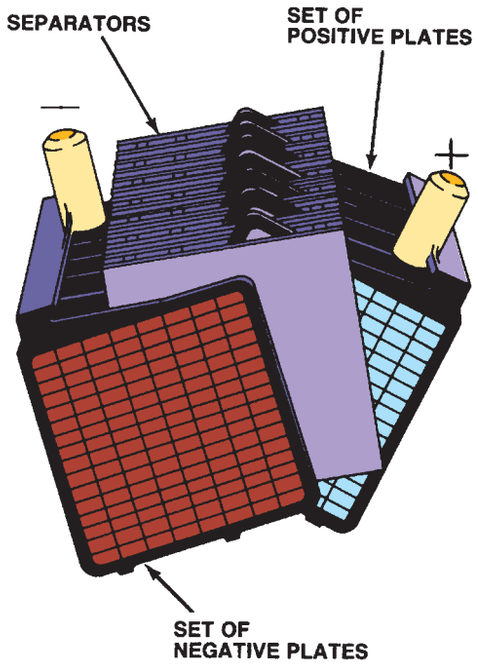

FIGURE 50–3 Two groups of plates are combined to form a battery element.

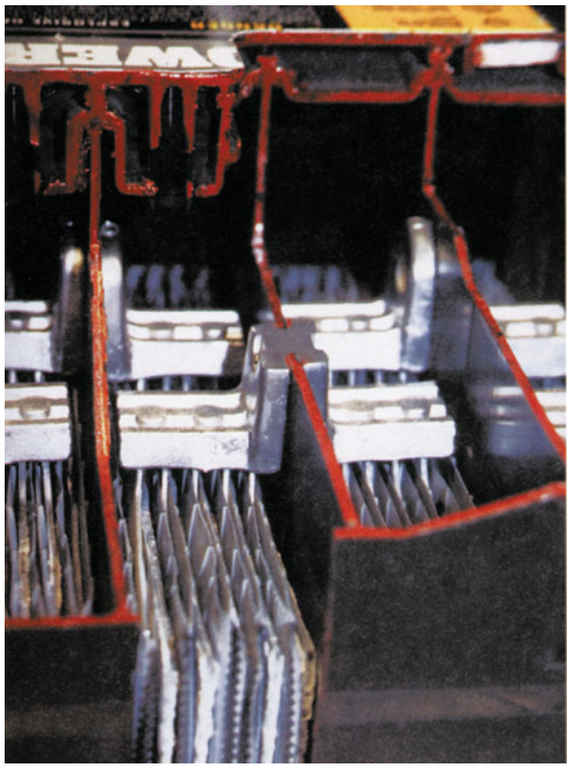

FIGURE 50–4 A cutaway battery showing the connection of the cells to each other through the partition.

cells directly through the partition connectors, which provide the shortest path for the current and the lowest resistance. ● **SEE FIGURE 50–4.**

ELECTROLYTE

Electrolyte is the term used to describe the acid solution in a battery. The electrolyte used in automotive batteries is a solution (liquid combination) of 36% sulfuric acid and 64% water. This electrolyte is used for both lead-antimony and lead-calcium (maintenance-free) batteries. The chemical symbol for this sulfuric acid solution is H_2SO_4.

H_2 = Symbol for hydrogen (the subscript 2 means that there are two atoms of hydrogen)

S = Symbol for sulfur

O_4 = Symbol for oxygen (the subscript 4 indicates that there are four atoms of oxygen)

Electrolyte is sold premixed in the proper proportion and is factory installed or added to the battery when the battery is sold. Additional electrolyte must *never* be added to any battery after the original electrolyte fill. It is normal for some water (H_2O) in the form of hydrogen and oxygen gases to escape during charging as a result of the chemical reactions. The escape of gases from a battery during charging or discharging is called gassing. Only pure distilled water should be added to a battery. If distilled water is not available, clean drinking water can be used.

HOW A BATTERY WORKS

PRINCIPLE INVOLVED

The principle of how a battery works is based on a scientific principle discovered years ago that states:

- When two dissimilar metals are placed in an acid, electrons flow between the metals if a circuit is connected between them.
- This can be demonstrated by pushing a steel nail and a piece of solid copper wire into a lemon. Connect a voltmeter to the ends of the copper wire and nail, and voltage will be displayed.

A fully charged lead-acid battery has a positive plate of lead dioxide (peroxide) and a negative plate of lead surrounded by a sulfuric acid solution (electrolyte). The difference in potential (voltage) between lead peroxide and lead in acid is approximately 2.1 volts.

DURING DISCHARGING

The positive plate lead dioxide (PbO_2) combines with the SO_4, forming $PbSO_4$ from the electrolyte and releases its O_2 into the electrolyte, forming H_2O. The negative plate also combines with the SO_4 from the electrolyte and becomes lead sulfate ($PbSO_4$). ● **SEE FIGURE 50–5.**

FULLY DISCHARGED STATE

When the battery is fully discharged, both the positive and the negative plates are $PbSO_4$ (lead sulfate) and the electrolyte has become water (H_2O). As the battery is being discharged, the plates and electrolyte approach the completely discharged state. There is also the danger of freezing when a battery is discharged, because the electrolyte is mostly water.

CAUTION: Never charge or jump start a frozen battery because the hydrogen gas can get trapped in the ice and ignite if a spark is caused during the charging process. The result can be an explosion.

DURING CHARGING

During charging, the sulfate from the acid leaves both the positive and the negative plates and returns to the electrolyte, where it becomes normal-strength sulfuric acid solution. The positive plate returns to lead dioxide (PbO_2), the negative plate is again pure lead (Pb), and the electrolyte becomes H_2SO_4. ● **SEE FIGURE 50–6.**

SPECIFIC GRAVITY

DEFINITION

The amount of sulfate in the electrolyte is determined by the electrolyte's **specific gravity,** which is the ratio of the weight of a given volume of a liquid to the weight of an equal volume of water. In other words, the more dense the liquid is, the higher its

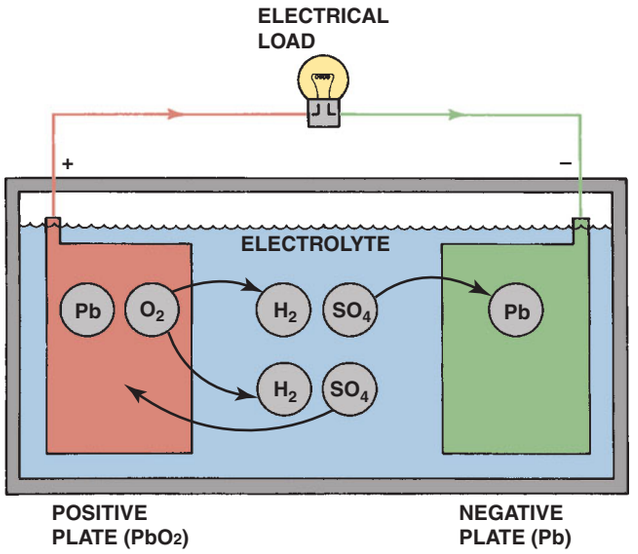

FIGURE 50–5 Chemical reaction for a lead-acid battery that is fully charged being discharged by the attached electrical load.

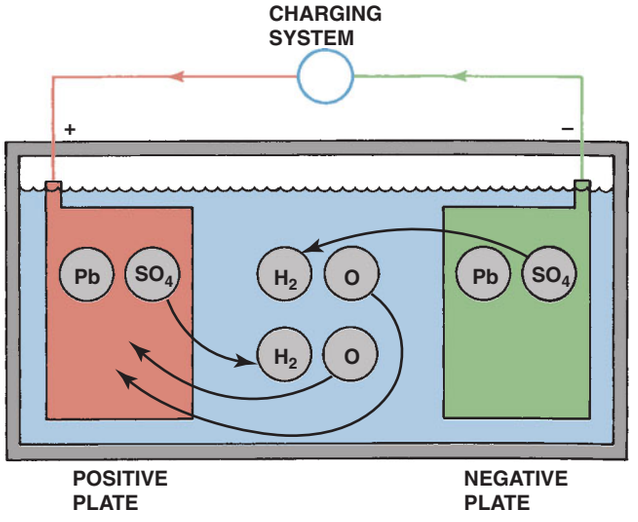

FIGURE 50–6 Chemical reaction for a lead-acid battery that is fully discharged being charged by the attached generator.

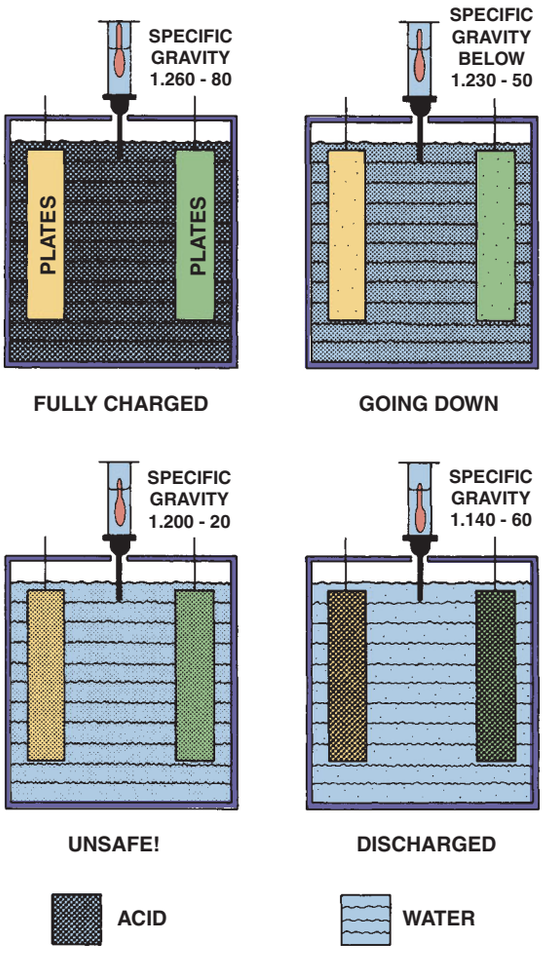

FIGURE 50–7 As the battery becomes discharged, the specific gravity of the battery acid decreases.

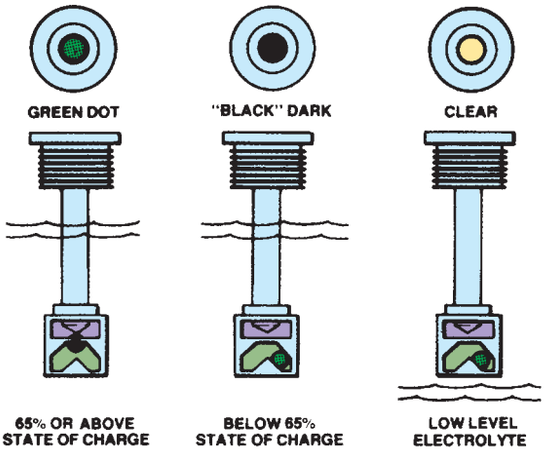

FIGURE 50–8 Typical battery charge indicator. If the specific gravity is low (battery discharged), the ball drops away from the reflective prism. When the battery is charged enough, the ball floats and reflects the color of the ball (usually green) back up through the sight glass and the sight glass is dark.

FREQUENTLY ASKED QUESTION

Is There an Easy Way to Remember How a Battery Works?

Yes. Think of the sulfuric acid solution in the electrolyte being deposited, then removed from the plates.

- **During discharge.** The acid (SO_4) is leaving the electrolyte and getting onto both plates.
- **During charging.** The acid (SO_4) is being forced from both plates and enters the electrolyte.

specific gravity. Pure water is the basis for this measurement and is given a specific gravity of 1.000 at 80°F (27°C). Pure sulfuric acid has a specific gravity of 1.835; the *correct* concentration of water and sulfuric acid (called electrolyte—64% water, 36% acid) is 1.260 to 1.280 at 80°F. The higher the battery's specific gravity, the more fully it is charged. ● **SEE FIGURE 50–7.**

CHARGE INDICATORS Some batteries are equipped with a built-in state-of-charge indicator, commonly called *green eyes.* This indicator is simply a small, ball-type hydrometer that is installed in one cell. This hydrometer uses a plastic ball that floats if the electrolyte density is sufficient (which it is when the battery is about 65% charged). When the ball floats, it appears in the hydrometer's sight glass, changing its color. ● **SEE FIGURE 50–8.**

VALVE REGULATED LEAD-ACID BATTERIES

TERMINOLOGY There are two basic types of **valve regulated lead-acid (VRLA),** also called **sealed valve-regulated (SVR)** or **sealed lead-acid (SLA),** batteries. These batteries use a low-pressure venting system that releases excess gas and automatically reseals if a buildup of gas is created due to overcharging. The two types include the following:

- **Absorbed glass mat.** The acid used in an **absorbed glass mat (AGM)** battery is totally absorbed into the separator, making the battery leakproof and spillproof. The battery is assembled by compressing the cell about 20%, then inserting it into the container. The compressed cell helps reduce damage caused by vibration and helps keep the acid tightly against the plates. The sealed maintenance-free design uses a pressure release valve in each cell. Unlike conventional batteries that use a liquid electrolyte, called **flooded cell batteries,** most of the hydrogen and oxygen given off during charging remains inside the battery. The separator or mat is only 90% to 95% saturated with electrolyte, thereby allowing a portion of the mat to be filled with gas. The gas spaces provide channels to allow the hydrogen and oxygen gases to recombine rapidly and safely. Because the acid is totally absorbed into the glass mat separator, an AGM battery can be mounted in any direction. AGM batteries also have a longer service life, often lasting 7 to 10 years. Absorbed glass mat batteries are used as standard equipment in some vehicles such as the Chevrolet Corvette and in most Toyota hybrid electric vehicles. ● **SEE FIGURE 50–9.**
- **Gelled electrolyte batteries.** In a gelled electrolyte battery, silica is added to the electrolyte, which turns the electrolyte into a substance similar to gelatin. This type of battery is also called a **gel battery.**

Both types of valve-regulated, lead-acid batteries are also called **recombinant battery** design. A recombinant-type battery means that the oxygen gas generated at the positive plate travels through the dense electrolyte to the negative plate. When the oxygen reaches the negative plate, it reacts with the lead, which consumes the oxygen gas and prevents the formation of hydrogen gas. It is because of this oxygen recombination that VRLA batteries do not use water.

FIGURE 50–9 An absorbed glass mat battery is totally sealed and is more vibration resistant than conventional lead-acid batteries.

CAUSES AND TYPES OF BATTERY FAILURE

NORMAL LIFE Most automotive batteries have a useful service life of three to seven years; however, proper care can help increase the life of a battery, but abuse can shorten it. The major cause of premature battery failure is overcharging.

CHARGING VOLTAGE The automotive charging circuit, consisting of an alternator and connecting wires, must be operating correctly to prevent damage to the battery.

- Charging voltages higher than 15.5 volts can damage a battery by warping the plates as a result of the heat of overcharging.
- AGM batteries can be damaged if charged at a voltage higher than 14.5 volts.

Overcharging also causes the active plate material to disintegrate and fall out of the supporting grid framework. Vibration or bumping can also cause internal damage similar to that caused by overcharging. It is important, therefore, to ensure that all automotive batteries are securely clamped down in the vehicle. The shorting of cell plates can occur without notice. If one of the six cells of a 12 volt battery is shorted, the resulting voltage of the battery is only 10 volts (12 − 2 = 10). With only 10 volts available, the starter *usually* will not be able to start the engine.

BATTERY HOLD-DOWNS All batteries must be attached securely to the vehicle to prevent battery damage. Normal vehicle vibrations can cause the active materials inside the battery to shed. Battery hold-down clamps or brackets help reduce vibration, which can greatly reduce the capacity and life of any battery. ● **SEE FIGURE 50–10.**

BATTERY RATINGS

Batteries are rated according to the amount of current they can produce under specific conditions.

COLD-CRANKING AMPERES Every automotive battery must be able to supply electrical power to crank the engine in cold weather and still provide battery voltage high enough to operate the ignition

FIGURE 50–10 A typical battery hold-down bracket. All batteries should use a bracket to prevent battery damage due to vibration and shock.

FIGURE 50–11 This battery has a cranking amperes (CA) rating of 1,000. This means that this battery is capable of cranking an engine for 30 seconds at a temperature of 32°F (0°C) at a minimum of 1.2 volts per cell (7.2 volts for a 12 volt battery).

FREQUENTLY ASKED QUESTION

What Determines Battery Capacity?

The capacity of any battery is determined by the amount of active plate material in the battery. A battery with a large number of thin plates can produce high current for a short period. If a few thick plates are used, the battery can produce low current for a long period. A trolling motor battery used for fishing must supply a low current for a long period of time. An automotive battery is required to produce a high current for a short period for cranking. Therefore, every battery is designed for a specific application.

FREQUENTLY ASKED QUESTION

What Is Deep Cycling?

Deep cycling is almost fully discharging a battery and then completely recharging it. Golf cart batteries are an example of lead-acid batteries that must be designed to be deep cycled. A golf cart must be able to cover two 18-hole rounds of golf and then be fully recharged overnight. Charging is hard on batteries because the internal heat generated can cause plate warpage, so these specially designed batteries use thicker plate grids that resist warpage. Normal automotive batteries are not designed for repeated deep cycling.

system for starting. The cold-cranking ampere rating of a battery is the number of amperes that can be supplied by a battery at 0°F (−18°C) for 30 seconds while the battery still maintains a voltage of 1.2 volts per cell or higher. This means that the battery voltage would be 7.2 volts for a 12 volt battery and 3.6 volts for a 6 volt battery. The cold-cranking performance rating is called **cold-cranking amperes (CCA).** Try to purchase a battery with the highest CCA for the money. See the vehicle manufacturer's specifications for recommended battery capacity.

CRANKING AMPERES The designation **CA** refers to the number of amperes that can be supplied by a battery at 32°F (0°C). This rating results in a higher number than the more stringent CCA rating. ● **SEE FIGURE 50–11.**

MARINE CRANKING AMPERES **Marine cranking amperes (MCA)** is similar to cranking amperes and is tested at 32°F (0°C).

RESERVE CAPACITY The **reserve capacity** rating for batteries is *the number of minutes* for which the battery can produce 25 amperes and still have a battery voltage of 1.75 volts per cell (10.5 volts for a 12 volt battery). This rating is actually a measurement of the time for which a vehicle can be driven in the event of a charging system failure.

AMPERE HOUR **Ampere hour** is an older battery rating system that measures how many amperes of current the battery can produce over a period of time. For example, a battery that has a 50 amp-hour (A-H) rating can deliver 50 amperes for one hour or 1 ampere for 50 hours or any combination that equals 50 amp-hours.

FIGURE 51–1 A visual inspection on this battery shows the electrolyte level was below the plates in all cells.

FIGURE 51–2 Corrosion on a battery cable could be an indication that the battery itself is either being overcharged or is sulfated, creating a lot of gassing of the electrolyte.

BATTERY SERVICE SAFETY CONSIDERATIONS

HAZARDS Batteries contain acid and release explosive gases (hydrogen and oxygen) during normal charging and discharging cycles.

SAFETY PROCEDURES To help prevent physical injury or damage to the vehicle, always adhere to the following safety procedures.

1. When working on any electrical component on a vehicle, disconnect the negative battery cable from the battery. When the negative cable is disconnected, all electrical circuits in the vehicle will be open, which will prevent accidental electrical contact between an electrical component and ground. Any electrical spark has the potential to cause explosion and personal injury.
2. Wear eye protection (goggles preferred) when working around any battery.
3. Wear protective clothing to avoid skin contact with battery acid.
4. Always adhere to all safety precautions as stated in the service procedures for the equipment used for battery service and testing.
5. Never smoke or use an open flame around any battery.

SYMPTOMS OF A WEAK OR DEFECTIVE BATTERY

The following warning signs indicate that a battery is near the end of its useful life.

- **Uses water in one or more cells.** This indicates that the plates are sulfated and that during the charging process, the water in the electrolyte is being turned into separate hydrogen and oxygen gases. ● **SEE FIGURE 51–1.**
- **Excessive corrosion on battery cables or connections.** Corrosion is more likely to occur if the battery is sulfated, creating hot spots on the plates. When the battery is being charged, the acid fumes are forced out of the vent holes and onto the battery cables, connections, and even on the battery tray underneath the battery. ● **SEE FIGURE 51–2.**
- **Slower than normal engine cranking.** When the capacity of the battery is reduced due to damage or age, it is less likely to be able to supply the necessary current for starting the engine, especially during cold weather.

BATTERY MAINTENANCE

NEED FOR MAINTENANCE Most new-style batteries are of a maintenance-free design that uses lead-calcium instead of lead-antimony plate grid construction. Because lead-calcium batteries do not release as much gas as the older-style, lead-antimony batteries, there is less consumption of water during normal service. Also, with less gassing, less corrosion is observed on the battery terminals, wiring, and support trays. If the electrolyte level can be checked, and if it is low, add only distilled water. Distilled water is recommended by all battery manufacturers, but if distilled water is not available, clean ordinary drinking water, low in mineral content, can be used.

Battery maintenance includes making certain that the battery case is clean and checking that the battery cables and hold-down fasteners are clean and tight.

BATTERY TERMINAL CLEANING Many battery-related faults are caused by poor electrical connections at the battery. Battery cable connections should be checked and cleaned to prevent voltage drop at the connections. One common reason for an engine to not start is loose or corroded battery cable connections. Perform an inspection and check for the following conditions.

- Loose or corroded connections at the battery terminals (should not be able to be moved by hand)
- Loose or corroded connections at the ground connector on the engine block
- Wiring that has been modified to add auxiliary power for a sound system, or other electrical accessory

If the connections are loose or corroded, use 1 tablespoon of baking soda in 1 quart (liter) of water and brush this mixture onto the battery and housing to neutralize the acid. Mechanically clean the connections and wash the area with water. ● **SEE FIGURE 51–3.**

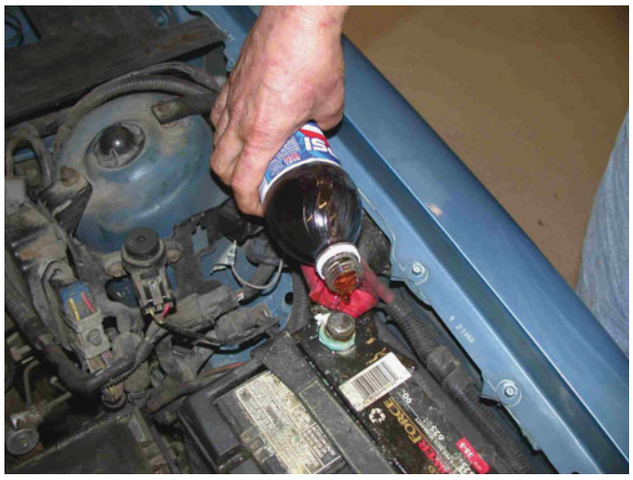

FIGURE 51–3 Besides baking soda and water, a sugar-free diet soft drink can also be used to neutralize the battery acid.

TECH TIP

Dynamic versus Open Circuit Voltage

Open circuit voltage is the voltage (usually of a battery) that exists *without* a load being applied. **Dynamic voltage** is the voltage of the power source (battery) with the circuit in operation. A vehicle battery, for example, may indicate that it has 12.6 volts or more, but that voltage will drop when the battery is put under a load such as cranking the engine. If the battery voltage drops too much, the starter motor will rotate more slowly and the engine may not start.

If the dynamic voltage is lower than specified, the battery may be weak or defective or the circuit may be defective.

BATTERY HOLD-DOWN The battery should also be secured with a hold-down bracket to prevent vibration from damaging the plates inside the battery. The hold-down bracket should be snug enough to prevent battery movement, yet not so tight as to cause the case to crack. Factory-original hold-down brackets are often available through local automobile dealers, and universal hold-down units are available through local automotive parts stores.

BATTERY VOLTAGE TEST

STATE OF CHARGE Testing the battery voltage with a voltmeter is a simple method for determining the state of charge of any battery. ● **SEE FIGURE 51–4.**

The voltage of a battery does not necessarily indicate whether the battery can perform satisfactorily, but it does indicate to the technician more about the battery's condition than a simple visual inspection. A battery that "looks good" may not be good. This test is commonly called an *open circuit battery voltage test* because it is conducted with an open circuit, no current flowing, and no load applied to the battery.

1. If the battery has just been charged or the vehicle has recently been driven, it is necessary to remove the surface charge from the battery before testing. A surface charge is a charge of higher-than-normal voltage that is just on the surface of the battery plates. The surface charge is quickly removed when the battery is loaded and therefore does not accurately represent the true state of charge of the battery.
2. To remove the surface charge, turn the headlights on high beam (brights) for one minute, then turn the headlights off and wait two minutes.

(b)

FIGURE 51–4 (a) A voltage reading of 12.28 volts indicates that the battery is not fully charged and should be charged before testing. (b) A battery that measures 12.6 volts or higher after the surface charge has been removed is 100% charged.

BATTERY VOLTAGE (V)	STATE OF CHARGE
12.6 or higher	100% charged
12.4	75% charged
12.2	50% charged
12.0	25% charged
11.9 or lower	Discharged

1.225	12.4	75% charged
1.190	12.2	50% charged
1.155	12.0	25% charged
Lower than 1.120	11.9 or lower	Discharged

CHART 51–2

Measuring the specific gravity can detect a defective battery. A battery should be at least 75% charged before being load tested.

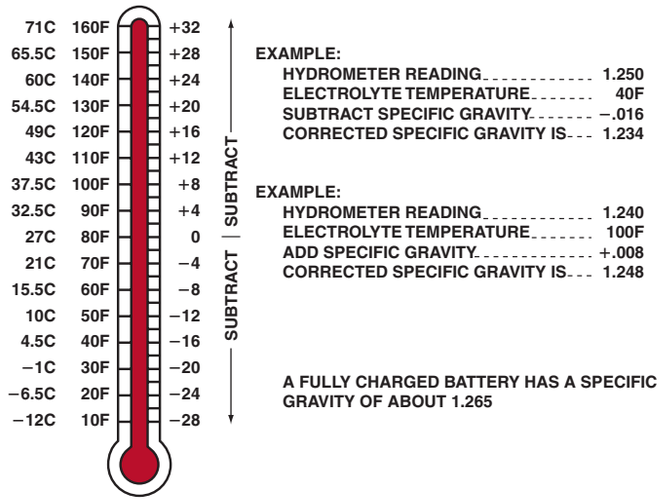

FIGURE 51–5 When testing a battery using a hydrometer, the reading must be corrected if the temperature is above or below 80°F (27°C).

FIGURE 51–6 This battery has cold-cranking amperes (CCA) of 550 A, cranking amperes (CA) of 680 A, and load test amperes of 270 A listed on the top label. Not all batteries have this complete information.

3. With the engine and all electrical accessories off, and the doors shut (to turn off the interior lights), connect a voltmeter to the battery posts. Connect the red positive lead to the positive post and the black negative lead to the negative post.

   NOTE: If the meter reads negative (−), the battery has been reverse charged (has reversed polarity) and should be replaced, or the meter has been connected incorrectly.

4. Read the voltmeter and compare the results with the state of charge. The voltages shown are for a battery at or near room temperature (70°F to 80°F, or 21°C to 27°C). ● **SEE CHART 51–1**.

HYDROMETER TESTING

If the battery has removable filler caps, the specific gravity of the electrolyte can also be checked. A **hydrometer** is a tester that measures the specific gravity. ● **SEE FIGURE 51–5.**

This test can also be performed on most maintenance-free batteries because their filler caps are removable, except for those produced by Delco (Delphi) Battery. The specific gravity test indicates the state of battery charge and can indicate a defective battery if the specific gravity of one or more cells varies by more than 0.050 from the value of the highest-reading cell. ● **SEE CHART 51–2.**

BATTERY LOAD TESTING

TERMINOLOGY One test to determine the condition of any battery is the **load test.** Most automotive starting and charging testers use a carbon pile to create an electrical load on the battery. The amount of the load is determined by the original CCA rating of the battery, which should be at least 75% charged before performing a load test. The capacity is measured in cold-cranking amperes, which is the number of amperes that a battery can supply at 0°F (−18°C) for 30 seconds.

TEST PROCEDURE To perform a battery load test, take the following steps.

STEP 1 **Determine the CCA rating of the battery.** The proper electrical load used to test a battery is half of the CCA rating or three times the ampere-hour rating, with a minimum 150 ampere load. ● **SEE FIGURE 51–6.**

STEP 2 **Connect the load tester to the battery.** Follow the instructions for the tester being used.

STEP 3 **Apply the load for a full 15 seconds.** Observe the voltmeter during the load testing and check the voltage at the end of the 15 sec. period while the battery is still under load. A good battery should indicate above 9.6 V.

FIGURE 51–7 An alternator regulator battery starter tester (ARBST) automatically loads the battery with a fixed load for 15 sec. to remove the surface charge, then removes the load for 30 sec. to allow the battery to recover, and then reapplies the load for another 15 sec. The results of the test are then displayed.

FREQUENTLY ASKED QUESTION

What Is the Three-Minute Charge Test?

A **three-minute charge test** is used to check if a battery is sulfated, and is performed as follows:

- Connect a battery charger and a voltmeter to the battery terminals.
- Charge the battery at a rate of 40 amperes for three minutes.
- At the end of three minutes, read the voltmeter.

Results: If the voltage is above 15.5 volts, replace the battery. If the voltage is below 15.5 volts, the battery is not sulfated and should be charged and retested.

This is *not* a valid test of many maintenance-free batteries, such as the Delphi Freedom. Due to the high internal resistance, a discharged Delphi Freedom battery may not start to accept a charge for several hours. Always use another alternative battery test before discarding a battery based on the results of the three-minute charge test.

STEP 4 **Repeat the test.** Many battery manufacturers recommend performing the load test twice, using the first load period to remove the surface charge on the battery and the second test to provide a truer indication of the condition of the battery. Wait 30 seconds between tests to allow time for the battery to recover. ● **SEE FIGURE 51–7.**

Results: If the battery fails the load test, recharge the battery and retest. If the load test is failed again, replacement of the battery is required.

ELECTRONIC CONDUCTANCE TESTING

TERMINOLOGY General Motors Corporation, Chrysler Corporation, and Ford specify that an electronic conductance tester be used to test batteries in vehicles still under factory warranty. Conductance is a measure of how well a battery can create current. This tester sends a small signal through the battery and then measures a part of the AC response. As a battery ages, the plates can become sulfated and shed active materials from the grids, reducing the battery capacity. Conductance testers can be used to test flooded or absorbed glass (AGM) type batteries. The unit can determine the following information about a battery.

- CCA
- State of charge
- Voltage of the battery
- Defects such as shorts and opens

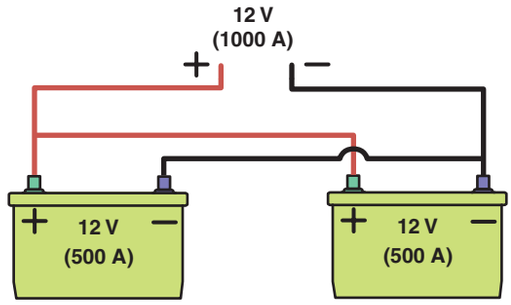

FIGURE 51–8 Most light-duty vehicles equipped with two batteries are connected in parallel as shown. Two 500 A, 12 volt batteries are capable of supplying 1,000 A at 12 volts, which is needed to start many diesel engines.

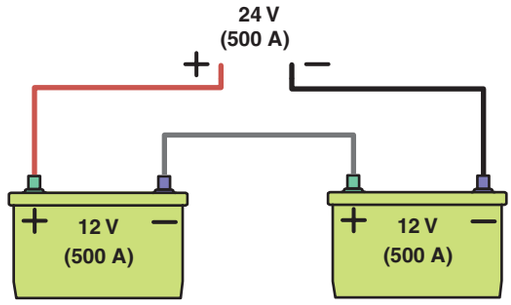

FIGURE 51–9 Many heavy-duty trucks and buses use two 12 volt batteries connected in series to provide 24 volts.

FREQUENTLY ASKED QUESTION

How Should You Test a Vehicle Equipped with Two Batteries?

Many vehicles equipped with a diesel engine use two batteries. These batteries are usually electrically connected in parallel to provide additional current (amperes) at the same voltage. ● **SEE FIGURE 51–8.**

Some heavy-duty trucks and buses connect two batteries in series to provide about the same current as one battery, but with twice the voltage, as shown in ● **FIGURE 51–9.**

To successfully test the batteries, they should be disconnected and tested separately. If just one battery is found to be defective, most experts recommend that both be replaced to help prevent future problems. Because the two batteries are electrically connected, a fault in one battery can cause the good battery to discharge into the defective battery, thereby affecting both even if just one battery is at fault.

However, a conductance tester is not designed to accurately determine the state of charge or CCA rating of a new battery. Unlike a battery load test, a conductance tester can be used on a battery that is discharged. This type of tester should only be used to test batteries that have been in service. ● **SEE FIGURE 51–10.**

TEST PROCEDURE

STEP 1 Connect the unit to the positive and negative terminals of the battery. If testing a side post battery, always use the lead adapters and *never* use steel bolts as these can cause an incorrect reading.

NOTE: Test results can be incorrectly reported on the display if proper, clean connections to the battery are not made. Also be sure that all accessories and the ignition switch are in the off position.

STEP 2 Enter the CCA rating (if known) and push the arrow keys.

STEP 3 The tester determines and displays one of the following:

- **Good battery.** The battery can return to service.
- **Charge and retest.** Fully recharge the battery and return it to service.
- **Replace the battery.** The battery is not serviceable and should be replaced.
- **Bad cell—replace.** The battery is not serviceable and should be replaced.

Some conductance testers can check the charging and cranking circuits, too.

FIGURE 51–10 A conductance tester is very easy to use and has proved to accurately determine battery condition if the connections are properly made. Follow the instructions on the display exactly for best results.

BATTERY CHARGING

CHARGING PROCEDURE

If the state of charge of a battery is low, it must be recharged. It is best to slow charge any battery to prevent possible overheating damage to the battery. Perform the following steps.

STEP 1 **Determine the charge rate.** The charge rate is based on the current state of charge (SOC) and charging rate. ● **SEE CHART 51–3** for the recommended charging rate.

STEP 2 **Connect a battery charger to the battery.** Be sure the charger is not plugged in when connecting a charger to a

SAFETY TIP

Never Charge or Jump Start a Frozen Battery

A discharged battery can freeze because the electrolyte becomes mostly water. Never attempt to charge or jump start a vehicle that has a frozen battery. When the battery freezes, it often bulges at the sides because water expands about 9% when it freezes, forming ice crystals that occupy more space than liquid water. The crystals can trap bubbles of hydrogen and oxygen that are created during the chemical processes in a battery. When attempting to charge or jump start the frozen battery, these pockets of gases can explode. Because the electrolyte expands, the freezing action usually destroys the plates and can loosen the active material from the grids. It is rare for a frozen battery to be restored to useful service.

FIGURE 51–11 A typical industrial battery charger. Be sure that the ignition switch is in the off position before connecting any battery charger. This helps prevent a voltage spike and spark that could occur if the charger happened to be accidentally left on. Always follow the battery charger manufacturer's instructions.

battery. Always follow the battery charger's instructions for proper use.

STEP 3 **Set the charging rate.** The initial charge rate should be about 35 A for 30 minutes to help start the charging process. Fast charging a battery increases the temperature of the battery and can cause warping of the plates inside the battery. Fast charging also increases the amount of gassing (release of hydrogen and oxygen), which can create a health and fire hazard. The battery temperature should not exceed 125°F (hot to the touch).

- Fast charge: 15 A maximum
- Slow charge: 5 A maximum

● **SEE FIGURE 51–11.**

CHARGING AGM BATTERIES Charging an absorbed glass mat (AGM) battery requires a different charger than is used to recharge a flooded-type battery. The differences include:

- The AGM can be charged with high current, up to 75% of the ampere-hour rating due to lower internal resistance.
- The charging voltage has to be kept at or below 14.4 volts to prevent damage.

Because most conventional battery chargers use a charging voltage of 16 volts or higher, a charger specifically designed to charge AGM batteries must be used.

Absorbed glass mat batteries are often used as auxiliary batteries in hybrid electric vehicles when the battery is located inside the vehicle. ● **SEE CHART 51–4** for a summary of the locations of the 12 volt auxiliary battery and high-voltage battery and safety switch/plug.

TECH TIP

Charge Batteries at 1% of Their CCA Rating

Many batteries are damaged due to being overcharged. To help prevent damage such as warped plates and excessive release of sulfur smell gases, charge batteries at a rate equal to 1% of the battery's CCA rating. For example, a battery with a 700 CCA rating should be charged at 7 amperes (700 × 0.01 = 7 amperes). No harm will occur to the battery at this charge rate even though it may take longer to achieve a full charge. This means that a battery may require eight or more hours to become fully charged depending on the battery capacity and state of charge (SOC).

TECH TIP

Always Use Adapters on Side Post Batteries

Side post batteries require that an adapter be used when charging the battery, if it is removed from the vehicle. Do not use steel bolts. If a bolt is threaded into the terminal, only the parts of the threads that contact the battery terminal will be conducting all of the charging current. An adapter or a bolt with a nut attached is needed to achieve full contact with the battery terminals. ● **SEE FIGURE 51–12.**

BATTERY CHARGE TIME

The time needed to charge a completely discharged battery can be estimated by using the reserve capacity rating of the battery in minutes divided by the charging rate.

Hours needed to charge the battery =
Reserve capacity ÷ Charge current

For example, if a 10 A charge rate is applied to a discharged battery that has a 90-minute reserve capacity, the time needed to charge the battery will be nine hours.

90 minutes ÷ 10 A = 9 hours

JUMP STARTING

To jump start another vehicle with a dead battery, connect good-quality copper jumper cables or a jump box to the good battery and the dead battery, as shown in ● **FIGURE 51–13.**

When using jumper cables or a battery jump box, the last connection made should always be on the engine block or an engine bracket on the dead vehicle as far from the battery as possible. ● **SEE FIGURE 51–14.**

It is normal for a spark to be created when the jumper cables finally complete the jumping circuit, and this spark could cause an explosion of the gases around the battery. Many newer vehicles have special ground and/or positive power connections built away from the battery just for the purpose of jump starting. Check the owner's manual or service information for the exact location.

FREQUENTLY ASKED QUESTION

Should Batteries Be Kept Off of Concrete Floors?

All batteries should be stored in a cool, dry place when not in use. Many technicians have been warned not to store or place a battery on concrete. According to battery experts, it is the temperature difference between the top and the bottom of the battery that causes a difference in the voltage potential between the top (warmer section) and the bottom (colder section). It is this difference in temperature that causes self-discharge to occur.

In fact, submarines cycle seawater around their batteries to keep all sections of the battery at the same temperature to help prevent self-discharge.

Therefore, always store or place batteries up off the floor and in a location where the entire battery can be kept at the same temperature, avoiding extreme heat and freezing temperatures. Concrete cannot drain the battery directly because the case of the battery is a very good electrical insulator.

TECH TIP

Look at the Battery Date Code

All major battery manufacturers stamp codes on the battery case that give the date of manufacture and other information. Most battery manufacturers use a number to indicate the year of manufacture and a letter to indicate the month of manufacture, except the letter I, because it can be confused with the number 1. For example:

A = January	G = July
B = February	H = August
C = March	J = September
D = April	K = October
E = May	L = November
F = June	M = December

The shipping date from the manufacturing plant is usually indicated by a *sticker* on the end of the battery. Almost every battery manufacturer uses just one letter and one number to indicate the month and year. ● **SEE FIGURE 51–15.**

BATTERY ELECTRICAL DRAIN TEST

TERMINOLOGY The **battery electrical drain test** determines if any component or circuit in a vehicle is causing a drain on the battery when everything is off. This test is also called the **ignition off draw (IOD)** or **parasitic load test.**

Many electronic components draw a continuous, slight amount of current from the battery when the ignition is off. These components include:

1. Electronically tuned radios for station memory and clock circuits
2. Computers and controllers, through slight diode leakage
3. The alternator, through slight diode leakage

These components may cause a voltmeter to read full battery voltage if it is connected between the negative battery terminal and the removed end of the negative battery cable. Because of

FIGURE 51–15 The code on the Delphi battery indicates that it was built in 2005 (5), in February (B), on the eleventh day (11), during third shift (C), and in the Canadian plant (Z).

FIGURE 51–16 This mini clamp-on digital multimeter is being used to measure the amount of battery electrical drain that is present. In this case, a reading of 20 mA (displayed on the meter as 00.02 A) is within the normal range of 20 to 30 mA. Be sure to clamp around all of the positive battery cable or all of the negative battery cable, whichever is easiest to get the clamp around.

this fact, voltmeters should not be used for battery drain testing. This test should be performed when one of the following conditions exists.

1. When a battery is being charged or replaced (a battery drain could have been the cause for charging or replacing the battery)
2. When the battery is suspected of being drained

PROCEDURE FOR BATTERY ELECTRICAL DRAIN TEST

- **Inductive DC ammeter.** The fastest and easiest method to measure battery electrical drain is to connect an inductive DC ammeter that is capable of measuring low current (10 mA). ● **SEE FIGURE 51–16** for an example of a clamp-on digital multimeter being used to measure battery drain.
- **DMM set to read milliamperes.** Following is the procedure for performing the battery electrical drain test using a DMM set to read DC amperes.

STEP 1 Make certain that all lights, accessories, and ignition are off.

STEP 2 Check all vehicle doors to be certain that the interior courtesy (dome) lights are off.

STEP 3 Disconnect the *negative* (−) battery cable and install a parasitic load tool, as shown in ● **FIGURE 51–17**.

STEP 4 Start the engine and drive the vehicle about 10 minutes, being sure to turn on all the lights and accessories including the radio.

STEP 5 Turn the engine and all accessories off including the underhood light.

STEP 6 Connect an ammeter across the parasitic load tool switch and wait 20 minutes for all computers and circuits to shut down.

STEP 7 Open the switch on the load tool and read the battery electrical drain on the meter display.

NOTE: Using a voltmeter or test light to measure battery drain is *not* recommended by most vehicle manufacturers. The high internal resistance of the voltmeter results in an irrelevant reading that does not provide the technician with adequate information about a problem.

FIGURE 51–17 After connecting the shut-off tool, start the engine and operate all accessories. Stop the engine and turn off everything. Connect the ammeter across the shut-off switch in parallel. Wait 20 minutes. This time allows all electronic circuits to "time out" or shut down. Open the switch—all current now will flow through the ammeter. A reading greater than specified (usually greater than 50 mA, or 0.05 A) indicates a problem that should be corrected.

- Normal = 20 to 30 mA (0.02 to 0.03 A)

RESET ALL MEMORY FUNCTIONS

Be sure to reset the clock, "auto up" windows, and antitheft radio if equipped. ● **SEE FIGURE 51–18.**

BATTERY DRAIN AND RESERVE CAPACITY

It is normal for a battery to self-discharge even if there is not an electrical load such as computer memory to drain the battery. According to General Motors, this self-discharge is about 13 mA (0.013 A).

Some vehicle manufacturers specify a maximum allowable parasitic draw or battery drain be based on the reserve capacity of the battery. The calculation used is the reserve capacity of the battery divided by 4; this equals the maximum allowable battery drain.

FIGURE 51–18 The battery was replaced in this Acura and the radio displayed "code" when the replacement battery was installed. Thankfully, the owner had the five-digit code required to unlock the radio.

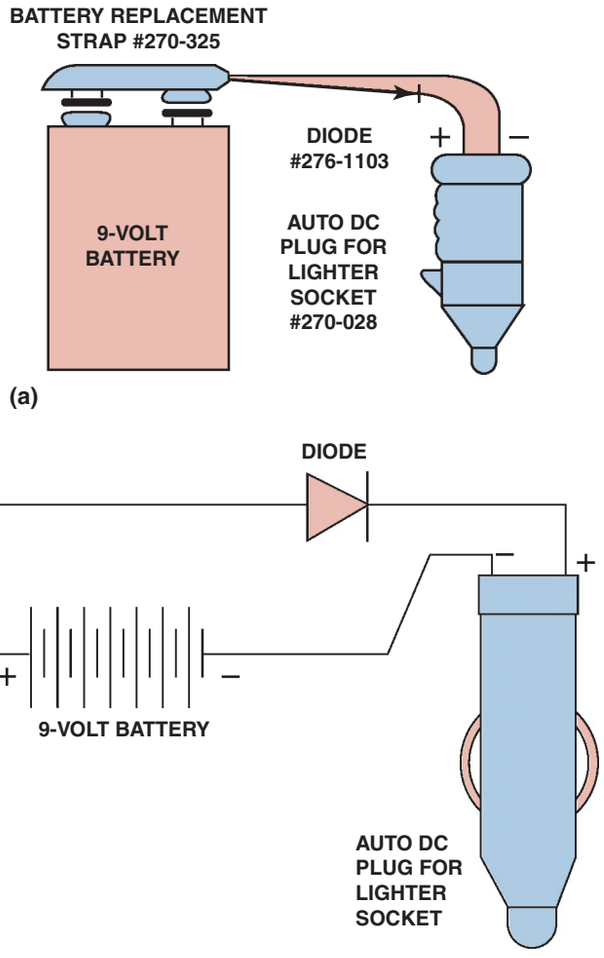

FIGURE 51–19 (a) Memory saver. The part numbers represent components from Radio Shack. (b) A schematic drawing of the same memory saver. Some experts recommend using a 12 volt lantern battery instead of a small 9 volt battery to help ensure that there will be enough voltage in the event that a door is opened while the vehicle battery is disconnected. Interior lights could quickly drain a small 9 volt battery.

REAL WORLD FIX

The Chevrolet Battery Story

A 2005 Chevrolet Impala was being diagnosed for a dead battery. Testing for a battery drain (parasitic draw) showed 2.25 A, which was clearly over the acceptable value of 0.050 or less. At the suggestion of the shop foreman, the technician used a Tech 2 scan tool to check if all of the computers and modules went to sleep after the ignition was turned off. The scan tool display indicated that the instrument panel (IP) showed that it remained awake after all of the others had gone into sleep mode. The IP cluster was unplugged and the vehicle was tested for an electrical drain again. This time, it was only 32 mA (0.032 A), well within the normal range. Replacing the IP cluster solved the excessive battery drain.

For example, a battery rated at 120 minutes reserve capacity should have a maximum battery drain of 30 mA.

120 minutes reserve capacity ÷ 4 = 30 mA

FINDING THE SOURCE OF THE DRAIN If there is a drain, check and temporarily disconnect the following components.

1. Underhood light
2. Glove compartment light
3. Trunk light

If after disconnecting these three components the battery drain draws more than 50 mA (0.05 A), disconnect one fuse at a time from the fuse box until the excessive drain drops to normal.

NOTE: Do not reinsert fuses after they have been removed as this action can cause modules to "wake up," leading to an inconclusive test.

If the excessive battery drain stops after one fuse is disconnected, the source of the drain is located in that particular circuit, as labeled on the fuse box. Continue to disconnect the *power-side* wire connectors from each component included in that particular circuit until the test light goes off. The source of the battery drain can then be traced to an individual component or part of one circuit.

TECH TIP

It Could Happen to You!

The owner of a Toyota replaced the battery. After doing so, the owner noted that the "airbag" amber warning lamp was lit and the radio was locked out. The owner had purchased the vehicle used and did not know the four-digit security code needed to unlock the radio. Determined to fix the problem, the owner tried three four-digit numbers, hoping that one of them would work. However, after three tries, the radio became permanently disabled.

Frustrated, the owner went to a dealer. It cost over $300 to fix the problem. A special tool was required to easily reset the airbag lamp. The radio had to be removed and sent out of state to an authorized radio service center and then reinstalled into the vehicle.

Therefore, before disconnecting the battery, check to be certain that the owner has the security code for a security-type radio. A "memory saver" may be needed to keep the radio powered up when the battery is being disconnected. ● **SEE FIGURE 51–19.**

FIGURE 51–20 Many newer vehicles have batteries that are sometimes difficult to find. Some are located under plastic panels under the hood, under the front fender, or even under the rear seat as shown here.

? FREQUENTLY ASKED QUESTION

Where Is the Battery?

Many vehicle manufacturers today place the battery under the backseat, under the front fender, or in the trunk. **SEE FIGURE 51–20.**

Often, the battery is not visible even if it is located under the hood. When testing or jump starting a vehicle, look for a battery access point.

WHAT TO DO IF A BATTERY DRAIN STILL EXISTS

If all the fuses have been disconnected and the drain still exists, the source of the drain has to be between the battery and the fuse box. The most common sources of drain under the hood include the following:

1. **The alternator.** Disconnect the alternator wires and retest. If the ammeter now reads a normal drain, the problem is a defective diode(s) in the alternator.
2. **The starter solenoid (relay) or wiring near its components.** These are also a common source of battery drain, due to high current flows and heat, which can damage the wire or insulation.

TECH TIP

Check the Battery Condition First

A discharged or defective battery has lower voltage potential than a good battery that is at least 75% charged. This lower battery voltage cannot properly power the starter motor. A weak battery could also prevent the charging voltage from reaching the voltage regulator cutoff point. This lower voltage could be interpreted as indicating a defective alternator and/or voltage regulator. If the vehicle continues to operate with low system voltage, the stator winding in the alternator can be overheated, causing alternator failure.

CRANKING CIRCUIT

PARTS INVOLVED For any engine to start, it must first be rotated using an external power source. It is the purpose and function of the cranking circuit to create the necessary power and transfer it from the battery to the starter motor, which rotates the engine.

The cranking circuit includes those mechanical and electrical components required to crank the engine for starting. The cranking force in the early 1900s was the driver's arm, because the driver had to physically crank the engine until it started. Modern cranking circuits include the following:

1. **Starter motor.** The starter is normally a 0.5 to 2.6 horsepower (0.4 to 2 kilowatts) electric motor that can develop nearly 8 horsepower (6 kilowatts) for a very short time when first cranking a cold engine. ● **SEE FIGURE 52–1.**
2. **Battery.** The battery must be of the correct capacity and be at least 75% charged to provide the necessary current and voltage for correct starter operation.

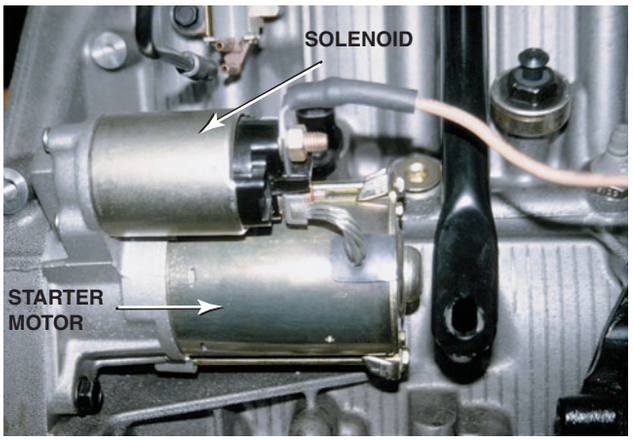

FIGURE 52–1 A typical solenoid-operated starter.

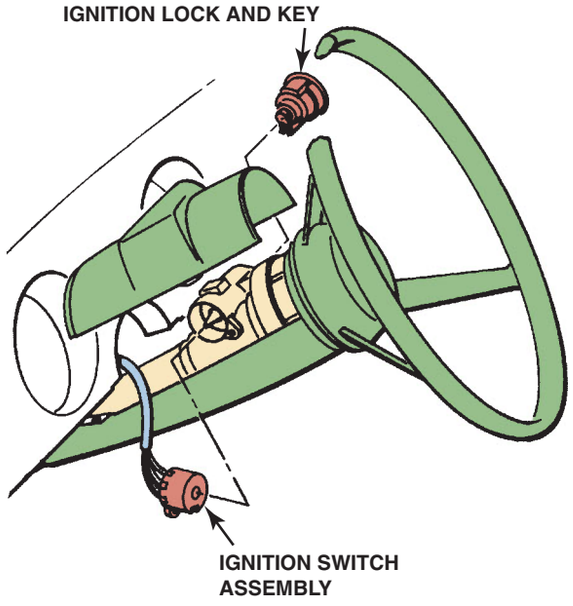

FIGURE 52–2 Some column-mounted ignition switches act directly on the electrical ignition switch itself, whereas others use a link from the lock cylinder to the ignition switch.

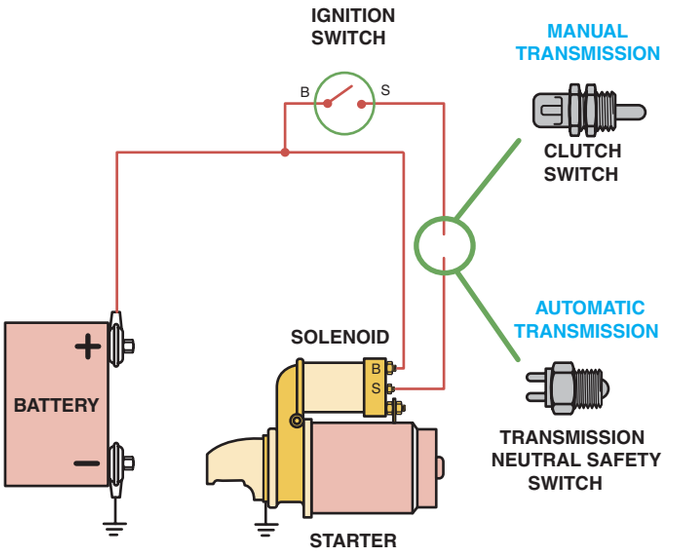

FIGURE 52–3 To prevent the engine from cranking, an electrical switch is usually installed to open the circuit between the ignition switch and the starter solenoid.

3. **Starter solenoid or relay.** The high current required by the starter must be able to be turned on and off. A large switch would be required if the current were controlled by the driver directly. Instead, a small current switch (ignition switch) operates a solenoid or relay that controls the high current to the starter.
4. **Starter drive.** The starter drive uses a small pinion gear that contacts the engine flywheel gear teeth and transmits starter motor power to rotate the engine.
5. **Ignition switch.** The ignition switch and safety control switches control the starter motor operation. ● **SEE FIGURE 52–2.**

CONTROL CIRCUIT PARTS AND OPERATION The engine is cranked by an electric motor that is controlled by a key-operated ignition switch. The ignition switch will not operate the starter unless the automatic transmission is in neutral or park, or the clutch pedal is depressed on manual transmission/transaxle vehicles. This is to prevent an accident that might result from the vehicle moving forward or rearward when the engine is started. The types of controls that are used to be sure that the vehicle will not move when being cranked include the following:

- Many automobile manufacturers use an electric switch called a **neutral safety switch,** which opens the circuit between the ignition switch and the starter to prevent starter motor operation, unless the gear selector is in neutral or park. The safety switch can be attached either to the steering column inside the vehicle near the floor or on the side of the transmission.
- Many manufacturers use a mechanical blocking device in the steering column to prevent the driver from turning the key switch to the start position unless the gear selector is in neutral or park.
- Many manual transmission vehicles also use a safety switch to permit cranking only if the clutch is depressed. This switch is commonly called the *clutch safety switch.* ● **SEE FIGURE 52–3**.

COMPUTER-CONTROLLED STARTING

OPERATION Some key-operated ignition systems and most push-button-to-start systems use the computer to crank the engine. The ignition switch start position on the push-to-start button is used as an input signal to the powertrain control module (PCM). Before the PCM cranks the engine, the following conditions must be met.

- The brake pedal is depressed.
- The gear selector is in park or neutral.
- The correct key fob (code) is present in the vehicle.

A typical push-button start system includes the following sequence.

- The ignition key can be turned to the start position, released, and the PCM cranks the engine until it senses that the engine has started.

FIGURE 52–4 Instead of using an ignition key to start the engine, some vehicles are using a start button which is also used to stop the engine, as shown on this Jaguar.

FIGURE 52–5 The top button on this key fob is the remote start button.

- The PCM can detect that the engine has started by looking at the engine speed signal.
- Normal cranking speed can vary between 100 and 250 RPM. If the engine speed exceeds 400 RPM, the PCM determines that the engine started and opens the circuit to the "S" (start) terminal of the starter solenoid that stops the starter motor.

Computer-controlled starting is almost always part of the system if a push-button start is used. ● **SEE FIGURE 52–4.**

REMOTE STARTING Remote starting, sometimes called **remote vehicle start (RVS),** is a system that allows the driver to start the engine of the vehicle from inside the house or a building at a distance of about 200 ft (65 m). The doors remain locked to reduce the possibility of theft. This feature allows the heating or air-conditioning system to start before the driver arrives. ● **SEE FIGURE 52–5.**

NOTE: Most remote start systems will turn off the engine after 10 minutes of run time unless reset by using the remote.

STARTER MOTOR OPERATION

PRINCIPLES A starter motor uses electromagnetic principles to convert electrical energy from the battery (up to 300 amperes) to mechanical power (up to 8 horsepower [6 kilowatts]) to crank the engine. Current for the starter motor or power circuit is controlled by a solenoid or relay, which is itself controlled by the driver-operated ignition switch.

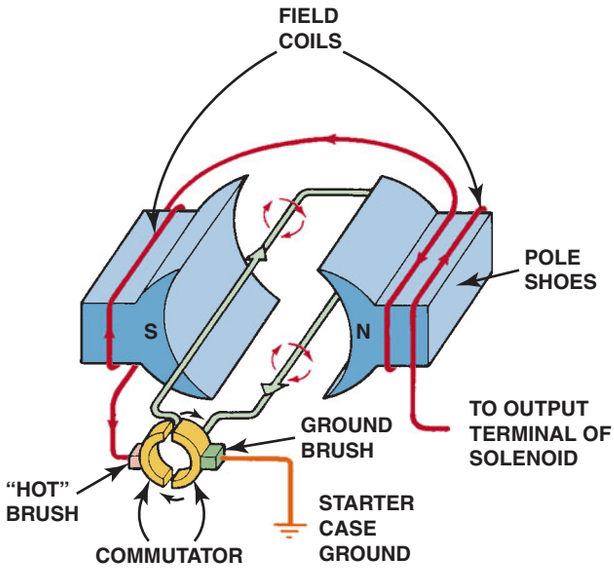

FIGURE 52–6 This series-wound electric motor shows the basic operation with only two brushes: one hot brush and one ground brush. The current flows through both field coils, then through the hot brush and the loop winding of the armature, before reaching ground through the ground brush.

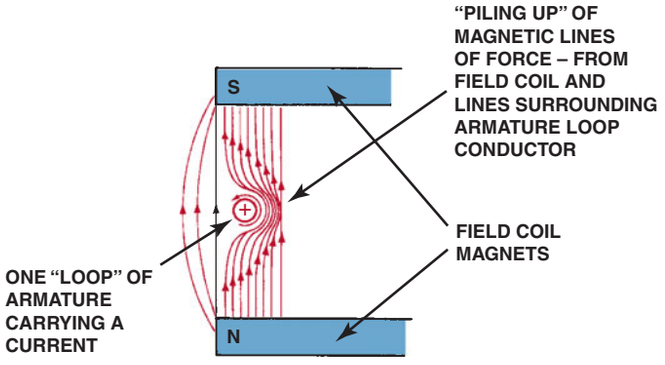

FIGURE 52–7 The interaction of the magnetic fields of the armature loops and field coils creates a stronger magnetic field on the right side of the conductor, causing the armature loop to move toward the left.

The current travels through the brushes and into the armature windings, where other magnetic fields are created around each copper wire loop in the armature. The two strong magnetic fields created inside the starter housing create the force that rotates the armature.

Inside the starter housing is a strong magnetic field created by the field coil magnets. The armature, a conductor, is installed inside this strong magnetic field, with little clearance between the armature and the field coils.

The two magnetic fields act together, and their lines of force "bunch up" or are strong on one side of the armature loop wire and become weak on the other side of the conductor. This causes the conductor (armature) to move from the area of strong magnetic field strength toward the area of weak magnetic field strength. ● **SEE FIGURES 52–6 AND 52–7.**

The difference in magnetic field strength causes the armature to rotate. This rotation force (torque) is increased as the current flowing through the starter motor increases. The torque of a starter is

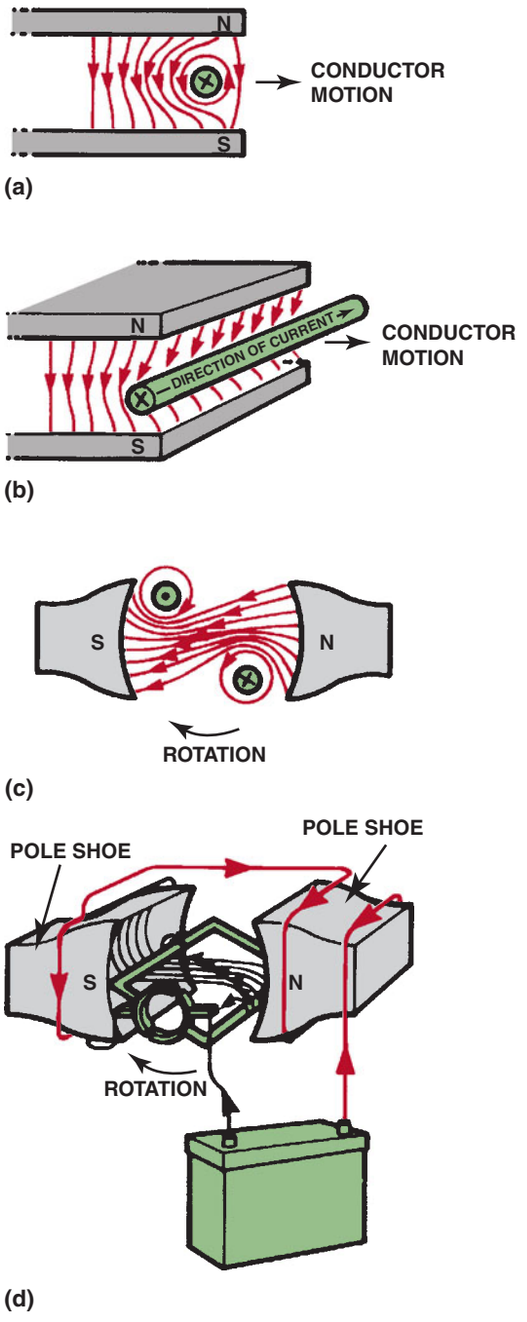

FIGURE 52–8 The armature loops rotate due to the difference in the strength of the magnetic field. The loops move from a strong magnetic field strength toward a weaker magnetic field strength.

determined by the strength of the magnetic fields inside the starter. Magnetic field strength is measured in ampere-turns. If the current or the number of turns of wire is increased, the magnetic field strength is increased.

The magnetic field of the starter motor is provided by two or more pole shoes and field windings. The pole shoes are made of iron and are attached to the frame with large screws. ● **SEE FIGURE 52–8**.

● **FIGURE 52–9** shows the paths of magnetic flux lines within a four-pole motor.

The field windings are usually made of a heavy copper ribbon to increase their current-carrying capacity and electromagnetic field strength. ● **SEE FIGURE 52–10**.

Automotive starter motors usually have four pole shoes and two to four field windings to provide a strong magnetic field within

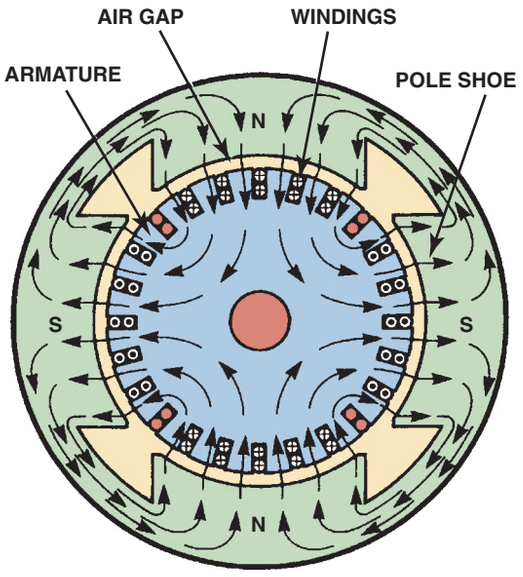

FIGURE 52–9 Magnetic lines of force in a four-pole motor.

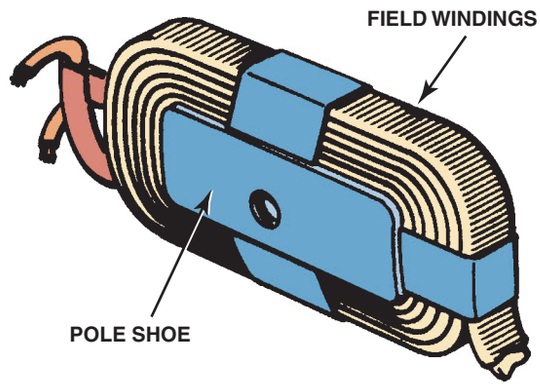

FIGURE 52–10 A pole shoe and field winding.

the motor. Pole shoes that do not have field windings are magnetized by flux lines from the wound poles.

SERIES MOTORS A series motor develops its maximum torque at the initial start (0 RPM) and develops less torque as the speed increases.

- A series motor is commonly used for an automotive starter motor because of its high starting power characteristics.
- A series starter motor develops less torque at high RPM, because a current is produced in the starter itself that acts against the current from the battery. Because this current works against battery voltage, it is called counterelectromotive force, or **CEMF.** This CEMF is produced by electromagnetic induction in the armature conductors, which are cutting across the magnetic lines of force formed by the field coils. This induced voltage operates against the applied voltage supplied by the battery, which reduces the strength of the magnetic field in the starter.
- Because the power (torque) of the starter depends on the strength of the magnetic fields, the torque of the starter decreases as the starter speed increases. A series-wound starter also draws less current at higher speeds and will keep increasing in speed under light loads. This could lead to the destruction of the starter motor unless controlled or prevented. ● **SEE FIGURE 52–11**.

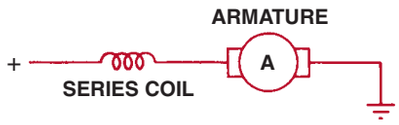

FIGURE 52–11 This wiring diagram illustrates the construction of a series-wound electric motor. Notice that all current flows through the field coils, then through the armature (in series) before reaching ground.

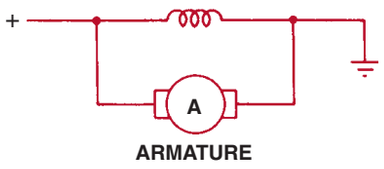

FIGURE 52–12 This wiring diagram illustrates the construction of a shunt-type electric motor, and shows the field coils in parallel (or shunt) across the armature.

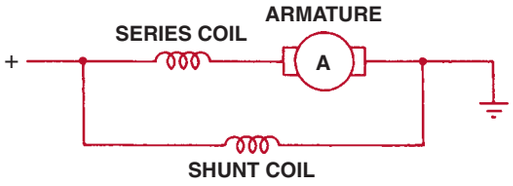

FIGURE 52–13 A compound motor is a combination of series and shunt types, using part of the field coils connected electrically in series with the armature and some in parallel (shunt).

SHUNT MOTORS

Shunt-type electric motors have the field coils in parallel (or shunt) across the armature.

A shunt-type motor has the following features.

- A shunt motor does not decrease in torque at higher motor RPM, because the CEMF produced in the armature does not decrease the field coil strength.
- A shunt motor, however, does not produce as high a starting torque as that of a series-wound motor, and is not used for starters. Some small electric motors, such as used for windshield wiper motors, use a shunt motor but most use permanent magnets rather than electromagnets.

● **SEE FIGURE 52–12**.

PERMANENT MAGNET MOTORS

A **permanent magnet (PM) starter** uses permanent magnets that maintain constant field strength, the same as a shunt-type motor, so they have similar operating characteristics. To compensate for the lack of torque, all PM starters use gear reduction to multiply starter motor torque. The permanent magnets used are an alloy of neodymium, iron, and boron, and are almost 10 times more powerful than previously used permanent magnets.

COMPOUND MOTORS

A compound-wound, or compound, motor has the operating characteristics of a series motor *and* a shunt-type motor, because some of the field coils are connected to the armature in series and some (usually only one) are connected directly to the battery in parallel (shunt) with the armature.

Compound-wound starter motors are commonly used in Ford, Chrysler, and some GM starters. The shunt-wound field coil is called a shunt coil and is used to limit the maximum speed of the starter. Because the shunt coil is energized as soon as the battery current is sent to the starter, it is used to engage the starter drive on older Ford positive engagement–type starters. ● **SEE FIGURE 52–13**.

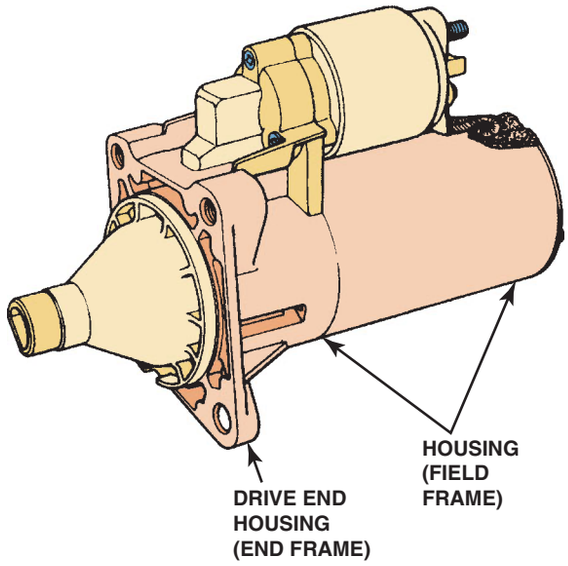

FIGURE 52–14 A typical starter motor showing the drive-end housing.

HOW THE STARTER MOTOR WORKS

PARTS INVOLVED

A starter consists of the main structural support of a starter called the main **field housing,** one end of which is called a **commutator-end** (or **brush-end) housing** and the other end a **drive-end housing.** The drive-end housing contains the drive pinion gear, which meshes with the engine flywheel gear teeth to start the engine. The commutator-end plate supports the end containing the starter brushes. **Through bolts** hold the three components together. ● **SEE FIGURE 52–14**.

- **Field coils.** The steel housing of the starter motor contains permanent magnets or four electromagnets that are connected directly to the positive post of the battery to provide a strong magnetic field inside the starter. The four electromagnets use heavy copper or aluminum wire wrapped around a soft-iron core, which is contoured to fit against the rounded internal surface of the starter frame. The soft-iron cores are called **pole shoes.** Two of the four pole shoes are wrapped with copper wire in one direction to create a north pole magnet, and the other two pole shoes are wrapped in the opposite direction to create a south pole magnet. These magnets, when energized, create strong magnetic fields inside the starter housing and, therefore, are called **field coils.** The soft-iron cores (pole shoes) are often called **field poles.** ● **SEE FIGURE 52–15**.
- **Armature.** Inside the field coils is an **armature** that is supported with either bushings or ball bearings at both ends, which permit it to rotate. The armature is constructed of thin, circular disks of steel laminated together and wound lengthwise with heavy-gauge insulated copper wire. The laminated iron core supports the copper loops of wire and helps concentrate the magnetic field produced by the coils. ● **SEE FIGURE 52–16**.

Insulation between the laminations helps to increase the magnetic efficiency in the core. For reduced resistance, the armature conductors are made of a thick copper wire. The two ends of each conductor are attached to two adjacent commutator bars.

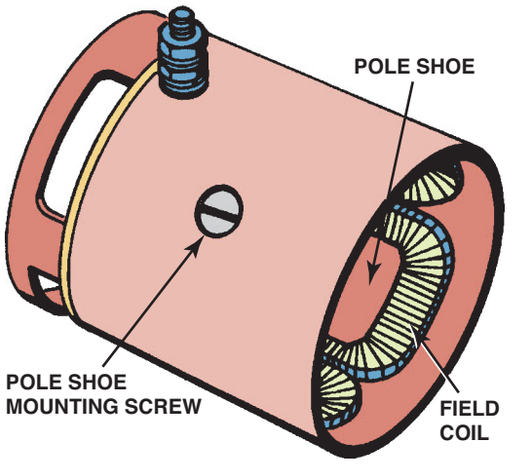

FIGURE 52–15 Pole shoes and field windings installed in the housing.

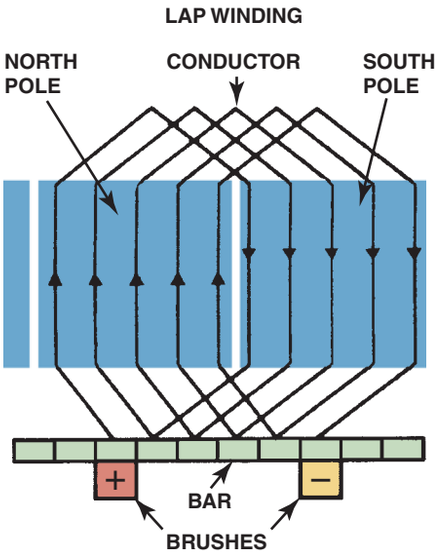

FIGURE 52–17 An armature showing how its copper wire loops are connected to the commutator.

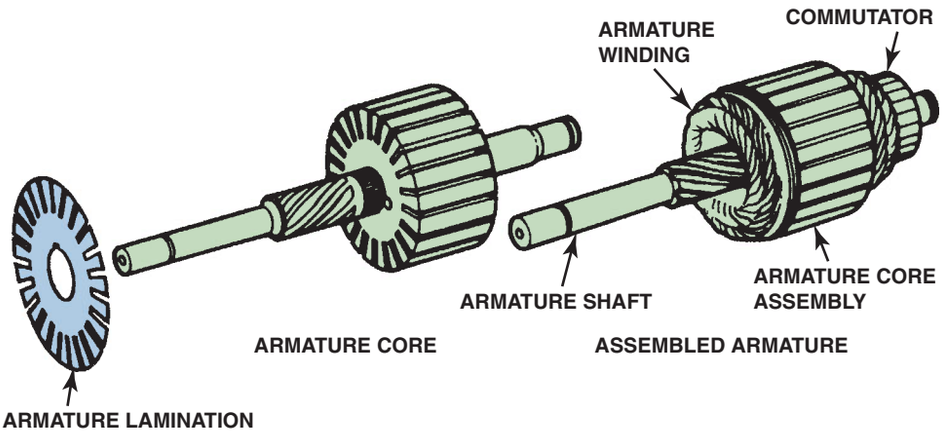

FIGURE 52–16 A typical starter motor armature. The armature core is made from thin sheet metal sections assembled on the armature shaft, which is used to increase the magnetic field strength.

The commutator is made of copper bars insulated from each other by mica or some other insulating material. ● **SEE FIGURE 52–17**.

The armature core, windings, and commutator are assembled on a long armature shaft. This shaft also carries the pinion gear that meshes with the engine flywheel ring gear.

STARTER BRUSHES

To supply the proper current to the armature, a four-pole motor must have four brushes riding on the commutator. Most automotive starters have two grounded and two insulated brushes, which are held against the commutator by spring force.

The ends of the copper armature windings are soldered to **commutator segments.** The electrical current that passes through the field coils is then connected to the commutator of the armature by brushes that can move over the segments of the rotating armature. These **brushes** are made of a combination of copper and carbon.

- The copper is a good conductor material.
- The carbon added to the starter brushes helps provide the graphite-type lubrication needed to reduce wear of the brushes and the commutator segments.

The starter uses four brushes—two brushes to transfer the current from the field coils to the armature, and two brushes to provide the ground return path for the current that flows through the armature.

The two sets of brushes include:

1. Two **insulated brushes,** which are in holders and are insulated from the housing.
2. Two **ground brushes,** which use bare, stranded copper wire connections to the brushes. The ground brush holders are not insulated and attach directly to the field housing or brush-end housing. ● **SEE FIGURE 52–18**.

PERMANENT MAGNET FIELDS

Permanent magnets are used in place of the electromagnetic field coils and pole shoes in many starters today. This eliminates the motor field circuit, which in turn eliminates the potential for field coil faults and other electrical problems. The motor has only an armature circuit.

GEAR-REDUCTION STARTERS

PURPOSE AND FUNCTION

Gear-reduction starters are used by many automotive manufacturers. The purpose of the gear reduction (typically 2:1 to 4:1) is to increase starter motor speed and provide the torque multiplication necessary to crank an engine.

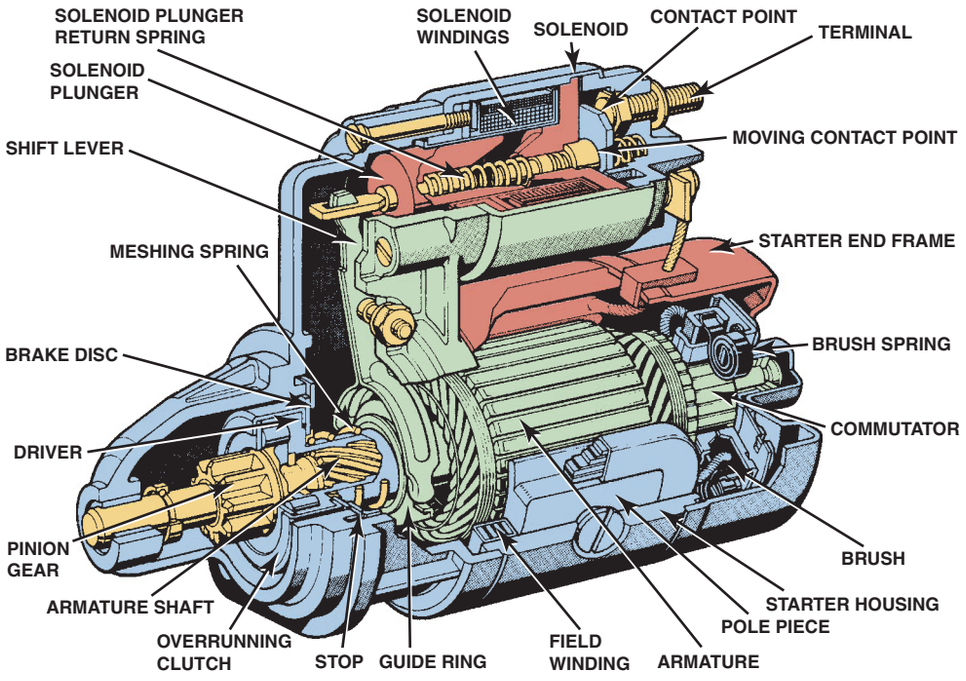

FIGURE 52–18 A cutaway of a typical starter motor showing the commutator, brushes, and brush spring.

FIGURE 52–19 This starter permanent magnet field housing was ruined when someone used a hammer on the field housing in an attempt to "fix" a starter that would not work. A total replacement is the only solution in this case.

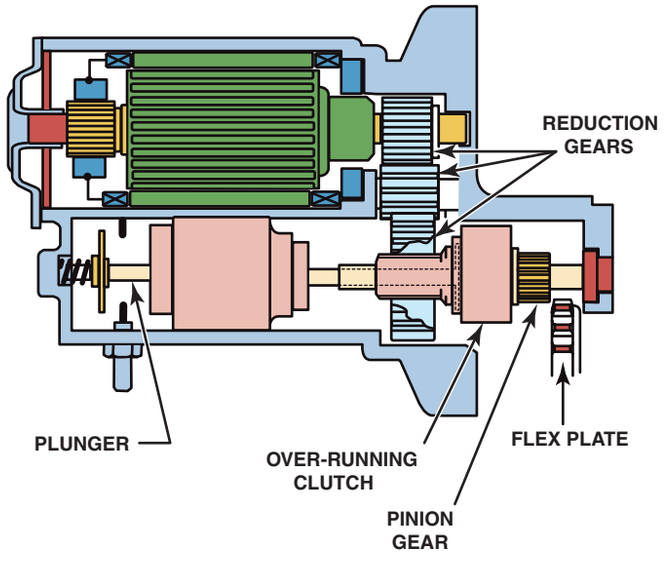

FIGURE 52–20 A typical gear-reduction starter.

TECH TIP

Don't Hit That Starter!

In the past, it was common to see service technicians hitting a starter in their effort to diagnose a no-crank condition. Often the shock of the blow to the starter aligned or moved the brushes, armature, and bushings. Many times, the starter functioned after being hit, even if only for a short time.

However, most starters today use permanent magnet fields, and the magnets can be easily broken if hit. A magnet that is broken becomes two weaker magnets. Some early PM starters used magnets that were glued or bonded to the field housing. If struck with a heavy tool, the magnets could be broken with parts of the magnet falling onto the armature and into the bearing pockets, making the starter impossible to repair or rebuild. ● **SEE FIGURE 52–19.**

As a series-wound motor increases in rotational speed, the starter produces less power, and less current is drawn from the battery because the armature generates greater CEMF as the starter speed increases. However, a starter motor's maximum torque occurs at 0 RPM and torque decreases with increasing RPM. A smaller starter using a gear-reduction design can produce the necessary cranking power with reduced starter amperage requirements. Lower current requirements mean that smaller battery cables can be used. Many permanent magnet starters use a planetary gear set (a type of gear reduction) to provide the necessary torque for starting. ● **SEE FIGURE 52–20.**

STARTER DRIVES

PURPOSE AND FUNCTION A **starter drive** includes small pinion gears that mesh with and rotate the larger gear on the engine flywheel or flex plate for starting. The pinion gear must engage with

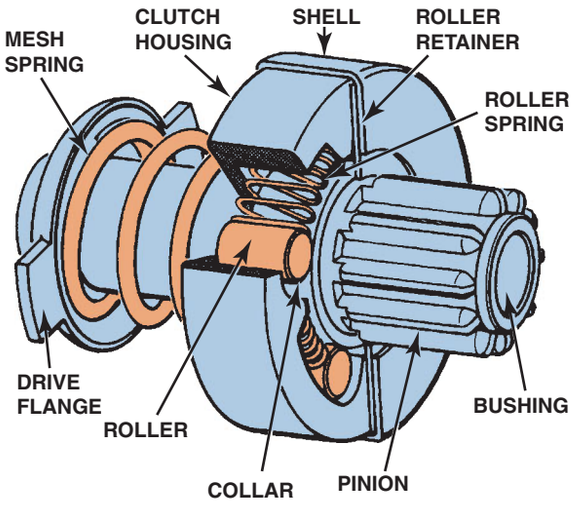

FIGURE 52–21 A cutaway of a typical starter drive showing all of the internal parts.

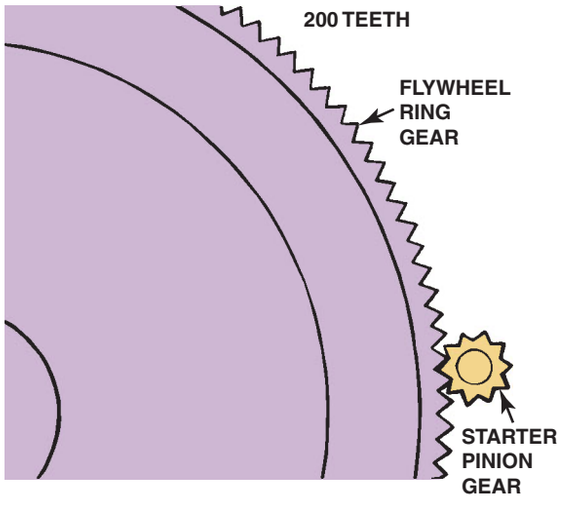

FIGURE 52–22 The ring gear to pinion gear ratio is usually 15:1 to 20:1.

the engine gear slightly *before* the starter motor rotates, to prevent serious damage to either the starter gear or the engine, but must be disengaged after the engine starts. The ends of the starter pinion gear are tapered to help the teeth mesh more easily without damaging the flywheel ring gear teeth. ● **SEE FIGURE 52–21**.

STARTER DRIVE GEAR RATIO The ratio of the number of teeth on the engine ring gear to the number on the starter pinion is between 15:1 and 20:1. A typical small starter pinion gear has 9 teeth that turn an engine ring gear with 166 teeth. This provides an 18:1 gear reduction; thus, the starter motor is rotating approximately 18 times faster than the engine. Normal cranking speed for the engine is 200 RPM (varies from 70 to 250 RPM). This means that the starter motor speed is 18 times faster, or 3600 starter RPM (200 × 18 = 3600). If the engine starts and is accelerated to 2000 RPM (normal cold engine speed), the starter will be destroyed by the high speed (36,000 RPM) if the starter was not disengaged from the engine. ● **SEE FIGURE 52–22**.

STARTER DRIVE OPERATION All starter drive mechanisms use a type of one-way clutch that allows the starter to rotate the engine, but then turns freely if the engine speed is greater than the starter motor speed. This clutch, called an **overrunning clutch,** protects the starter motor from damage if the ignition switch is held in the start position after the engine starts. The overrunning clutch, which is built in as a part of the starter drive unit, uses steel balls or rollers installed in tapered notches. ● **SEE FIGURE 52–23**.

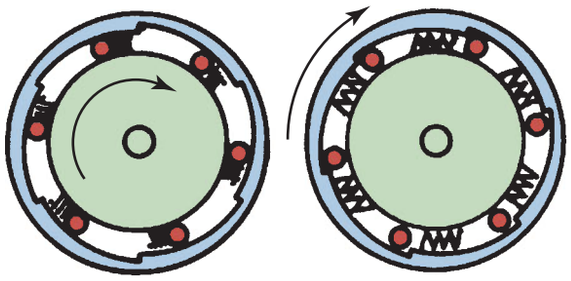

FIGURE 52–23 Operation of the overrunning clutch. (a) Starter motor is driving the starter pinion and cranking the engine. The rollers are wedged against spring force into their slots. (b) The engine has started and is rotating faster than the starter armature. Spring force pushes the rollers so they can rotate freely.

? FREQUENTLY ASKED QUESTION

What Is a Bendix?

Older-model starters often used a Bendix drive mechanism, which used inertia to engage the starter pinion with the engine flywheel gear. Inertia is the tendency of a stationary object to remain stationary, because of its weight, unless forced to move. On these older-model starters, the small starter pinion gear was attached to a shaft with threads, and the weight of this gear caused it to be spun along the threaded shaft and mesh with the flywheel whenever the starter motor spun. If the engine speed was greater than the starter speed, the pinion gear was forced back along the threaded shaft and out of mesh with the flywheel gear. The Bendix drive mechanism has generally not been used since the early 1960s, but some technicians use this term when describing a starter drive.

This taper forces the balls or rollers tightly into the notch, when rotating in the direction necessary to start the engine. When the engine rotates faster than the starter pinion, the balls or rollers are forced out of the narrow tapered notch, allowing the pinion gear to turn freely (overrun).

The spring between the drive tang or pulley and the overrunning clutch and pinion is called a **mesh spring.** It helps to cushion and control the engagement of the starter drive pinion with the engine flywheel gear. This spring is also called a **compression spring,** because the starter solenoid or starter yoke compresses the spring and the spring tension causes the starter pinion to engage the engine flywheel.

FAILURE MODE A starter drive is generally a dependable unit and does not require replacement unless defective or worn. The major wear occurs in the overrunning clutch section of the starter drive unit. The steel balls or rollers wear and often do not wedge tightly into the tapered notches as is necessary for engine cranking. A worn starter drive can cause the starter motor to operate and then stop cranking the engine and creating a "whining" noise. The whine indicates that the starter motor is operating and that the starter drive is not rotating the engine flywheel. The entire starter drive is replaced

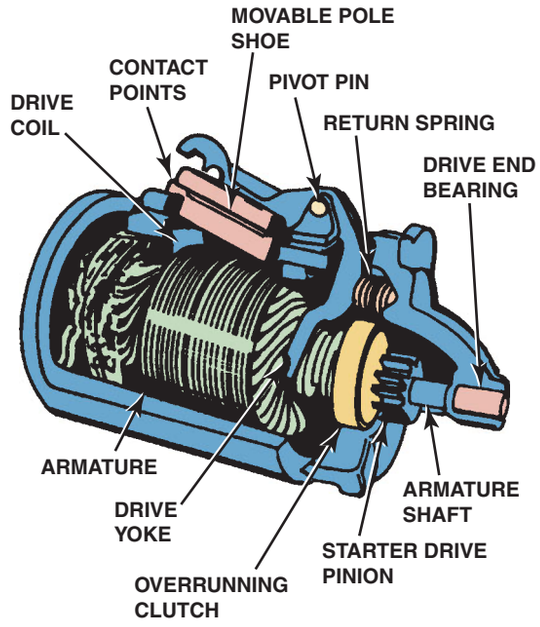

FIGURE 52–24 A Ford movable pole shoe starter.

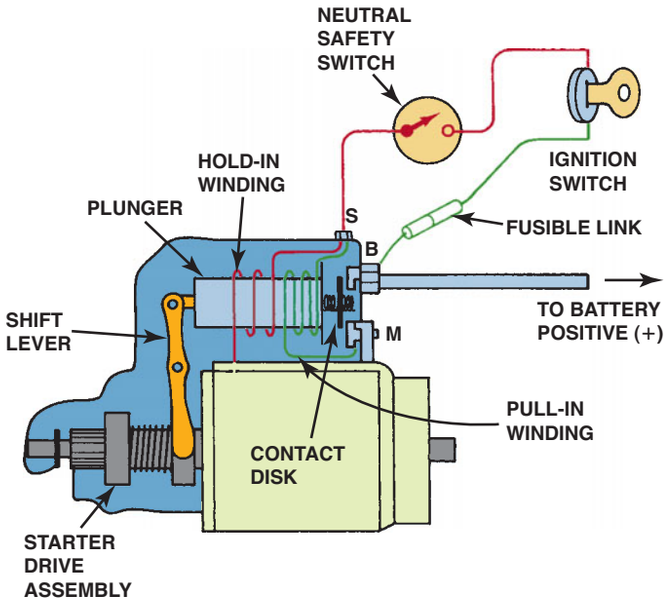

FIGURE 52–25 Wiring diagram of a typical starter solenoid. Notice that both the pull-in winding and the hold-in winding are energized when the ignition switch is first turned to the "start" position. As soon as the solenoid contact disk makes electrical contact with both the B and M terminals, the battery current is conducted to the starter motor and electrically neutralizes the pull-in winding.

as a unit. The overrunning clutch section of the starter drive cannot be serviced or repaired separately because the drive is a sealed unit. Starter drives are most likely to fail intermittently at first and then more frequently, until replacement becomes necessary to start the engine. Intermittent starter drive failure (starter whine) is often most noticeable during cold weather.

POSITIVE ENGAGEMENT STARTERS

OPERATION Positive engagement starters (direct drive) were used on Ford engines from 1973 to 1990. These starters use the shunt coil winding and a movable pole shoe to engage the starter drive. The high starting current is controlled by an ignition switch–operated starter solenoid, usually mounted near the positive post of the battery. When this control circuit is closed, current flows through a hollow coil (called a drive coil) that attracts a movable pole shoe.

As soon as the starter drive has engaged the engine flywheel, a tang on the movable pole shoe "opens" a set of contact points. The contact points provide the ground return path for the drive coil operation. After these grounding contacts are opened, all of the starter current can flow through the remaining three field coils and through the brushes to the armature, causing the starter to operate.

The movable pole shoe is held down (which keeps the starter drive engaged) by a smaller coil on the inside of the main drive coil. This coil, called the *holding coil*, is strong enough to hold the starter drive engaged while permitting the flow of the maximum possible current to operate the starter. ● **SEE FIGURE 52–24**.

ADVANTAGES The movable metal pole shoe is attached to and engages the starter drive with a lever (called the plunger lever). As a result, this type of starter does not use a solenoid to engage the starter drive.

DISADVANTAGES If the grounding contact points are severely pitted, the starter may not operate the starter drive or the starter motor because of the resulting poor ground for the drive coil. If the contact points are bent or damaged enough to prevent them from opening, the starter will "clunk" the starter drive into engagement but will not allow the starter motor to operate.

SOLENOID-OPERATED STARTERS

SOLENOID OPERATION A **starter solenoid** is an electromagnetic switch containing two separate, but connected, electromagnetic windings. This switch is used to engage the starter drive and control the current from the battery to the starter motor.

SOLENOID WINDINGS The two internal windings contain approximately the same number of turns but are made from different-gauge wire. Both windings together produce a strong magnetic field that pulls a metal plunger into the solenoid. The plunger is attached to the starter drive through a shift fork lever. When the ignition switch is turned to the start position, the motion of the plunger into the solenoid causes the starter drive to move into mesh with the flywheel ring gear.

1. The heavier-gauge winding (called the **pull-in winding**) is needed to draw the plunger into the solenoid and is grounded through the starter motor.
2. The lighter-gauge winding (called the **hold-in winding**), which is grounded through the starter frame, produces enough magnetic force to keep the plunger in position. The main purpose of using two separate windings is to permit as much current as possible to operate the starter and yet provide the strong magnetic field required to move the starter drive into engagement. ● **SEE FIGURE 52–25**.

OPERATION

1. The solenoid operates as soon as the ignition or computer-controlled relay energizes the "S" (start) terminals. At that

FREQUENTLY ASKED QUESTION

How Are Starters Made So Small?

Starters and most components in a vehicle are being made as small and as light in weight as possible to help increase vehicle performance and fuel economy. A starter can be constructed smaller due to the use of gear reduction and permanent magnets to achieve the same cranking torque as a straight drive starter, but using much smaller components. ● **SEE FIGURE 52–26** for an example of an automotive starter armature that is palm size.

FIGURE 52–26 A palm-size starter armature.

instant, the plunger is drawn into the solenoid enough to engage the starter drive.

2. The plunger makes contact with a metal disk that connects the battery terminal post of the solenoid to the motor terminal. This permits full battery current to flow through the solenoid to operate the starter motor.
3. The contact disk also electrically disconnects the pull-in winding. The solenoid *has* to work to supply current to the starter. Therefore, if the starter motor operates at all, the solenoid is working, even though it may have high external resistance that could cause slow starter motor operation.

STARTING SYSTEM TROUBLESHOOTING PROCEDURE

OVERVIEW The proper operation of the starting system depends on a good battery, good cables and connections, and a good starter motor. Because a starting problem can be caused by a defective component anywhere in the starting circuit, it is important to check for the proper operation of each part of the circuit to diagnose and repair the problem quickly.

STEPS INVOLVED Following are the steps involved in the diagnosis of a fault in the cranking circuit.

STEP 1 **Verify the customer concern.** Sometimes the customer is not aware of how the cranking system is supposed to work, especially if it is computer controlled.

STEP 2 **Visually inspect the battery and battery connections.** The starter is the highest amperage draw device used in a vehicle and any faults, such as corrosion on battery terminals, can cause cranking system problems.

STEP 3 **Test battery condition.** Perform a battery load or conductance test on the battery to be sure that the battery is capable of supplying the necessary current for the starter.

STEP 4 **Check the control circuit.** An open or high resistance anywhere in the control circuit can cause the starter motor to not engage. Items to check include:

- "S" terminal of the starter solenoid
- Neutral safety or clutch switch
- Starter enable relay (if equipped)
- Antitheft system fault (If the engine does not crank or start and the theft indicator light is on or flashing, there is likely a fault in the theft deterrent system. Check service information for the exact procedures to follow before attempting to service the cranking circuit. ● **SEE FIGURE 53–1.**)

STEP 5 **Check voltage drop of the starter circuit.** Any high resistance in either the power side or ground side of the starter circuit will cause the starter to rotate slowly or not at all.

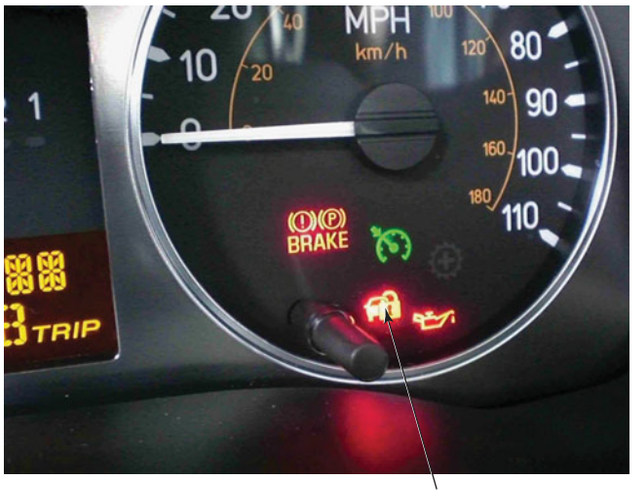

FIGURE 53–1 A theft deterrent indicator lamp on the dash. A flashing lamp usually indicates a fault in the system, and the engine may not start.

VOLTAGE DROP TESTING

PURPOSE **Voltage drop** is the drop in voltage that occurs when current is flowing through a resistance. For example, a voltage drop is the difference between voltage at the source and voltage at the electrical device to which it is flowing. The higher the voltage drop is, the greater the resistance in the circuit. Even though voltage drop testing can be performed on any electrical circuit, the most common areas of testing include the cranking circuit and the charging circuit wiring and connections. Voltage drop testing should be performed on both the power side and ground side of the circuit.

A high voltage drop (high resistance) in the cranking circuit wiring can cause slow engine cranking with less than normal starter amperage drain as a result of the excessive circuit resistance. If the voltage drop is high enough, such as that caused by dirty battery terminals, the starter may not operate. A typical symptom of high resistance in the cranking circuit is a "clicking" of the starter solenoid.

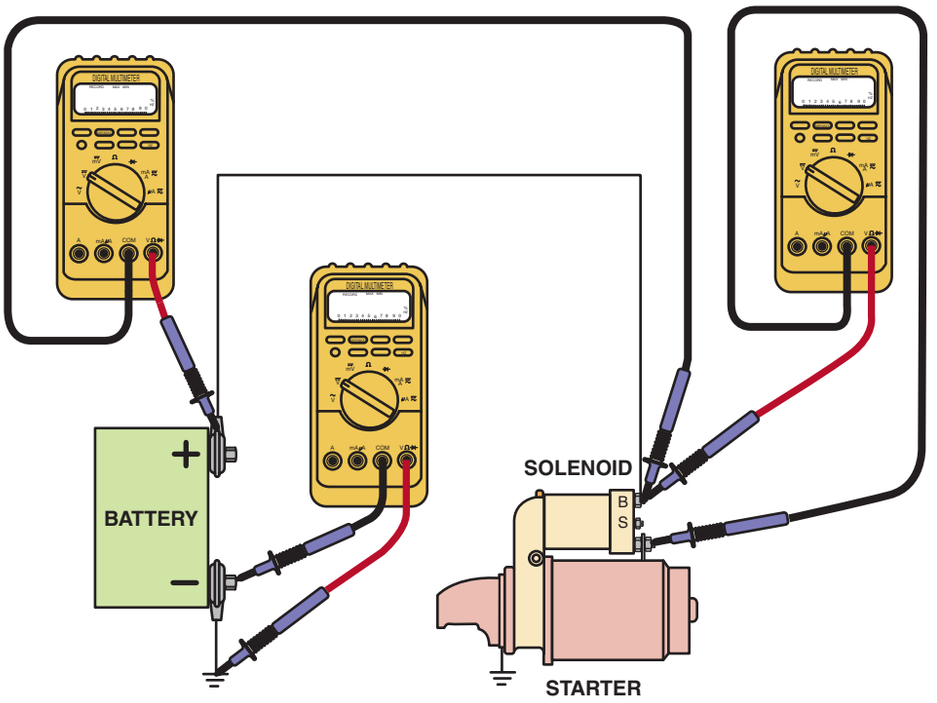

FIGURE 53–2 Voltmeter hookups for voltage drop testing of a solenoid-type cranking circuit.

TECH TIP

Voltage Drop Is Resistance

Many technicians have asked, "Why measure voltage drop when the resistance can be easily measured using an ohmmeter?" Think of a battery cable with all the strands of the cable broken, except for one strand. If an ohmmeter were used to measure the resistance of the cable, the reading would be very low, probably less than 1 ohm. However, the cable is not capable of conducting the amount of current necessary to crank the engine. In less severe cases, several strands can be broken, thereby affecting the operation of the starter motor. Although the resistance of the battery cable will not indicate an increase, the restriction to current flow will cause heat and a drop of voltage available at the starter. Because resistance is not effective until current flows, measuring the voltage drop (differences in voltage between two points) is the most accurate method of determining the true resistance in a circuit.

How much is too much? According to Bosch Corporation, all electrical circuits should have a maximum of 3% loss of the circuit voltage to resistance. Therefore, in a 12 volt circuit, the maximum loss of voltage in cables and connections should be 0.36 volt (12 × 0.03 = 0.36 volt). The remaining 97% of the circuit voltage (11.64 volts) is available to operate the electrical device (load). Just remember:

- Low-voltage drop = Low resistance
- High-voltage drop = High resistance

TECH TIP

A Warm Cable Equals High Resistance

If a cable or connection is warm to the touch, there is electrical resistance in the cable or connection. The resistance changes electrical energy into heat energy. Therefore, if a voltmeter is not available, touch the battery cables and connections while cranking the engine. If any cable or connection is hot to the touch, it should be cleaned or replaced.

TEST PROCEDURE Voltage drop testing of the wire involves connecting a voltmeter set to read DC volts to the suspected high-resistance cable ends and cranking the engine. ● **SEE FIGURES 53–2 THROUGH 53–4.**

NOTE: Before a difference in voltage (voltage drop) can be measured between the ends of a battery cable, current must be flowing through the cable. *Resistance is not effective unless current is flowing.* If the engine is not being cranked, current is not flowing through the battery cables and the voltage drop cannot be measured.

STEP 1 Disable the ignition or fuel injection as follows:

- Disconnect the primary (low-voltage) electrical connection(s) from the ignition module or ignition coils.
- Remove the fuel-injection fuse or relay, or the electrical connection leading to all of the fuel injectors.

CAUTION: Never disconnect the high-voltage ignition wires unless they are connected to ground. The high voltage that could occur when cranking can cause the ignition coil to fail (arc internally).

STEP 2 Connect one lead of the voltmeter to the starter motor battery terminal and the other end to the positive battery terminal.

STEP 3 Crank the engine and observe the reading while cranking. (Disregard the first higher reading.) The reading should be less than 0.20 volt (200 mV).

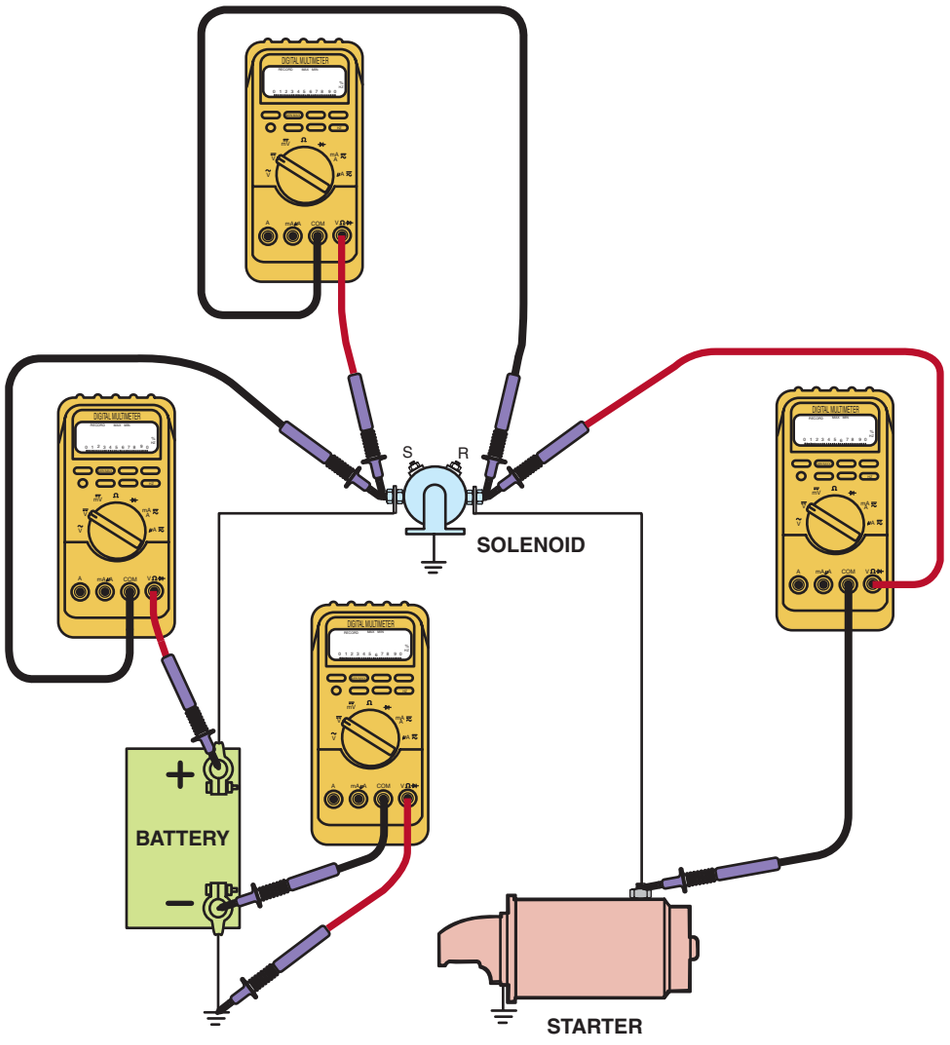

FIGURE 53–3 Voltmeter hookups for voltage drop testing of a Ford cranking circuit.

FIGURE 53–4 To test the voltage drop of the battery cable connection, place one voltmeter lead on the battery terminal and the other voltmeter lead on the cable end and crank the engine. The voltmeter will read the difference in voltage between the two leads, which should not exceed 0.20 volt (200 mV).

STEP 4 If accessible, test the voltage drop across the "B" and "M" terminals of the starter solenoid with the engine cranking. The voltage drop should be less than 0.20 volt (200 mV).

STEP 5 Repeat the voltage drop on the ground side of the cranking circuit by connecting one voltmeter lead to the negative battery terminal and the other at the starter housing. Crank the engine and observe the voltmeter display. The voltage drop should be less than 0.2 volt (200 mV).

CONTROL CIRCUIT TESTING

PARTS INVOLVED The control circuit for the starting circuit includes the battery, ignition switch, neutral or clutch safety switch, theft deterrent system, and starter solenoid. When the ignition switch is rotated to the start position, current flows through the ignition switch and neutral safety switch to activate the solenoid. High current then flows directly from the battery through the solenoid and to the starter motor. Therefore, an open or break anywhere in the control circuit will prevent the operation of the starter motor.

If a starter is inoperative, first check for voltage at the "S" (start) terminal of the starter solenoid. Check for faults with the following:

- Neutral safety or clutch switch
- Blown crank fuse
- Open at the ignition switch in the crank position

Some models with antitheft controls use a relay to open this control circuit to prevent starter operation.

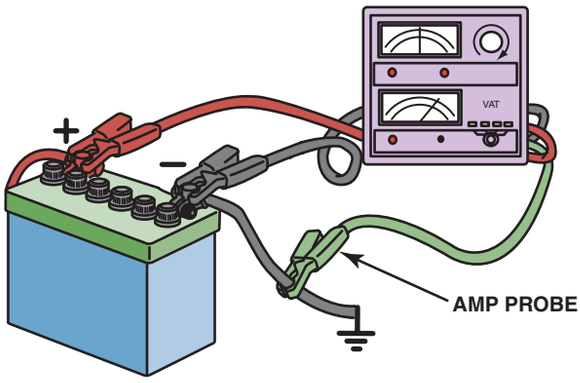

FIGURE 53–5 A starter amperage tester uses an amp probe around the positive or negative battery cables.

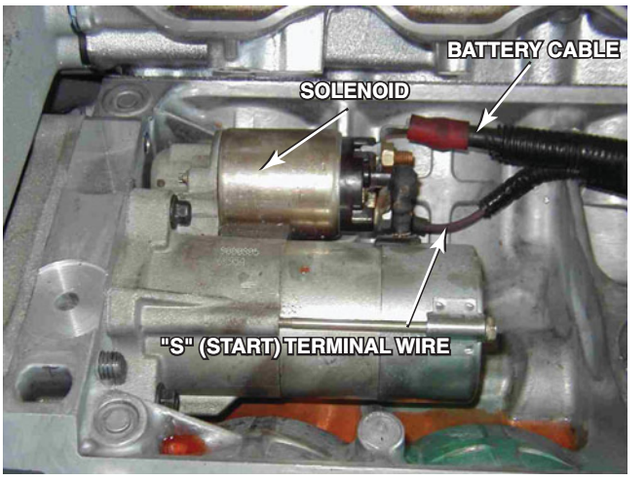

FIGURE 53–6 The starter is located under the intake manifold on this Cadillac Northstar engine.

TECH TIP

Watch the Dome Light

When diagnosing any starter-related problem, open the door of the vehicle and observe the brightness of the dome or interior light(s).

The brightness of any electrical lamp is proportional to the voltage of the battery.

Normal operation of the starter results in a slight dimming of the dome light.

If the light remains bright, the problem is usually an open in the control circuit.

If the light goes out or almost goes out, there could be a problem with the following:

- A shorted or grounded armature of field coils inside the starter
- Loose or corroded battery connections or cables
- Weak or discharged battery

STARTER AMPERAGE TEST

REASON FOR A STARTER AMPERAGE TEST A starter should be tested to see if the reason for slow or no cranking is due to a fault with the starter motor or another problem. A voltage drop test is used to find out if the battery cables and connections are okay. A starter amperage draw test determines if the starter motor is the cause of a no or slow cranking concern.

TEST PREPARATION Before performing a starter amperage test, be certain that the battery is sufficiently charged (75% or more) and capable of supplying adequate starting current. Connect a starter amperage tester following the tester's instructions. ● **SEE FIGURE 53–5.**

A starter amperage test should be performed when the starter fails to operate normally (is slow in cranking) or as part of a routine electrical system inspection.

SPECIFICTIONS Some service manuals specify normal starter amperage for starter motors being tested on the vehicle; however, most service manuals only give the specifications for bench testing a starter without a load applied. These specifications are helpful in making certain that a repaired starter meets exact specifications, but they do not apply to starter testing on the vehicle. If exact specifications are not available, the following can be used as general *maximum* amperage draw specifications for testing a starter on the vehicle.

- **4-cylinder engines** = 150 to 185 amperes (normally less than 100 A) at room temperature
- **6-cylinder engines** = 160 to 200 amperes (normally less than 125 A) at room temperature
- **8-cylinder engines** = 185 to 250 amperes (normally less than 150 A) at room temperature

Excessive current draw may indicate one or more of the following:

1. Binding of starter armature as a result of worn bushings
2. Oil too thick (viscosity too high) for weather conditions
3. Shorted or grounded starter windings or cables
4. Tight or seized engine
5. Shorted starter motor (usually caused by fault with the field coils or armature)
   - High mechanical resistance = High starter amperage draw
   - High electrical resistance = Low starter amperage draw

Lower amperage draw and slow or no cranking may indicate one or more of the following:

- Dirty or corroded battery connections
- High internal resistance in the battery cable(s)
- High internal starter motor resistance
- Poor ground connection between the starter motor and the engine block

STARTER REMOVAL

PROCEDURE After testing has confirmed that a starter motor may need to be replaced, most vehicle manufacturers recommend the following general steps and procedures.

STEP 1 Disconnect the negative battery cable.

STEP 2 Hoist the vehicle safely.

NOTE: This step may not be necessary. Check service information for the specified procedure for the vehicle being serviced. Some starters are located under the intake manifold. ● **SEE FIGURE 53–6.**

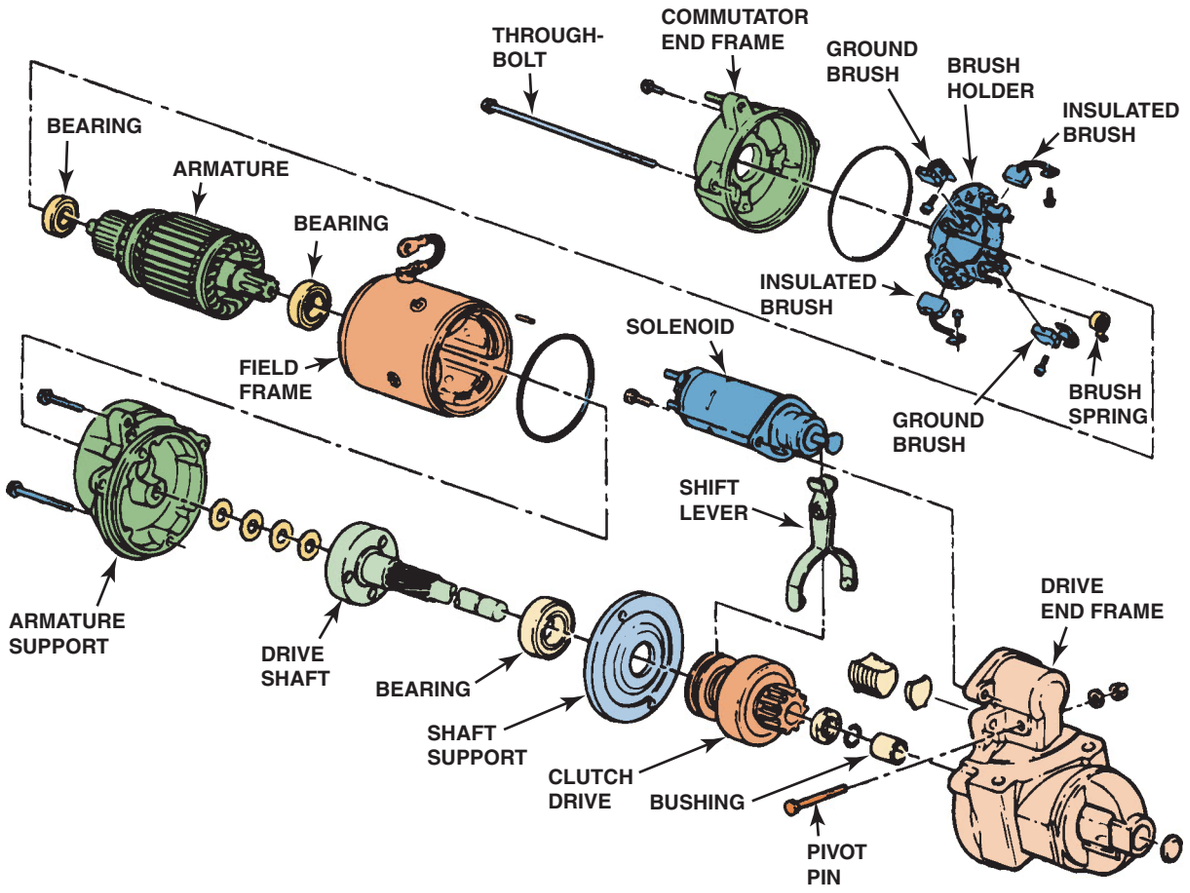

FIGURE 53–7 An exploded view of a typical solenoid-operated starter.

STEP 3 Remove the starter retaining bolts and lower the starter to gain access to the wire(s) connection(s) on the starter.

STEP 4 Disconnect and label the wire(s) from the starter and remove the starter.

STEP 5 Inspect the flywheel (flexplate) for ring gear damage. Also check that the mounting holes are clean and the mounting flange is clean and smooth. Service as needed.

STARTER MOTOR SERVICE

PURPOSE Most starter motors are replaced as an assembly or not easily disassembled or serviced. However, some starters, especially on classic muscle or collector vehicles, can be serviced.

DISASSEMBLY PROCEDURE Disassembly of a starter motor usually includes the following steps.

STEP 1 Remove the starter solenoid assembly.

STEP 2 Mark the location of the through bolts on the field housing to help align them during reassembly.

STEP 3 Remove the drive-end housing and then the armature assembly.

● **SEE FIGURE 53–7.**

INSPECTION AND TESTING The various parts should be inspected and tested to see if the components can be used to restore the starter to serviceable condition.

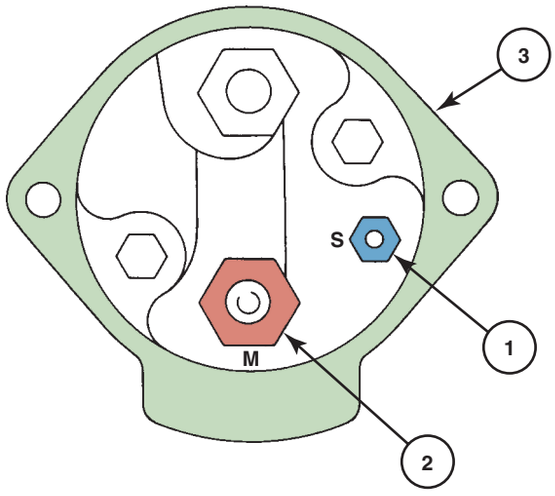

FIGURE 53–8 GM solenoid ohmmeter check. The reading between 1 and 3 (S terminal and ground) should be 0.4 to 0.6 ohm (hold-in winding). The reading between 1 and 2 (S terminal and M terminal) should be 0.2 to 0.4 ohm (pull-in winding).

- **Solenoid.** Check the resistance of the solenoid winding. The solenoid can be tested using an ohmmeter to check for the proper resistance in the hold-in and pull-in windings. ● **SEE FIGURE 53–8.**

Most technicians replace the solenoid whenever the starter is replaced and is usually included with a replacement starter.

- **Starter armature.** After the starter drive has been removed from the armature, it can be checked for runout using a dial indicator and V-blocks, as shown in ● **FIGURE 53–9.**

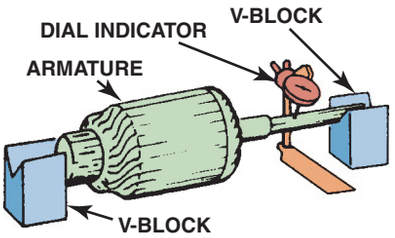

FIGURE 53–9 Measuring an armature shaft for runout using a dial indicator and V-blocks.

- **Growler.** Because the loops of copper wire are interconnected in the armature of a starter, an armature can be accurately tested only by use of a **growler.** A growler is a 110 volt AC test unit that generates an alternating (60 hertz) magnetic field around an armature. A starter armature is placed into the V-shaped top portion of a laminated soft-iron core surrounded by a coil of copper wire. Plug the growler into a 110 volt outlet and then follow the instructions for testing the armature.
- **Starter motor field coils.** With the armature removed from the starter motor, the field coils should be tested for opens and grounds using a powered test light or an ohmmeter. To test for a grounded field coil, touch one lead of the tester to a field brush (insulated or hot) and the other end to the starter field housing. The ohmmeter should indicate infinity (no continuity), and the test light should *not* light. If there is continuity, replace the field coil housing assembly. The ground brushes should show continuity to the starter housing.

  NOTE: Many starters use removable field coils. These coils must be rewound using the proper equipment and insulating materials. Usually, the cost involved in replacing defective field coils exceeds the cost of a replacement starter.

- **Starter brush inspection.** Starter brushes should be replaced if the brush length is less than half of its original length (less than 0.5 in. [13 mm]). On some models of starter motors, the field brushes are serviced with the field coil assembly and the ground brushes with the brush holder. Many starters use brushes that are held in with screws and are easily replaced, whereas other starters may require soldering to remove and replace the brushes. ● **SEE FIGURE 53–10.**

BENCH TESTING

Every starter should be tested before installation in a vehicle. **Bench testing** is the usual method and involves clamping the starter in a vise to prevent rotation during operation and connecting heavy-gauge jumper wires (minimum 4 gauge) to both a battery known to be good and the starter. The starter motor should rotate as fast as specifications indicate and not draw more than the free-spinning amperage permitted. A typical amperage specification for a starter being tested on a bench (not installed in a vehicle) usually ranges from 60 to 100 amperes.

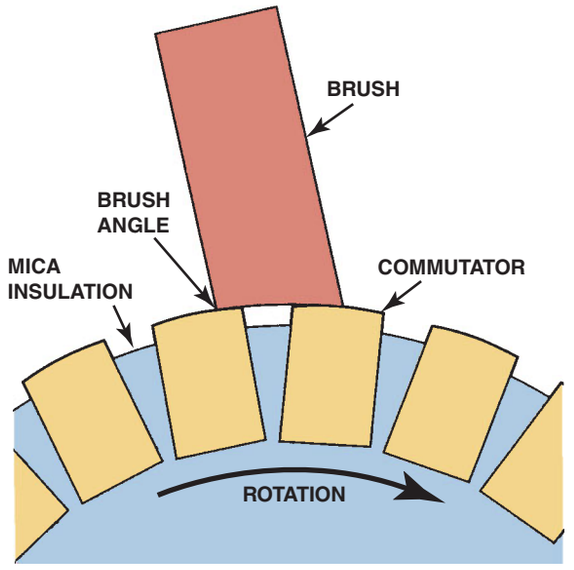

FIGURE 53–10 Replacement starter brushes should be installed so the beveled edge matches the rotation of the commutator.

STARTER INSTALLATION

After verifying that the starter assembly is functioning correctly, verify that the negative battery cable has been disconnected. Then safely hoist the vehicle, if necessary. Following are the usual steps to install a starter. Be sure to check service information for the exact procedures to follow for the vehicle being serviced.

STEP 1 Check service information for the exact wiring connections to the starter and/or solenoid.

STEP 2 Verify that all electrical connections on the starter motor and/or solenoid are correct for the vehicle and that they are in good condition.

NOTE: Be sure that the locking nuts for the studs are tight. Often, the retaining nut that holds the wire to the stud will be properly tightened, but if the stud itself is loose, cranking problems can occur.

STEP 3 Attach the power and control wires.

STEP 4 Install the starter, and torque all the fasteners to factory specifications and tighten evenly.

STEP 5 Perform a starter amperage draw test and check for proper engine cranking.

CAUTION: Be sure to install all factory heat shields to help ensure problem starter operation under all weather and driving conditions.

STARTER DRIVE-TO-FLYWHEEL CLEARANCE

NEED FOR SHIMS For the proper operation of the starter and absence of abnormal starter noise, there must be a slight clearance between the starter pinion and the engine flywheel ring gear. Many

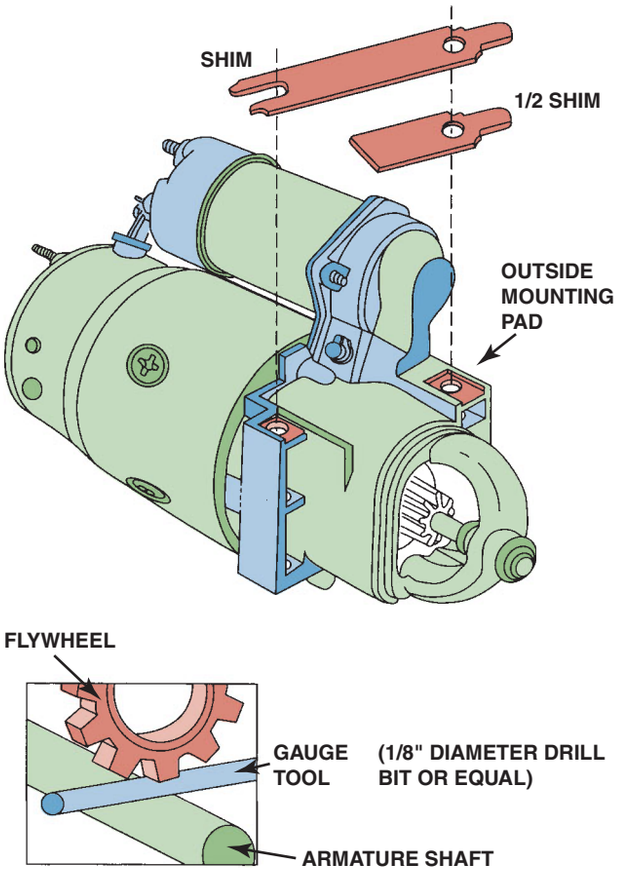

FIGURE 53–11 A shim (or half shim) may be needed to provide the proper clearance between the flywheel teeth of the engine and the pinion teeth of the starter.

starters use **shims,** which are thin metal strips between the flywheel and the engine block mounting pad to provide the proper clearance. ● **SEE FIGURE 53–11.**

Some manufacturers use shims under the starter drive-end housings during production. Other manufacturers *grind* the mounting pads at the factory for proper starter pinion gear clearance. If a GM starter is replaced, the starter pinion should be checked and corrected as necessary to prevent starter damage and excessive noise.

SYMPTOMS OF CLEARANCE PROBLEMS

- If the clearance is too great, the starter will produce a high-pitched whine *during* cranking.
- If the clearance is too small, the starter may bind, crank slowly, or produce a high-pitched whine *after* the engine starts, just as the ignition key is released.

PROCEDURE FOR PROPER CLEARANCE

To be sure that the starter is shimmed correctly, use the following procedure.

STEP 1 Place the starter in position and finger-tighten the mounting bolts.

STEP 2 Use a 1/8 in. diameter drill bit (or gauge tool) and insert between the armature shaft and a tooth of the engine flywheel.

STEP 3 If the gauge tool cannot be inserted, use a full-length shim across both mounting holes to move the starter away from the flywheel.

STEP 4 Remove a shim (or shims) if the gauge tool is loose between the shaft and the tooth of the engine flywheel.

TECH TIP

Reuse Drive-End Housing to Be Sure

Most GM starter motors use a pad mount and attach to the engine with bolts through the drive-end (nose) housing. Many times when a starter is replaced on a GM vehicle, the starter makes noise because of improper starter pinion-to-engine flywheel ring gear clearance. Instead of spending a lot of time shimming the new starter, simply remove the drive-end housing from the original starter and install it on the replacement starter. Service the bushing in the drive-end housing if needed. Because the original starter did not produce excessive gear engagement noise, the replacement starter will also be okay. Reuse any shims that were used with the original starter. This is preferable to removing and reinstalling the replacement starter several times until the proper clearance is determined.

STEP 5 If no shims have been used and the fit of the gauge tool is too loose, add a half shim to the outside pad only. This moves the starter closer to the teeth of the engine flywheel.

PRINCIPLES OF ALTERNATOR OPERATION

TERMINOLOGY It is the purpose and function of the charging system to keep the battery fully charged. The Society of Automotive Engineers (SAE) term for the unit that generates electricity is *generator.* The term **alternator** is most commonly used in the trade and will be used in this title.

PRINCIPLES All electrical alternators use the principle of electromagnetic induction to generate electrical power from mechanical power. Electromagnetic induction involves the generation of an electrical current in a conductor when the conductor is moved through a magnetic field. The amount of current generated can be increased by the following factors.

1. Increasing the *speed* of the conductors through the magnetic field
2. Increasing the *number* of conductors passing through the magnetic field
3. Increasing the *strength* of the magnetic field

CHANGING AC TO DC An alternator generates an alternating current (AC) because the current changes polarity during the alternator's rotation. However, a battery cannot "store" alternating current; therefore, this alternating current is changed to direct current (DC) by diodes inside the alternator. Diodes are one-way electrical check valves that permit current to flow in only one direction.

ALTERNATOR CONSTRUCTION

HOUSING An alternator is constructed using a two-piece cast aluminum housing. Aluminum is used because of its lightweight, nonmagnetic properties and heat transfer properties needed to help keep the alternator cool. A front ball bearing is pressed into the front housing, called the **drive-end (DE) housing,** to provide the support and friction reduction necessary for the belt-driven rotor assembly. The rear housing, or the **slip-ring-end (SRE) housing,** usually contains either a roller bearing or ball bearing support for the rotor and mounting for the brushes, diodes, and internal voltage regulator (if so equipped). ● **SEE FIGURES 54–1 AND 54–2.**

ALTERNATOR OVERRUNNING PULLEYS

PURPOSE AND FUNCTION Many alternators are equipped with an **overrunning alternator pulley (OAP),** also called an *overrunning clutch pulley* or an *alternator clutch pulley*. The purpose of this pulley is to help eliminate noise and vibration in the accessory drive belt system, especially when the engine is at idle speed. At idle, engine impulses are transmitted to the alternator through the accessory drive belt. The mass of the rotor of the alternator tends to want to keep spinning, but the engine crankshaft speeds up and slows down slightly due to the power impulses. Using a one-way clutch in the alternator pulley allows the belt to apply power to the alternator in only one direction, thereby reducing fluctuations in the belt. ● **SEE FIGURES 54–3 AND 54–4.**

FIGURE 54–1 A typical alternator on a Chevrolet V-8 engine.

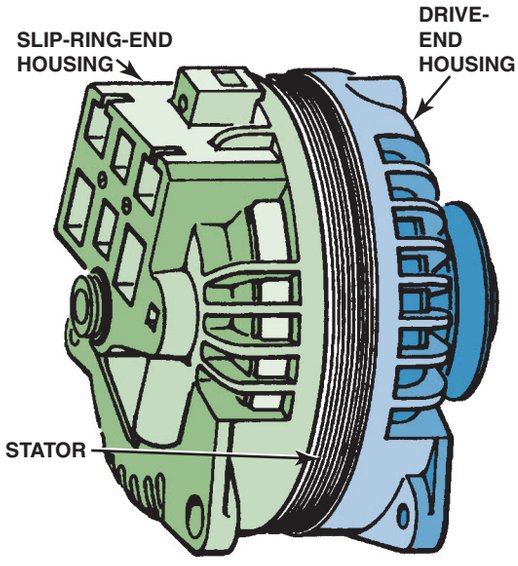

FIGURE 54–2 The end frame toward the drive belt is called the drive-end housing and the rear section is called the slip-ring-end housing.

A conventional drive pulley attaches to the alternator (rotor) shaft with a nut and lock washer. In the overrunning clutch pulley, the inner race of the clutch acts as the nut as it screws on to the shaft. Special tools are required to remove and install this type of pulley.

Another type of alternator pulley uses a dampener spring inside, plus a one-way clutch. These units have the following names.

- **Isolating Decoupler Pulley (IDP)**
- Active Alternator Pulley (AAP)
- Alternator Decoupler Pulley (ADP)
- Alternator Overrunning Decoupler Pulley
- **Overrunning Alternator Dampener (OAD)** (most common term)

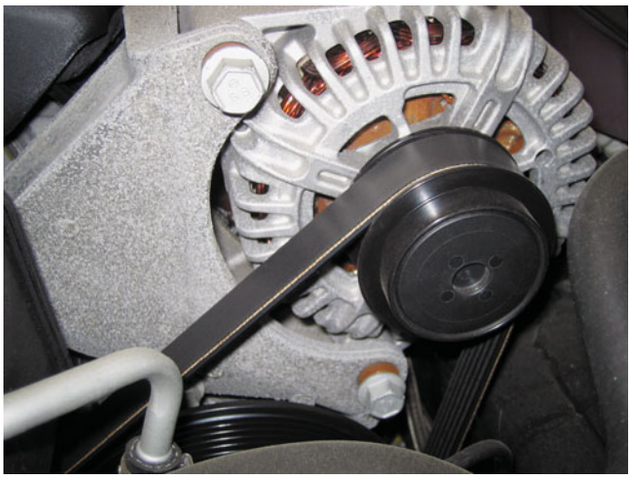

FIGURE 54–3 An OAP on a Chevrolet Corvette alternator.

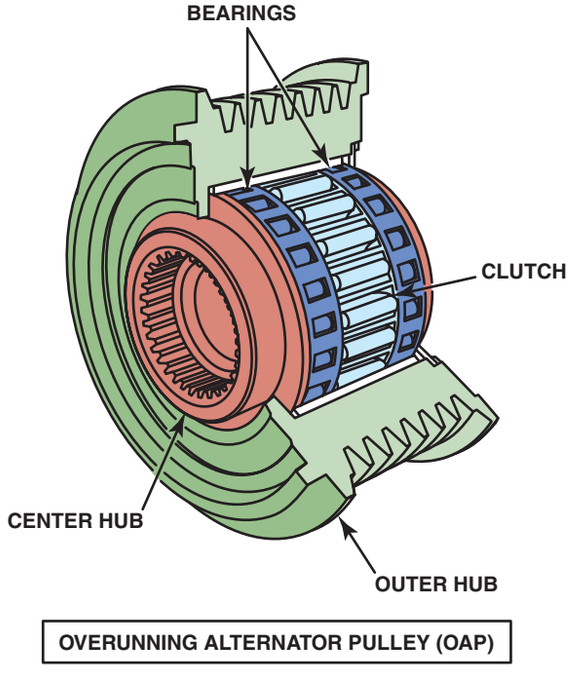

FIGURE 54–4 An exploded view of an overrunning alternator pulley showing all of the internal parts.

OAP or OAD pulleys are primarily used on vehicles equipped with diesel engines or on luxury vehicles where noise and vibration need to be kept at a minimum. Both are designed to:

- Reduce accessory drive belt noise
- Improve the life of the accessory drive belt
- Improve fuel economy by allowing the engine to be operated at a low idle speed

ALTERNATOR COMPONENTS AND OPERATION

ROTOR CONSTRUCTION The **rotor** is the rotating part of the alternator and is driven by the accessory drive belt. The rotor creates the magnetic field of the alternator and produces a current by

TECH TIP

Alternator Horsepower and Engine Operation

Many technicians are asked how much power certain accessories require. A 100 ampere alternator requires about 2 horsepower from the engine. One horsepower is equal to 746 watts. Watts are calculated by multiplying amperes times volts.

Power in watts = 100 A × 14.5 V = 1,450 W
1 hp = 746 W

Therefore, 1,450 watts is about 2 horsepower.

Allowing about 20% for mechanical and electrical losses adds another 0.4 horsepower. Therefore, when someone asks how much power it takes to produce 100 amperes from an alternator, the answer is 2.4 horsepower.

Many alternators delay the electrical load to prevent the engine from stumbling when a heavy electrical load is applied. The voltage regulator or vehicle computer is capable of gradually increasing the output of the alternator over a period of several minutes. Even though 2 horsepower does not sound like much, a sudden demand for 2 horsepower from an idling engine can cause the engine to run rough or stall. The difference in part numbers of various alternators is often an indication of the time interval over which the load is applied. Therefore, using the wrong replacement alternator could cause the engine to stall!

FREQUENTLY ASKED QUESTION

Can I Install an OAP or an OAD to My Alternator?

Usually, no. An alternator needs to be equipped with the proper shaft to allow the installation of an OAP or OAD. This also means that a conventional pulley often cannot be used to replace a defective overrunning alternator pulley or dampener with a conventional pulley. Check service information for the exact procedure to follow.

TECH TIP

Always Check the OAP or OAD First

Overrunning alternator pulleys and overrunning alternator dampeners can fail. The most common factor is the one-way clutch. If it fails, it can freewheel and not power the alternator or it can lock up and not provide the dampening as designed. If the charging system is not working, the OAP or OAD could be the cause, rather than a fault in the alternator itself.

In most cases, the entire alternator assembly will be replaced because each OAP or OAD is unique for each application and both require special tools to remove and replace.

SEE FIGURE 54–5.

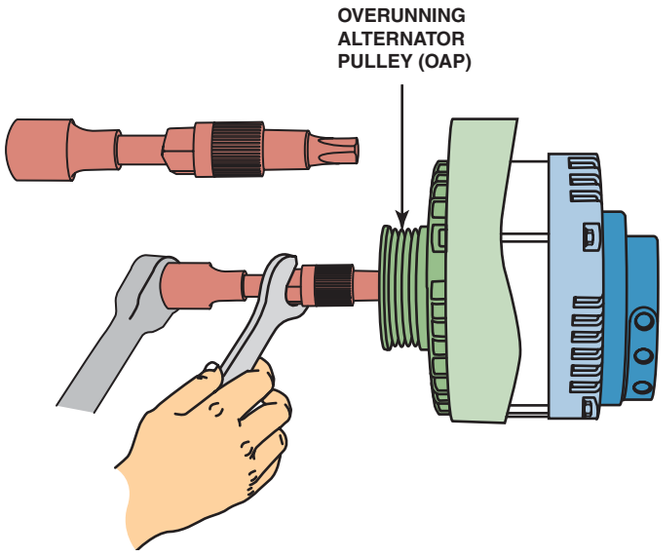

FIGURE 54–5 A special tool is needed to remove and install overrunning alternator pulleys or dampeners.

electromagnetic induction in the stationary stator windings. The rotor is constructed of many turns of copper wire coated with a varnish insulation wound over an iron core. The iron core is attached to the rotor shaft.

At both ends of the rotor windings are heavy-gauge metal plates bent over the windings with triangular fingers called **claw poles.** These pole fingers do not touch, but alternate or interlace, as shown in ● **FIGURE 54–6.**

HOW ROTORS CREATE MAGNETIC FIELDS

The two ends of the rotor winding are connected to the rotor's slip rings. Current for the rotor flows from the battery into one brush that rides on one of the slip rings, then flows through the rotor winding, then exits the rotor through the other slip ring and brush. One alternator brush is considered to be the "positive" brush and one is considered to be the "negative" or "ground" brush. The voltage regulator is connected to either the positive or the negative brush and controls the field current through the rotor that controls the output of the alternator.

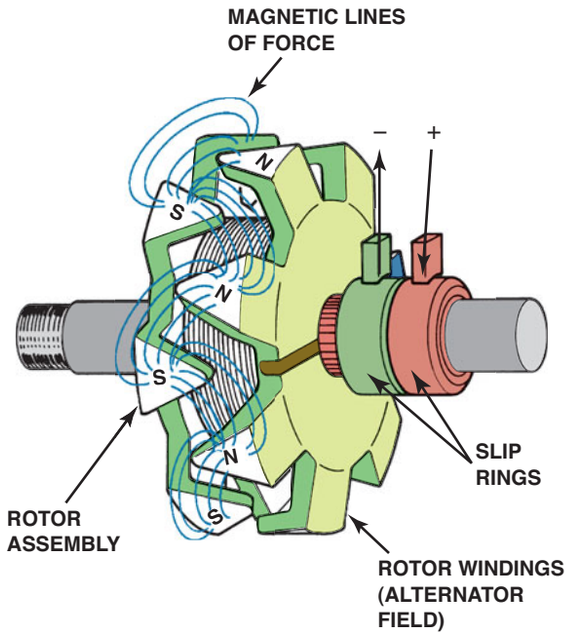

FIGURE 54–7 Rotor assembly of a typical alternator. Current through the slip rings causes the "fingers" of the rotor to become alternating north and south magnetic poles. As the rotor revolves, these magnetic lines of force induce a current in the stator windings.

If current flows through the rotor windings, the metal pole pieces at each end of the rotor become electromagnets. Whether a north or a south pole magnet is created depends on the *direction* in which the wire coil is wound. Because the pole pieces are attached to each end of the rotor, one pole piece will be a north pole magnet. The other pole piece is on the opposite end of the rotor and therefore is viewed as being wound in the opposite direction, creating a south pole. Therefore, the rotor fingers are alternating north and south magnetic poles. The magnetic fields are created between the alternating pole piece fingers. These individual magnetic fields produce a current by electromagnetic induction in the stationary stator windings. ● **SEE FIGURE 54–7.**

ROTOR CURRENT

The current necessary for the field (rotor) windings is conducted through slip rings with carbon brushes. The maximum rated alternator output in amperes depends on the number and gauge of the rotor windings. Substituting rotors from one alternator to another can greatly affect maximum output. Many commercially rebuilt alternators are tested and then display a sticker to indicate their tested output. The original rating stamped on the housing is then ground off.

The current for the field is controlled by the voltage regulator and is conducted to the slip rings through carbon brushes. The brushes conduct only the field current which is usually between 2 and 5 amperes.

STATOR CONSTRUCTION

The **stator** consists of the stationary coil windings inside the alternator. The stator is supported between the two halves of the alternator housing, with three copper wire windings that are wound on a laminated metal core.

As the rotor revolves, its moving magnetic field induces a current in the stator windings. ● **SEE FIGURE 54–8.**

DIODES

Diodes are constructed of a semiconductor material (usually silicon) and operate as a one-way electrical check valve that permits the current to flow in only one direction. Alternators often

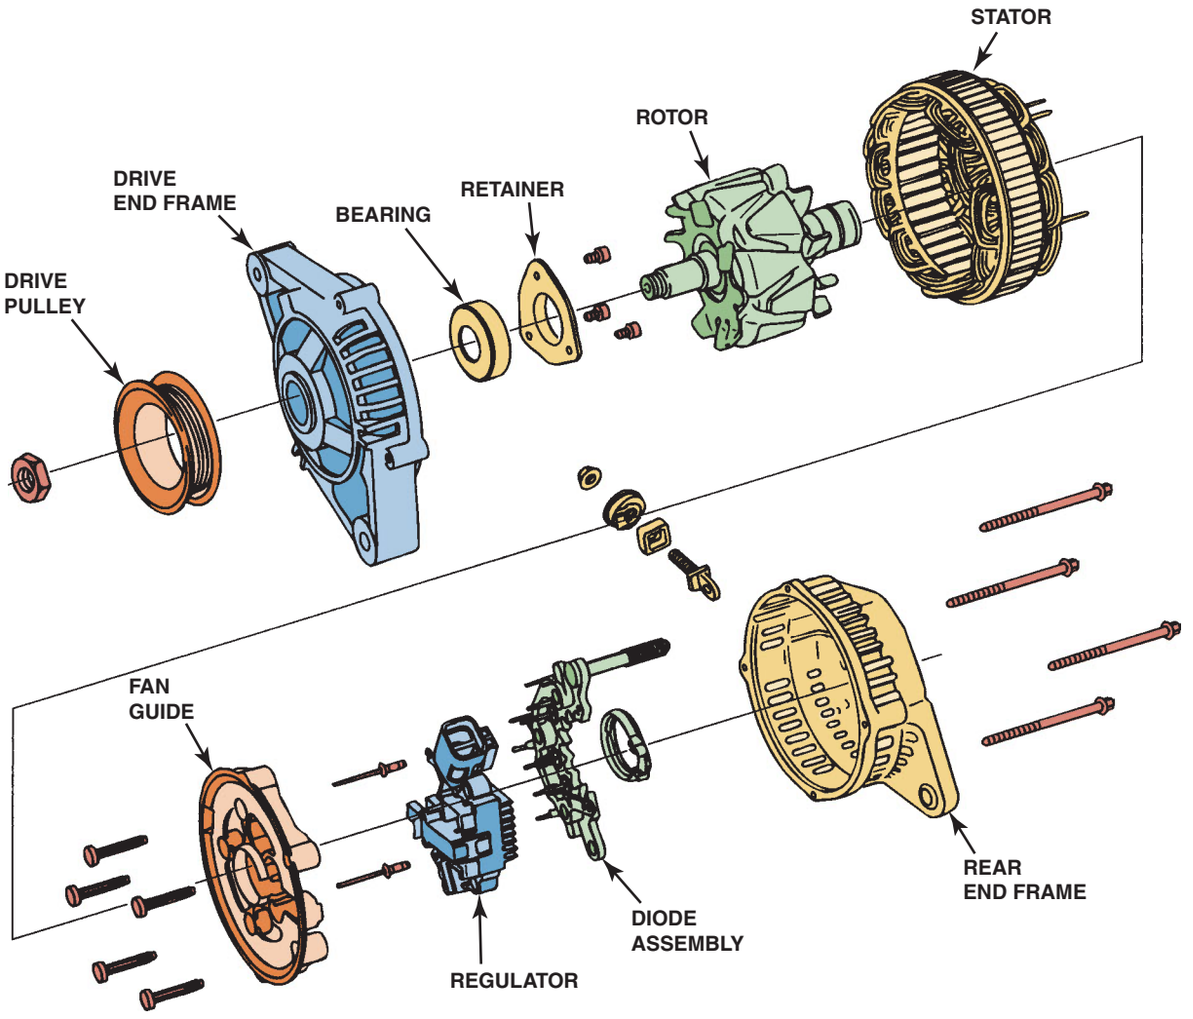

FIGURE 54–8 An exploded view of a typical alternator showing all of its internal parts including the stator windings.

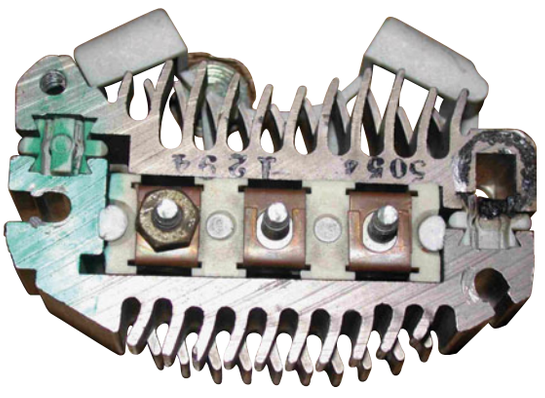

FIGURE 54–9 A rectifier usually includes six diodes in one assembly and is used to rectify AC voltage from the stator windings into DC voltage suitable for use by the battery and electrical devices in the vehicle.

use six diodes (one positive and one negative set for each of the three stator windings) to convert alternating current to direct current.

Diodes used in alternators are included in a single part called a **rectifier,** or *rectifier bridge*. A rectifier not only includes the diodes (usually six), but also the cooling fins and connections for the stator windings and the voltage regulator. ● **SEE FIGURE 54–9.**

DIODE TRIO Some alternators are equipped with a diode trio that supplies current to the brushes from the stator windings. A diode trio uses three diodes, in one housing, with one diode for each of the three stator windings and then one output terminal.

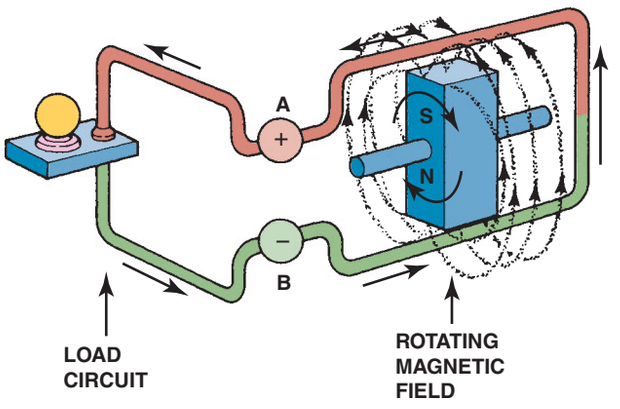

FIGURE 54–10 Magnetic lines of force cutting across a conductor induce a voltage and current in the conductor.

HOW AN ALTERNATOR WORKS

FIELD CURRENT IS PRODUCED A rotor inside an alternator is turned by a belt and drive pulley which are turned by the engine. The magnetic field of the rotor generates a current in the stator windings by electromagnetic induction. ● **SEE FIGURE 54–10.**

Field current flowing through the slip rings to the rotor creates an alternating north and south pole on the rotor, with a magnetic field between each finger of the rotor.

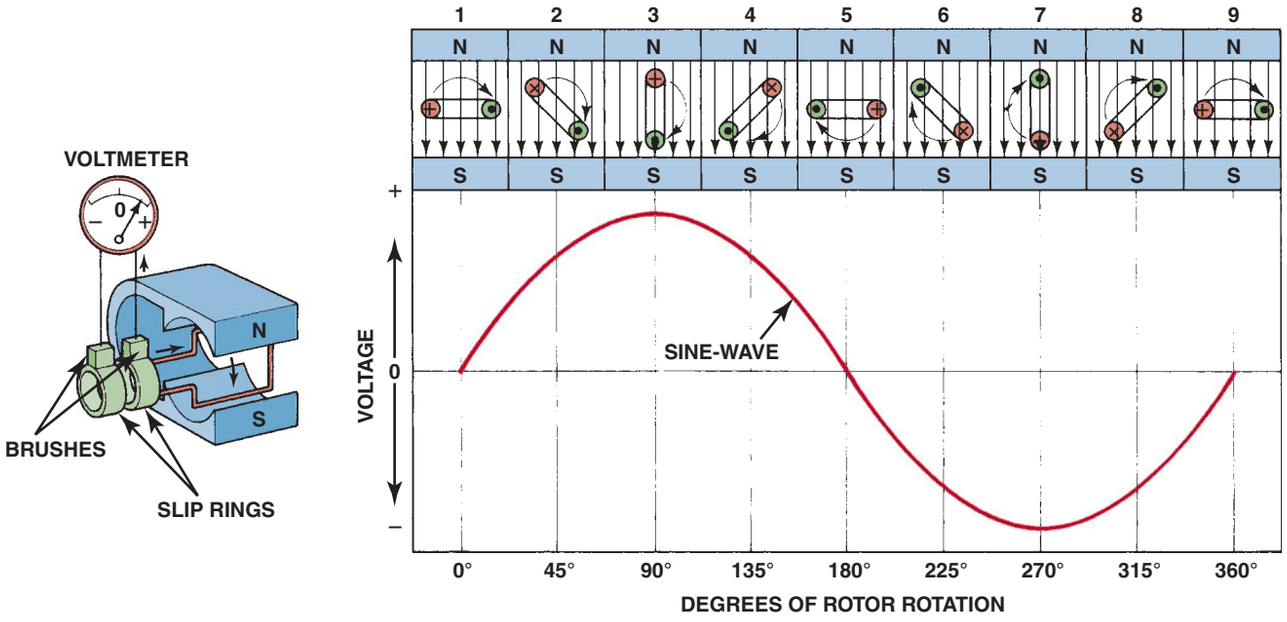

FIGURE 54–11 A sine wave (shaped like the letter *S* on its side) voltage curve is created by one revolution of a winding as it rotates in a magnetic field.

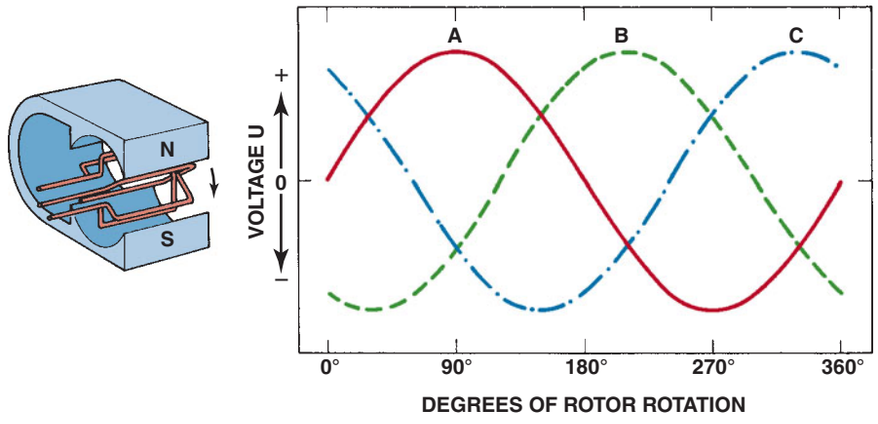

FIGURE 54–12 When three windings (A, B, and C) are present in a stator, the resulting current generation is represented by the three sine waves. The voltages are 120 degrees out of phase. The connection of the individual phases produces a three-phase alternating voltage.

CURRENT IS INDUCED IN THE STATOR

The induced current in the stator windings is an alternating current because of the alternating magnetic field of the rotor. The induced current starts to increase as the magnetic field starts to induce current in each winding of the stator. The current then peaks when the magnetic field is the strongest and starts to decrease as the magnetic field moves away from the stator winding. Therefore, the current generated is described as being of a sine wave or alternating current pattern. ● **SEE FIGURE 54–11.**

As the rotor continues to rotate, this sine wave current is induced in each of the three windings of the stator.

Because each of the three windings generates a sine wave current, as shown in ● **FIGURE 54–12,** the resulting currents combine to form a three-phase voltage output.

The current induced in the stator windings connects to diodes (one-way electrical check valves) that permit the alternator output current to flow in only one direction. All alternators contain six diodes, one pair (a positive and a negative diode) for each of the three stator windings. Some alternators contain eight diodes with another pair connected to the center connection of a wye-type stator.

WYE-CONNECTED STATORS

The Y (pronounced "wye" and generally so written) type or star pattern is the most commonly used alternator stator winding connection. ● **SEE FIGURE 54–13.**

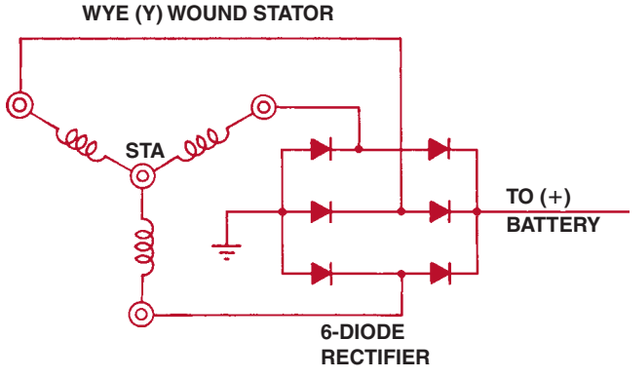

FIGURE 54–13 Wye-connected stator winding.

The output current with a wye-type stator connection is constant over a broad alternator speed range.

Current is induced in each winding by electromagnetic induction from the rotating magnetic fields of the rotor. In a wye-type stator connection, the currents must combine because two windings are always connected in series. ● **SEE FIGURE 54–14.**

The current produced in each winding is added to the other windings' current and then flows through the diodes to the alternator output terminal. One-half of the current produced is available at the

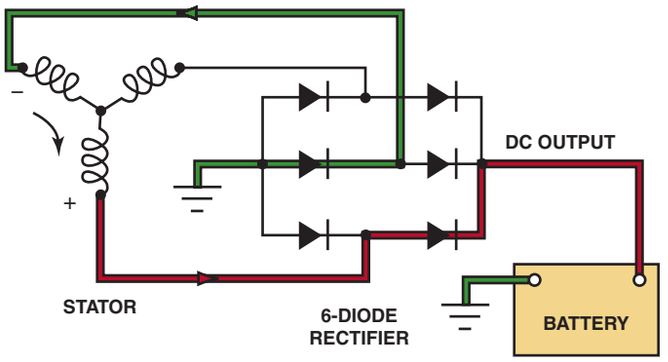

FIGURE 54–14 As the magnetic field, created in the rotor, cuts across the windings of the stator, a current is induced. Notice that the current path includes passing through one positive (+) diode on the way to the battery and one negative (−) diode as a complete circuit is completed through the rectifier and stator.

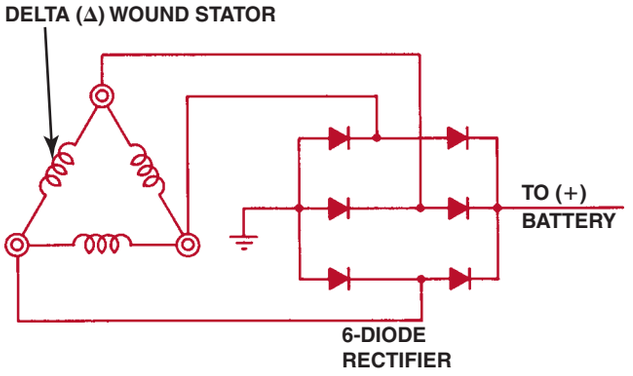

FIGURE 54–15 Delta-connected stator winding.

neutral junction (usually labeled "STA" for stator). The voltage at this center point is used by some alternator manufacturers (especially Ford) to control the charge indicator light or is used by the voltage regulator to control the rotor field current.

DELTA-CONNECTED STATORS The **delta winding** is connected in a triangular shape. Delta is a Greek letter shaped like a triangle. ● **SEE FIGURE 54–15.**

Current induced in each winding flows to the diodes in a parallel circuit. More current can flow through two parallel circuits than can flow through a series circuit (as in a wye-type stator connection).

Delta-connected stators are used on alternators where high output at high-alternator RPM is required. The delta-connected alternator can produce 73% more current than the same alternator with wye-type stator connections. For example, if an alternator with a wye-connected stator can produce 55 A, the *same* alternator with delta-connected stator windings can produce 73% more current, or 95 A (55 × 1.73 = 95). The delta-connected alternator, however, produces lower current at low speed and must be operated at high speed to produce its maximum output.

ALTERNATOR OUTPUT FACTORS

The output voltage and current of an alternator depend on the following factors.

1. **Speed of rotation.** Alternator output is increased with alternator rotational speed up to the alternator's maximum possible ampere output. Alternators normally rotate at a speed two to three times faster than engine speed, depending on the relative pulley sizes used for the belt drive. For example, if an engine is operating at 5000 RPM, the alternator will be rotating at about 15,000 RPM.
2. **Number of conductors.** A high-output alternator contains more turns of wire in the stator windings. Stator winding connections (whether wye or delta) also affect the maximum alternator output. ● **SEE FIGURE 54–16** for an example of a stator that has six rather than three windings, which greatly increases the amperage output of the alternator.
3. **Strength of the magnetic field.** If the magnetic field is strong, a high output is possible because the current generated by electromagnetic induction is dependent on the number of magnetic lines of force that are cut.
   a. The strength of the magnetic field can be increased by increasing the number of turns of conductor wire wound on the rotor. A higher output alternator rotor has more turns of wire than an alternator rotor with a low rated output.
   b. The strength of the magnetic field also depends on the current through the field coil (rotor). Because magnetic field strength is measured in ampere-turns, the greater the amperage or the number of turns, or both, the greater the alternator output.

FIGURE 54–16 A stator assembly with six, rather than the normal three, windings.

ALTERNATOR VOLTAGE REGULATION

PRINCIPLES An automotive alternator must be able to produce electrical pressure (voltage) higher than battery voltage to charge the battery. Excessively high voltage can damage the battery, electrical components, and the lights of a vehicle. Basic principles include the following:

- If no (zero) amperes of current existed throughout the field coil of the alternator (rotor), alternator output would be zero because without field current a magnetic field does not exist.
- The field current required by most automotive alternators is less than 3 amperes. It is the *control* of the *field* current that controls the output of the alternator.
- Current for the rotor flows from the battery positive post, through the rotor positive brush, into the rotor field winding, and exits the rotor winding through the rotor ground brush. Most voltage regulators control field current by controlling the amount of field current through the ground brush.
- The voltage regulator simply opens the field circuit if the voltage reaches a predetermined level, then closes the field

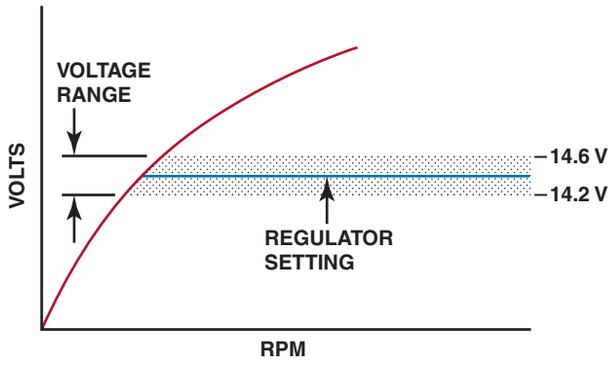

FIGURE 54–17 Typical voltage regulator range.

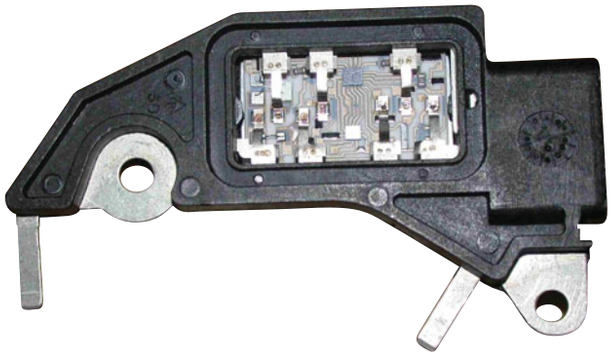

FIGURE 54–18 A typical electronic voltage regulator with the cover removed showing the circuits inside.

circuit again as necessary to maintain the correct charging voltage. ● **SEE FIGURE 54–17.**

- The electronic circuit of the voltage regulator cycles between 10 and 7,000 times per *second* as needed to accurately control the field current through the rotor, and therefore control the alternator output.

REGULATOR OPERATION

- The control of the field current is accomplished by opening and closing the *ground* side of the field circuit through the rotor on most alternators.
- The zener diode is a major electronic component that makes voltage regulation possible. A zener diode blocks current flow until a specific voltage is reached, then it permits current to flow. Alternator voltage from the stator and diodes is first sent through a thermistor, which changes resistance with temperature, and then to a zener diode. When the upper-limit voltage is reached, the zener diode conducts current to a transistor, which then opens the field (rotor) circuit. The electronics are usually housed in a separate part inside the alternator. ● **SEE FIGURES 54–18 AND 54–19.**

BATTERY CONDITION AND CHARGING VOLTAGE If the automotive battery is discharged, its voltage will be lower than the voltage of a fully charged battery. The alternator will supply charging current, but it may not reach the maximum charging voltage. For example, if a vehicle is jump started and run at a fast idle (2,000 RPM), the charging voltage may be only 12 volts. In this case, the following may occur.

- As the battery becomes charged and the battery voltage increases, the charging voltage will also increase, until the voltage regulator limit is reached.

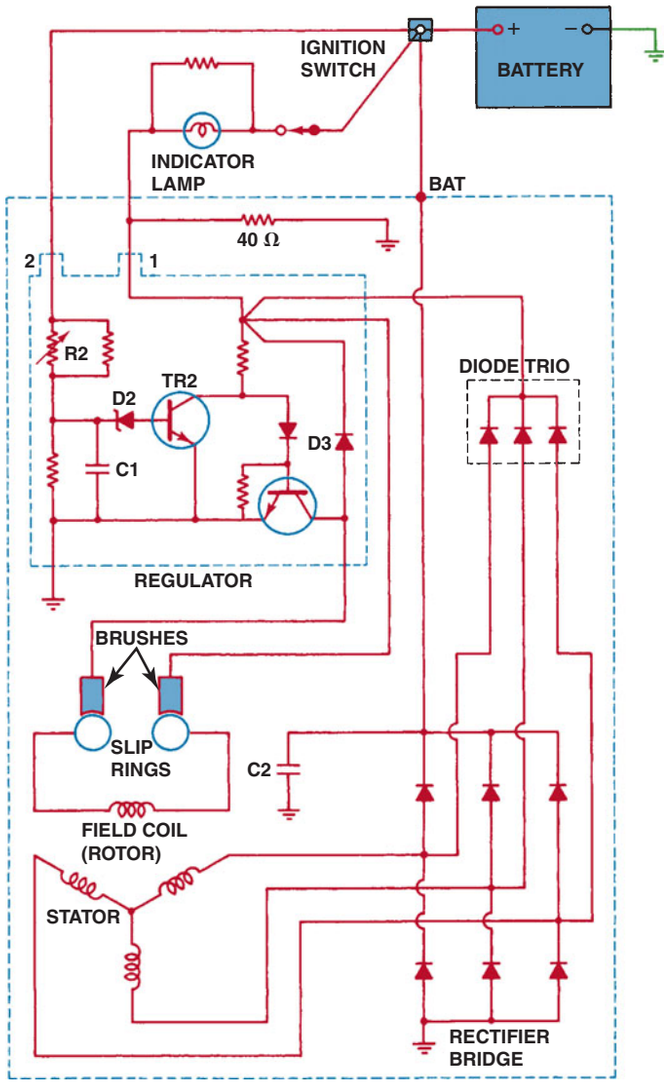

FIGURE 54–19 Typical General Motors SI-style alternator with an integral voltage regulator. Voltage present at terminal 2 is used to reverse bias the zener diode (D2) that controls TR2. The positive brush is fed by the ignition current (terminal I) plus current from the diode trio.

- Then the voltage regulator will start to control the charging voltage. A good, but discharged, battery should be able to convert into chemical energy all the current the alternator can produce. As long as alternator voltage is higher than battery voltage, current will flow from the alternator (high voltage) to the battery (lower voltage).
- Therefore, if a voltmeter is connected to a discharged battery with the engine running, it may indicate charging voltage that is lower than normally acceptable.

In other words, the condition and voltage of the battery *do* determine the charging rate of the alternator. It is often stated that the battery is the true "voltage regulator" and that the voltage regulator simply acts as the upper-limit voltage control. This is the reason why all charging system testing *must* be performed with a reliable and known to be good battery, at least 75% charged, to be assured of accurate test results. If a discharged battery is used during charging system testing, tests could mistakenly indicate a defective alternator and/or voltage regulator and could cause the stator windings to overheat.

TEMPERATURE COMPENSATION All voltage regulators (mechanical or electronic) provide a method for increasing the charging

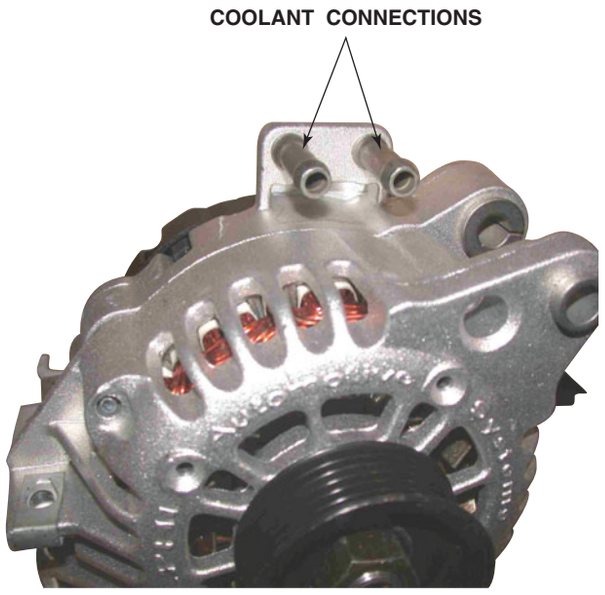

FIGURE 54–20 A coolant-cooled alternator showing the hose connections where coolant from the engine flows through the rear frame of the alternator.

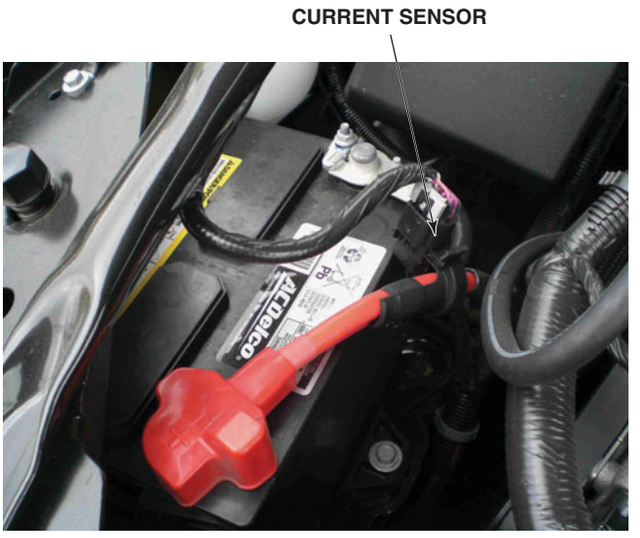

FIGURE 54–21 A Hall-effect current sensor attached to the positive battery cable is used as part of the EPM system.

voltage slightly at low temperatures and for lowering the charging voltage at high temperatures. A battery requires a higher charging voltage at low temperatures because of the resistance to chemical reaction changes. However, the battery would be overcharged if the charging voltage were not reduced during warm weather. Electronic voltage regulators use a temperature-sensitive resistor in the regulator circuit. This resistor, called a **thermistor,** provides lower resistance as the temperature increases. A thermistor is used in the electronic circuits of the voltage regulator to control charging voltage over a wide range of underhood temperatures.

NOTE: Voltmeter test results may vary according to temperature. Charging voltage tested at 32°F (0°C) will be higher than for the same vehicle tested at 80°F (27°C) because of the temperature-compensation factors built into voltage regulators.

ALTERNATOR COOLING

Alternators create heat during normal operation and this heat must be removed to protect the components inside, especially the diodes and voltage regulator. The types of cooling include:

- External fan
- Internal fan(s)
- Both an external fan and an internal fan
- Coolant cooled (● **SEE FIGURE 54–20.**)

COMPUTER-CONTROLLED ALTERNATORS

TYPES OF SYSTEMS

Computers can interface with the charging system in three ways.

1. The computer can *activate* the charging system by turning on and off the field current to the rotor. In other words, the computer, usually the powertrain control module (PCM), controls the field current to the rotor.
2. The computer can *monitor* the operation of the alternator and increase engine speed if needed during conditions when a heavy load is demanded by the alternator.
3. The computer can *control* the alternator by controlling alternator output to match the needs of the electrical system. This system detects the electrical needs of the vehicle and commands the alternator to charge only when needed to improve fuel economy.

GM ELECTRICAL POWER MANAGEMENT SYSTEM

A typical system used on some General Motors vehicles is called **electrical power management (EPM).** It uses a Hall-effect sensor attached to the negative or positive battery cable to measure the current leaving and entering the battery. ● **SEE FIGURE 54–21.**

The engine control module (ECM) controls the alternator by changing the on-time of the current through the rotor. ● **SEE FIGURE 54–22.**

The on-time, called **duty cycle,** varies from 5% to 95%. ● **SEE CHART 54–1.**

This system has six modes of operation.

1. **Charge mode.** The charge mode is activated when any of the following occurs.
   - Electric cooling fans are on high speed.
   - Rear window defogger is on.
   - Battery state of charge (SOC) is less than 80%.
   - Outside (ambient) temperature is less than 32°F (0°C).
2. **Fuel economy mode.** This mode reduces the load on the engine from the alternator for maximum fuel economy. This mode is activated when the following conditions are met.
   - Ambient temperature is above 32°F (0°C).
   - The state of charge of the battery is 80% or higher.
   - The cooling fans and rear defogger are off.

   The target voltage is 13 volts and will return to the charge mode, if needed.
3. **Voltage reduction mode.** This mode is commanded to reduce the stress on the battery during low-load conditions. This mode is activated when the following conditions are met.
   - Ambient temperature is above 32°F (0°C).
   - Battery discharge rate is less than 7 amperes.
   - Rear defogger is off.
   - Cooling fans are on low or off.
   - Target voltage is limited to 12.7 volts.

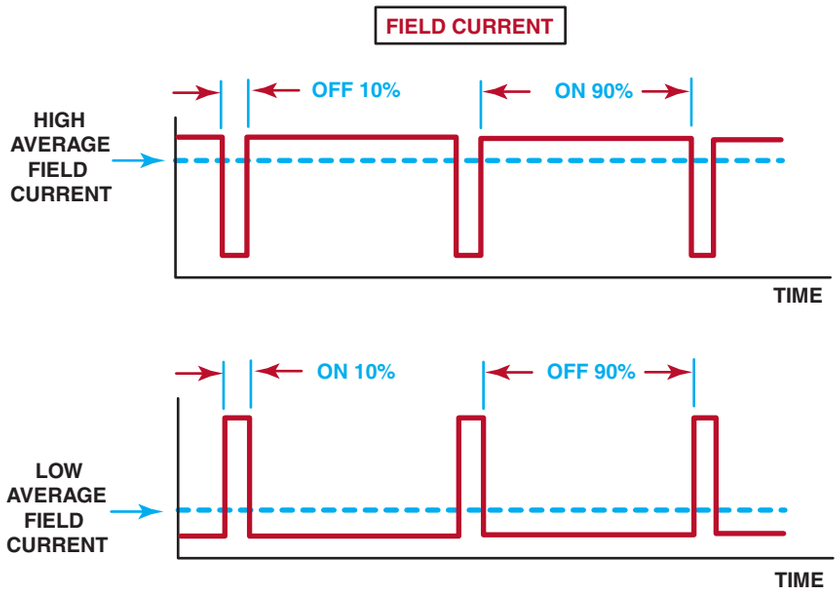

FIGURE 54–22 The amount of time current is flowing through the field (rotor) determines the alternator output.

TECH TIP

The Voltage Display Can Be a Customer Concern

A customer may complain that the voltmeter reading on the dash fluctuates up and down. This may be normal as the computer-controlled charging system commands various modes of operation based on the operating conditions. Follow the vehicle manufacturer's recommended procedures to verify proper operation.

4. **Start-up mode.** This mode is selected after engine start and commands a charging voltage of 14.5 volts for 30 seconds. After 30 seconds, the mode is changed depending on conditions.
5. **Battery sulfation mode.** This mode is commanded if the output voltage is less than 13.2 volts for 45 minutes, which can indicate that sulfated plates could be the cause. The target voltage is 13.9 to 15.5 volts for three minutes. After three minutes, the system returns to another mode based on conditions.
6. **Headlight mode.** This mode is selected when the headlights are on and the target voltage is 14.5 volts.

COMPUTER-CONTROLLED CHARGING SYSTEMS

Computer control of the charging system has the following advantages.

1. The computer controls the field of the alternator, which can pulse it on or off as needed for maximum efficiency, thereby saving fuel.

   NOTE: Some vehicle manufacturers, such as Honda/Acura, use an *electronic load control (ELC)*, which turns on the alternator when decelerating, where the additional load on the engine is simply used to help slow the vehicle. This allows the battery to be charged without placing a load on the engine, helping to increase fuel economy.

2. Engine idle can also be improved by turning on the alternator slowly, rather than all at once, if an electrical load is switched on, such as the air-conditioning system.
3. Most computers can also reduce the load on the electrical system if the demand exceeds the capacity of the charging system by reducing fan speed, shutting off rear window defoggers, or increasing engine speed to cause the alternator to increase the amperage output.

   NOTE: A commanded higher-than-normal idle speed may be the result of the computer compensating for an abnormal electrical load. This higher idle speed could indicate a defective battery or other electrical system faults.

4. The computer can monitor the charging system and set diagnostic trouble codes (DTCs) if a fault is detected. Many systems allow the service technician to control the charging of the alternator using a scan tool.
5. Because the charging system is computer controlled, it can be checked using a scan tool. Some vehicle systems allow the scan tool to activate the alternator field and then monitor the output to help detect fault locations. Always follow the vehicle manufacturer's diagnostic procedure.

CHARGING SYSTEM TESTING AND SERVICE

BATTERY STATE OF CHARGE

The charging system can be tested as part of a routine vehicle inspection or to determine the reason for a no-charge or reduced charging circuit performance. The battery *must* be at least 75% charged before testing the alternator and the charging system. A weak or defective battery will cause inaccurate test results. If in doubt, replace the battery with a known good shop battery for testing.

CHARGING VOLTAGE TEST

The **charging voltage test** is the easiest way to check the charging system voltage at the battery. Use a digital multimeter to check the voltage, as follows:

STEP 1 Select DC volts.

STEP 2 Connect the red meter lead to the positive (+) terminal of the battery and the black meter lead to the negative (−) terminal of the battery.

NOTE: The polarity of the meter leads is not too important when using a digital multimeter. If the meter leads are connected backward on the battery, the resulting readout will simply have a negative (−) sign in front of the voltage reading.

STEP 3 Start the engine and increase the engine speed to about 2000 RPM (fast idle) and record the charging voltage. ● **SEE FIGURE 55–1**.

Specifications for charging voltage = 13.5 to 15 V

- If the voltage is too high, check that the alternator is properly grounded.
- If the voltage is lower than specifications, then there is a fault with the wiring or the alternator.
- If the wiring and the connections are okay, then additional testing is required to help pinpoint the root cause. Replacement of the alternator and/or battery is often required if the charging voltage is not within factory specifications.

? FREQUENTLY ASKED QUESTION

What Is a Full-Fielding Test?

Full fielding is a procedure used on older noncomputerized vehicles for bypassing the voltage regulator that could be used to determine if the alternator is capable of producing its designed output. This test is no longer performed for the following reasons.

- The voltage regulator is built into the alternator, therefore requiring that the entire assembly be replaced even if just the regulator is defective.
- When the regulator is bypassed, the alternator can produce a high voltage (over 100 volts in some cases) which could damage all of the electronic circuits in the vehicle.

Always follow the vehicle manufacturer's recommended testing procedures.

SCAN TESTING THE CHARGING CIRCUIT

Most vehicles that use a computer-controlled charging system can be diagnosed using a scan tool. Not only can the charging voltage be monitored, but also in many vehicles, the field circuit can be controlled and the output voltage monitored to check that the system is operating correctly. ● **SEE FIGURE 55–2**.

NOTE: Some charging systems, such as those on many Honda/Acura vehicles, use an electronic load detection circuit that energizes the field circuit only when an electrical load is detected. For example, if the engine is running and there are no accessories on, the voltage read at the battery may be 12.6 V, which could indicate that the charging system is not operating. In this situation, turning on the headlights or an accessory should cause the computer to activate the field circuit, and the alternator should produce normal charging voltage.

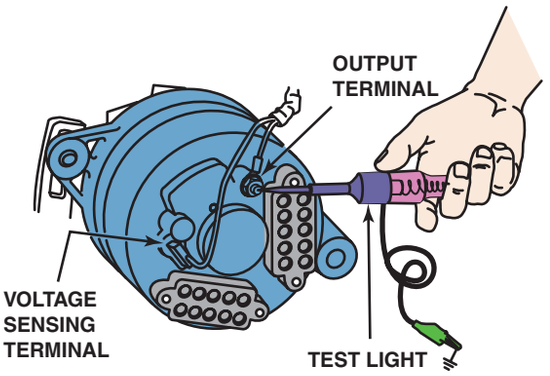

FIGURE 55–3 Before replacing an alternator, the wise technician checks that battery voltage is present at the output and battery voltage sense terminals. If not, then there is a fault in the wiring.

TECH TIP

Use a Test Light to Check for a Defective Fusible Link

Most alternators use a fusible link or mega fuse between the output terminal and the positive (+) terminal of the battery. If this fusible link or fuse is defective (blown), then the charging system will not operate at all. Many alternators have been replaced repeatedly because of a blown fusible link that was not discovered until later. A quick and easy test to check if the fusible link is okay is to touch a test light to the output terminal. With the other end of the test light attached to a good ground, the fusible link or mega fuse is okay if the light lights. This test confirms that the circuit between the alternator and the battery has continuity. ● **SEE FIGURE 55–3**.

DRIVE BELT INSPECTION AND ADJUSTMENT

BELT VISUAL INSPECTION It is generally recommended that all belts be inspected regularly and replaced as needed. Replace any serpentine belt that has more than three cracks in any one rib that appears in a 3 in. span. Check service information for the specified procedure and recommended replacement interval. ● **SEE FIGURE 55–4**.

BELT TENSION MEASUREMENT If the vehicle does not use a belt tensioner, then a belt tension gauge is needed to achieve the specified belt tension. Install the belt and operate the engine with all of the accessories turned on to "run-in" the belt for at least five minutes. Adjust the tension of the accessory drive belt to factory specifications or use the following table for an example of the proper tension based on the size of the belt.

There are four ways that vehicle manufacturers specify that the belt tension is within factory specifications.

1. **Belt tension gauge.** A belt tension gauge is needed to determine if it is at the specified belt tension. Install the belt and operate the engine with all of the accessories turned on to "run-in" the belt for at least five minutes. Adjust the tension of the accessory drive belt to factory specifications, or see ● **CHART 55–1** for an example of the proper tension based on the size of the belt.
2. **Marks on a tensioner.** Many tensioners have marks that indicate the normal operating tension range for the accessory drive belt. Check service information for the preferred location of the tensioner mark. ● **SEE FIGURE 55–5**.

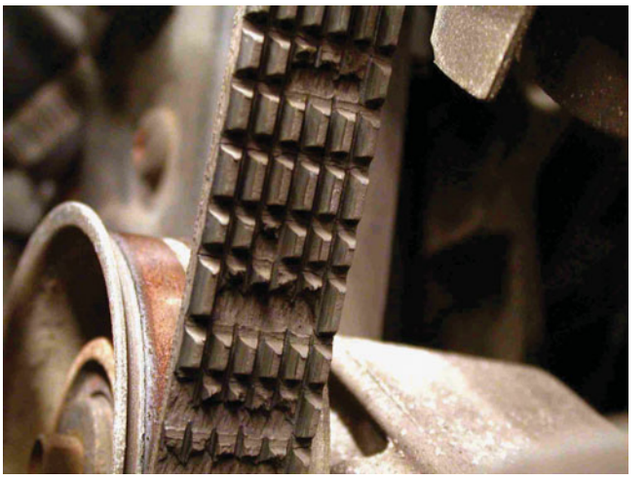

FIGURE 55–4 This accessory drive belt is worn and requires replacement. Newer belts are made from ethylene propylene diene monomer (EPDM). This rubber does not crack like older belts and may not show wear even though the ribs do wear and can cause slippage.

TECH TIP

The Hand Cleaner Trick

Lower-than-normal alternator output could be the result of a loose or slipping drive belt. All belts (V and serpentine multigroove) use an interference angle between the angle of the Vs of the belt and the angle of the Vs on the pulley. As the belt wears, the interference angles are worn off of both edges of the belt. As a result, the belt may start to slip and make a squealing sound even if tensioned properly.

A common trick used to determine if the noise is belt related is to use grit-type hand cleaner or scouring powder. With the engine off, sprinkle some powder onto the pulley side of the belt. Start the engine. The excess powder will fly into the air, so get away from under the hood when the engine starts. If the belts are now quieter, you know that it was the glazed belt that made the noise.

The noise can sound exactly like a noisy bearing. Therefore, before you start removing and replacing parts, try the hand cleaner trick.

Often, the grit from the hand cleaner will remove the glaze from the belt and the noise will not return. However, if the belt is worn or loose, the noise will return and the belt should be replaced. A fast, alternative method to see if the noise is from the belt is to spray water from a squirt bottle at the belt with the engine running. If the noise stops, the belt is the cause of the noise. The water quickly evaporates and, therefore, unlike the gritty hand cleaner, water simply finds the problem—it does not provide a short-term fix.

Typical belt tension for various widths of belts. Tension is the force needed to depress the belt as displayed on a belt tension gauge.

FIGURE 55–5 Check service information for the exact marks where the tensioner should be located for proper belt tension.

3. **Torque wrench reading.** Some vehicle manufacturers specify that a beam-type torque wrench be used to determine the torque needed to rotate the tensioner. If the torque reading is below specifications, the tensioner must be replaced.
4. **Deflection.** Depress the belt between the two pulleys that are the farthest apart; the flex or deflection should be 1/2 in. (13 mm).

AC RIPPLE VOLTAGE CHECK

PRINCIPLES A good alternator should produce very little AC voltage or current output. It is the purpose of the diodes in the alternator to rectify or convert most AC voltage into DC voltage. While it is normal to measure some AC voltage from an alternator, excessive AC voltage, called AC ripple, is undesirable and indicates a fault with the rectifier diodes or stator windings inside the alternator.

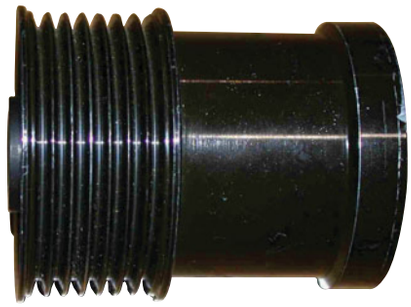

FIGURE 55–6 This overrunning alternator dampener (OAD) is longer than an overrunning alternator pulley (OAP) because it contains a dampener spring as well as a one way clutch. Be sure to check that it locks in one direction.

TECH TIP

Check the Overrunning Clutch

If low or no alternator output is found, remove the alternator drive belt and check the overrunning alternator pulley (OAP) or overrunning alternator dampener (OAD) for proper operation. Both types of overrunning clutches use a one-way clutch. Therefore, the pulley should freewheel in one direction and rotate the alternator rotor when rotated in the opposite direction. ● **SEE FIGURE 55–6.**

TESTING AC RIPPLE VOLTAGE The procedure to check for **AC ripple voltage** includes the following steps.

STEP 1 Set the digital meter to read AC volts.

STEP 2 Start the engine and operate it at 2000 RPM (fast idle).

STEP 3 Connect the voltmeter leads to the positive and negative battery terminals.

STEP 4 Turn on the headlights to provide an electrical load on the alternator.

NOTE: A more accurate reading can be obtained by touching the meter lead to the output or "battery" terminal of the alternator. ● SEE FIGURE 55–7.

The results should be interpreted as follows: If the rectifier diodes are good, the voltmeter should read *less* than 400 mV (0.4 volt) AC. If the reading is over 500 mV (0.5 volt) AC, the rectifier diodes are defective.

NOTE: Many conductance testers, such as Midtronic and Snap-On, automatically test for AC ripple.

TESTING AC RIPPLE CURRENT

All alternators should create direct current (DC) if the diodes and stator windings are functioning correctly. A mini clamp-on meter capable of measuring AC amperes can be used to check the alternator. A good alternator should produce less than 10% of its rated amperage output in AC ripple amperes. For example, an alternator rated at 100 amperes should not produce more than 10 amperes AC ripple (100 × 10% = 10). It is normal for a good alternator to produce 3 or 4 A of AC ripple current to the battery. Only if the AC ripple current exceeds 10% of the rating of the alternator should the alternator be repaired or replaced.

MEASURING THE AC RIPPLE FROM THE ALTERNATOR TELLS A LOT ABOUT ITS CONDITION. IF THE AC RIPPLE IS ABOVE 500 MILLIVOLTS, OR 0.5 VOLTS, LOOK FOR A PROBLEM IN THE DIODES OR STATOR. IF THE RIPPLE IS BELOW 500 MILLIVOLTS, CHECK THE ALTERNATOR OUTPUT TO DETERMINE ITS CONDITION.

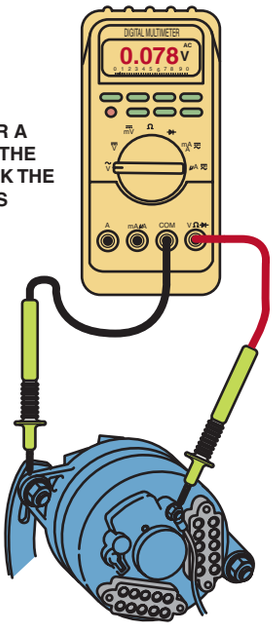

FIGURE 55–7 Testing AC ripple at the output terminal of the alternator is more accurate than testing at the battery due to the resistance of the wiring between the alternator and the battery. The reading shown on the meter, set to AC volts, is only 78 mV (0.078 V), far below what the reading would be if a diode were defective.

FIGURE 55–8 Charging system voltage can be easily checked at the lighter plug by connecting a lighter plug to the voltmeter through a double banana plug.

TECH TIP

The Lighter Plug Trick

Battery voltage measurements can be read through the lighter socket. Simply construct a test tool using a lighter plug at one end of a length of two-conductor wire and the other end connected to a double banana plug. The double banana plug will fit most meters in the common (COM) terminal and the volt terminal of the meter. This is handy to use while road testing the vehicle under real-life conditions. Both DC voltage and AC ripple voltage can be measured. ● **SEE FIGURE 55–8**.

FIGURE 55–9 A mini clamp-on meter can be used to measure alternator output as shown here (105.2 Amp). Then the meter can be used to check AC current ripple by selecting AC Amps on the rotary dial. AC ripple current should be less than 10% of the DC current output.

TEST PROCEDURE To measure the AC current to the battery, perform the following steps.

STEP 1 Start the engine and turn on the lights to create an electrical load on the alternator.

STEP 2 Using a mini clamp-on digital multimeter, place the clamp around either all of the positive (+) battery cables or all of the negative (−) battery cables.

An AC/DC current clamp adapter can also be used with a conventional digital multimeter set on the DC millivolts scale.

STEP 3 To check for AC current ripple, switch the meter to read AC amperes and record the reading. Read the meter display.

STEP 4 The results should be within 10% of the specified alternator rating. A reading of greater than 10 amperes AC indicates defective alternator diodes. ● **SEE FIGURE 55–9**.

CHARGING SYSTEM VOLTAGE DROP TESTING

ALTERNATOR WIRING For the proper operation of any charging system, there must be good electrical connections between the battery positive terminal and the alternator output terminal. The alternator must also be properly grounded to the engine block.

Many manufacturers of vehicles run the lead from the output terminal of the alternator to other connectors or junction blocks that are electrically connected to the positive terminal of the battery. If there is high resistance (a high voltage drop) in these connections or in the wiring itself, the battery will not be properly charged.

VOLTAGE DROP TEST PROCEDURE When there is a suspected charging system problem (with or without a charge indicator light on), simply follow these steps to measure the voltage drop of the insulated (power-side) charging circuit.

STEP 1 Start the engine and run it at a fast idle (about 2000 engine RPM).

STEP 2 Turn on the headlights to ensure an electrical load on the charging system.

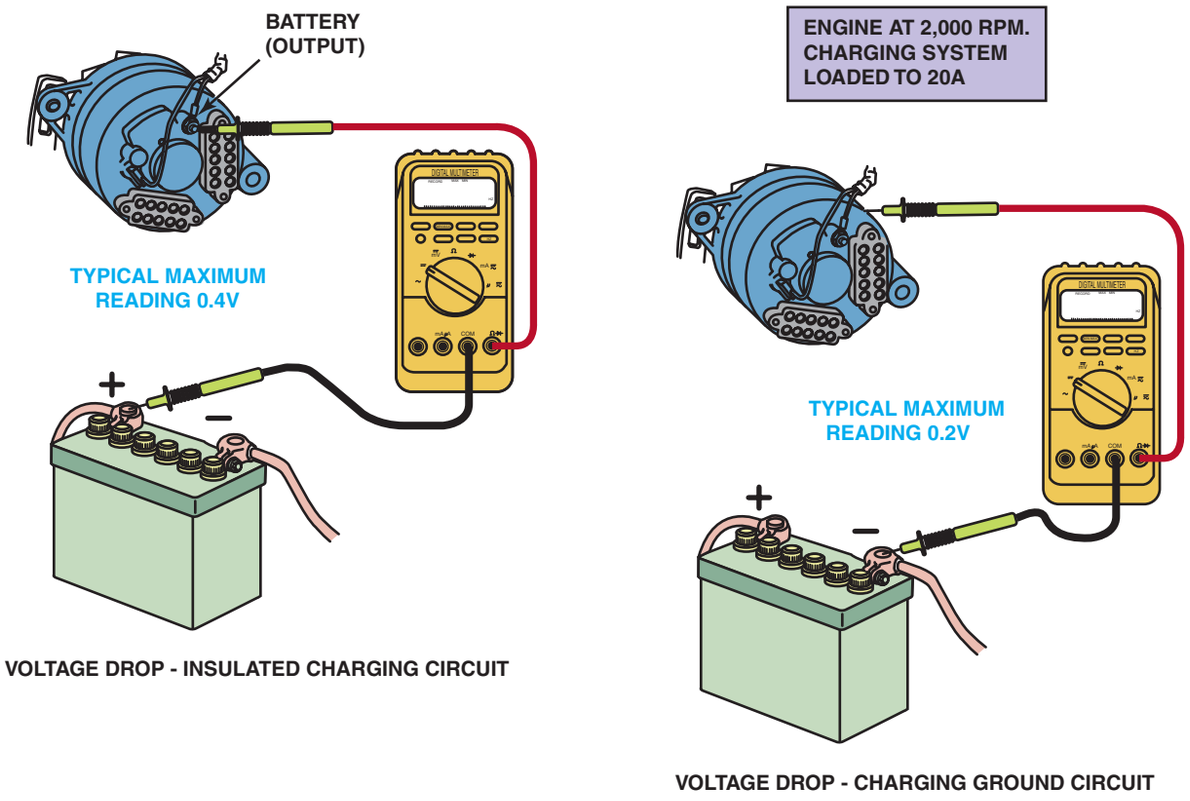

FIGURE 55–10 Voltmeter hookup to test the voltage drop of the charging circuit.

STEP 3 Using any voltmeter set to read DC volts, connect the positive test lead (red) to the output terminal of the alternator. Attach the negative test lead (black) to the positive post of the battery.

The results should be interpreted as follows:

1. If there is less than a 0.4 volt (400 mV) reading, then all wiring and connections are satisfactory.
2. If the voltmeter reads higher than 0.4 volt, there is excessive resistance (voltage drop) between the alternator output terminal and the positive terminal of the battery.
3. If the voltmeter reads battery voltage (or close to battery voltage), there is an open circuit between the battery and the alternator output terminal.

To determine whether the alternator is correctly grounded, maintain the engine speed at 2000 RPM with the headlights on. Connect the positive voltmeter lead to the case of the alternator and the negative voltmeter lead to the negative terminal of the battery. The voltmeter should read less than 0.2 volt (200 mV) if the alternator is properly grounded. If the reading is over 0.2 volt, connect one end of an auxiliary ground wire to the case of the alternator and the other end to a good engine ground. ● **SEE FIGURE 55–10**.

FIGURE 55–11 A typical tester used to test batteries as well as the cranking and charging system. Always follow the operating instructions.

ALTERNATOR OUTPUT TEST

PRELIMINARY CHECKS

An **alternator output test** measures the current (amperes) of the alternator. A charging circuit may be able to produce correct charging circuit voltage, but not be able to produce adequate amperage output. If in doubt about charging system output, first check the condition of the alternator drive belt. With the engine off, attempt to rotate the fan of the alternator by hand. Replace or tighten the drive belt if the alternator fan can be rotated this way.

CARBON PILE TEST PROCEDURE

A carbon pile tester uses plates of carbon to create an electrical load. A carbon pile test is used to load test a battery and/or an alternator. ● **SEE FIGURE 55–11**.

The testing procedure for alternator output is as follows:

STEP 1 Connect the starting and charging test leads according to the manufacturer's instructions, which usually include installing the amp clamp around the output wire near the alternator.

STEP 2 Turn off all electrical accessories to be sure that the tester is measuring the true output of the alternator.

STEP 3 Start the engine and operate it at 2000 RPM (fast idle). Turn the load increase control slowly to obtain the highest reading on the ammeter scale. Do not allow the voltage to drop below 12.6 volts. Note the ampere reading.

STEP 4 Add 5 to 7 amperes to the reading because this amount of current is used by the ignition system to operate the engine.

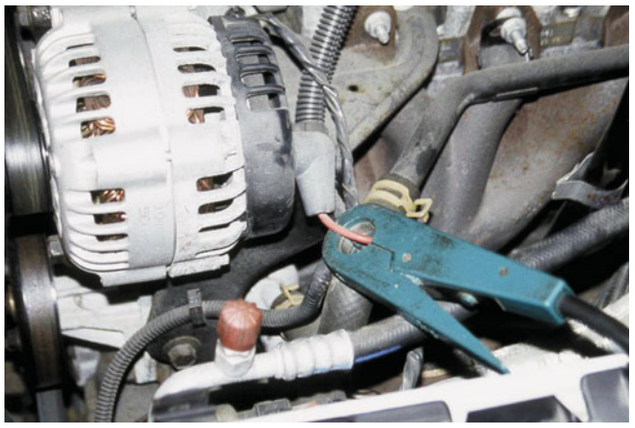

FIGURE 55–12 The best place to install a charging system tester amp probe is around the alternator output terminal wire, as shown.

STEP 5 Compare the output reading to factory specifications. The rated output may be stamped on the alternator or can be found in service information.

CAUTION: *NEVER* disconnect a battery cable with the engine running. All vehicle manufacturers warn not to do this, because this was an old test, before alternators, to see if a generator could supply current to operate the ignition system without a battery. When a battery cable is removed, the alternator (or PCM) will lose the battery voltage sense signal. Without a battery voltage sense circuit, the alternator will do one of two things, depending on the make and model of vehicle.

- **The alternator output can exceed 100 volts. This high voltage may not only damage the alternator but also electrical components in the vehicle, including the PCM and all electronic devices.**
- **The alternator stops charging as a fail safe measure to protect the alternator and all of the electronics in the vehicle from being damaged due to excessively high voltage.**

MINIMUM REQUIRED ALTERNATOR OUTPUT

PURPOSE All charging systems must be able to supply the electrical demands of the electrical system. If lights and accessories are used constantly and the alternator cannot supply the necessary ampere output, the battery will be drained. To determine the minimum electrical load requirements, connect an inductive ammeter probe around either battery cable or the alternator output cable. ● **SEE FIGURE 55–12.**

NOTE: If using an inductive pickup ammeter, be certain that the pickup is over *all* the wires leaving the battery terminal.

Failure to include the small body ground wire from the negative battery terminal to the body or the small positive wire (if testing from the positive side) will *greatly decrease* the current flow readings.

PROCEDURE After connecting an ammeter correctly in the battery circuit, continue as follows:

1. Start the engine and operate to about 2000 RPM (fast idle).
2. Turn the heat selector to air conditioning (if the vehicle is so equipped).

TECH TIP

Use a Fused Jumper Wire as a Diagnostic Tool

When diagnosing an alternator charging problem, try using a fused jumper wire to connect the positive and negative terminals of the alternator directly to the positive and negative terminals of the battery. If a definite improvement is noticed, the problem is in the wiring of the vehicle. High resistance, due to corroded connections or loose grounds, can cause low alternator output, repeated regulator failures, slow cranking, and discharged batteries. A voltage drop test of the charging system can also be used to locate excessive resistance (high voltage drop) in the charging circuit, but using a fused jumper wire is often faster and easier.

TECH TIP

Bigger Is Not Always Better

Many technicians are asked to install a higher output alternator to allow the use of emergency equipment or other high-amperage equipment such as a high-wattage sound system.

Although many higher output units can be physically installed, it is important not to forget to upgrade the wiring and the fusible link(s) in the alternator circuit. Failure to upgrade the wiring could lead to overheating. The usual failure locations are at junctions or electrical connectors.

3. Turn the blower motor to high speed.
4. Turn the headlights on bright.
5. Turn on the rear defogger.
6. Turn on the windshield wipers.
7. Turn on any other accessories that may be used continuously (do not operate the horn, power door locks, or other units that are not used for more than a few seconds).
8. Observe the ammeter. The current indicated is the electrical load that the alternator is able to exceed to keep the battery fully charged.

TEST RESULTS The minimum acceptable alternator output is 5 amperes greater than the accessory load. A negative (discharge) reading indicates that the alternator is not capable of supplying the current (amperes) that may be needed.

ALTERNATOR REMOVAL

After diagnosis of the charging system has determined that there is a fault with the alternator, it must be removed safely from the vehicle. Always check service information for the exact procedure to follow on the vehicle being serviced. A typical removal procedure includes the following steps.

STEP 1 Before disconnecting the negative battery cable, use a test light or a voltmeter and check for battery voltage at the output terminal of the alternator. A complete circuit must

FIGURE 55–13 Replacing an alternator is not always as easy as it is from a Buick with a 3800 V-6, where the alternator is easy to access. Many alternators are difficult to access, and require the removal of other components.

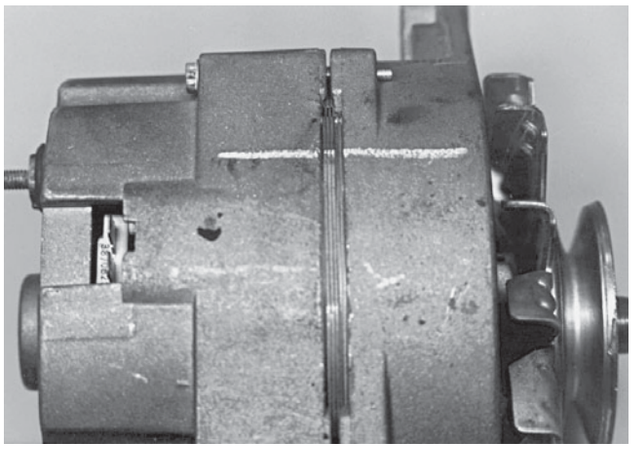

FIGURE 55–14 Always mark the case of the alternator before disassembly to be assured of correct reassembly.

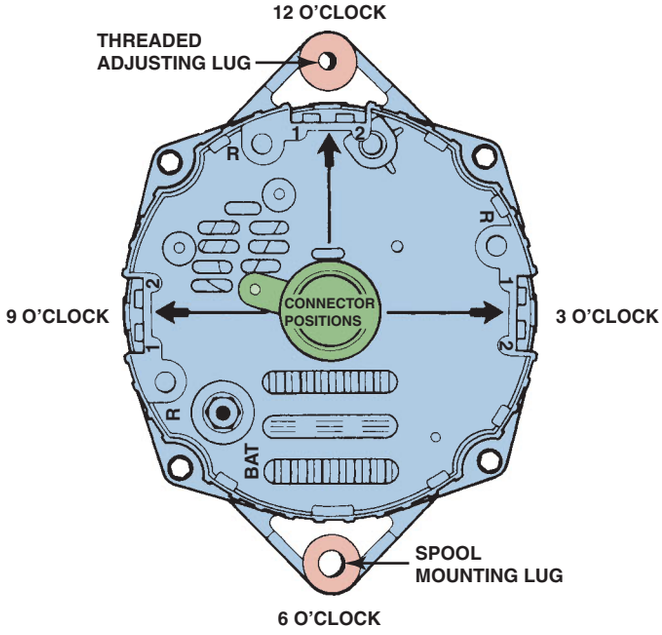

FIGURE 55–15 Explanation of clock positions. Because the four through bolts are equally spaced, it is possible for an alternator to be installed in one of four different clock positions. The connector position is determined by viewing the alternator from the diode end with the threaded adjusting lug in the up or 12 o'clock position. Select the 3 o'clock, 6 o'clock, 9 o'clock, or 12 o'clock position to match the unit being replaced.

TECH TIP

The Sniff Test

When checking for the root cause of an alternator failure, one test that a technician could do is to sniff (smell) the alternator. If the alternator smells like a dead rat (rancid smell), the stator windings have been overheated by trying to charge a discharged or defective battery. If the battery voltage is continuously low, the voltage regulator will continue supplying full-field current to the alternator. The voltage regulator is designed to cycle on and off to maintain a narrow charging system voltage range.

If the battery voltage is continually below the cutoff point of the voltage regulator, the alternator is continually producing current in the stator windings. This constant charging can often overheat the stator and burn the insulating varnish covering the stator windings. If the alternator fails the sniff test, the technician should replace the stator and other alternator components that are found to be defective and replace or recharge and test the battery.

exist between the alternator and the battery. If there is no voltage at the alternator output terminal, check for a blown fusible link or other electrical circuit fault.

STEP 2 Disconnect the negative (−) terminal from the battery. (Use a memory saver to maintain radio, memory seats, and other functions.)

STEP 3 Remove the accessory drive belt that drives the alternator.

STEP 4 Remove electrical wiring, fasteners, spacers, and brackets, as necessary, and remove the alternator from the vehicle. ● **SEE FIGURE 55–13**.

ALTERNATOR DISASSEMBLY

DISASSEMBLY PROCEDURE

STEP 1 Mark the case with a scratch or with chalk to ensure proper reassembly of the alternator case. ● **SEE FIGURE 55–14**.

STEP 2 After the through bolts have been removed, carefully separate the two halves. The stator windings must stay with the

FREQUENTLY ASKED QUESTION

What Is a "Clock Position"?

Most alternators of a particular manufacturer can be used on a variety of vehicles, which may require wiring connections placed in various locations. For example, a Chevrolet and a Buick alternator may be identical except for the position of the rear section containing the electrical connections. The four through bolts that hold the two halves together are equally spaced; therefore, the rear alternator housing *can* be installed in any one of four positions to match the wiring needs of various models. Always check the clock position of the original and be sure that it matches the replacement unit. ● **SEE FIGURE 55–15**.

rear case. When this happens, the brushes and springs will fall out.

STEP 3 Remove the rectifier assembly and voltage regulator.

ROTOR TESTING

The slip rings on the rotor should be smooth and round (within 0.002 in. of being perfectly round).

- If grooved, the slip rings can be machined to provide a suitable surface for the brushes. Do not machine beyond the minimum slip-ring dimension as specified by the manufacturer.
- If the slip rings are discolored or dirty, they can be cleaned with 400-grit or fine emery (polishing) cloth. The rotor must be turned while being cleaned to prevent flat spots on the slip rings.
- Measure the resistance between the slip rings using an ohmmeter. Typical resistance values and results include the following:

1. The resistance measured between either slip ring and the steel rotor shaft should be infinity (OL). If there is continuity, then the rotor is shorted to ground.
2. Rotor resistance range is normally between 2.4 and 6 ohms.
3. If the resistance is below specification, the rotor is shorted.
4. If the resistance is above specification, the rotor connections are corroded or open.

If the rotor is found to be bad, it must be replaced or repaired at a specialized shop. ● **SEE FIGURE 55–16**.

NOTE: The cost of a replacement rotor may exceed the cost of an entire rebuilt alternator. Be certain, however, that the rebuilt alternator is rated at the same output as the original or higher.

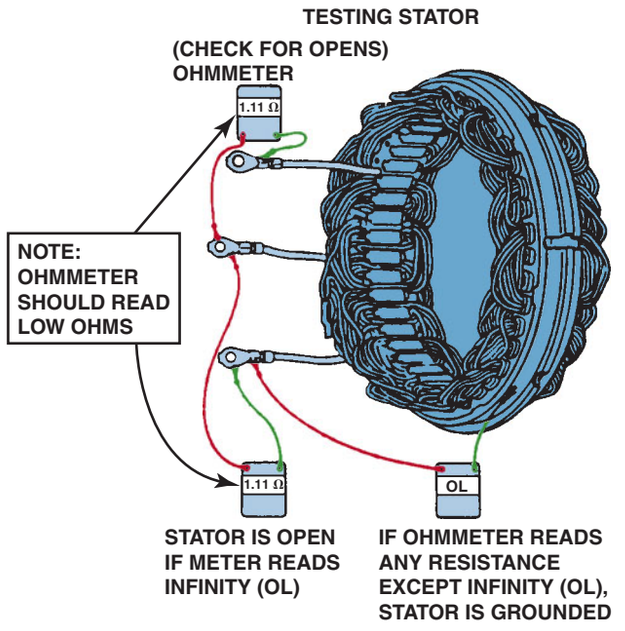

FIGURE 55–17 If the ohmmeter reads infinity between any two of the three stator windings, the stator is open and, therefore, defective. The ohmmeter should read infinity between any stator lead and the steel laminations. If the reading is less than infinity, the stator is grounded. Stator windings cannot be tested if shorted because the normal resistance is very low.

STATOR TESTING

The stator must be disconnected from the diodes (rectifiers) before testing. Because all three windings of the stator are electrically connected (either wye or delta), an ohmmeter can be used to check a stator.

- There should be low resistance at all three stator leads (continuity).
- There should *not* be continuity (in other words, there should be a meter reading of infinity ohms) when the stator is tested between any stator lead and the metal stator core.
- If there is continuity, the stator is shorted-to-ground and must be repaired or replaced. ● **SEE FIGURE 55–17**.

NOTE: Because the resistance is very low for a normal stator, it is generally *not* possible to test for a *shorted* (copper-to-copper) stator. A shorted stator will, however, greatly reduce alternator output. An ohmmeter cannot detect an open stator if the stator is delta wound. The ohmmeter will still indicate low resistance because all three windings are electrically connected.

TESTING THE DIODE TRIO

Many alternators are equipped with a diode trio. A diode is an electrical one-way check valve that permits current to flow in only one direction. Because *trio* means "three," a diode trio is three diodes connected together. ● **SEE FIGURE 55–18**.

The diode trio is connected to all three stator windings. The current generated in the stator flows through the diode trio to the internal voltage regulator. The diode trio is designed to supply current for the field (rotor) and turns off the charge indicator light when the alternator voltage equals or exceeds the battery voltage. If one of the three diodes in the diode trio is defective (usually open), the alternator may produce close-to-normal output; however, the charge indicator light will be on dimly.

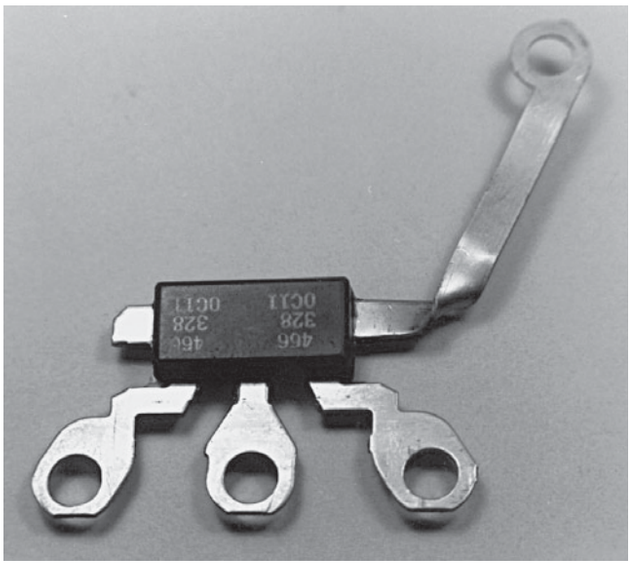

FIGURE 55–18 Typical diode trio. If one leg of a diode trio is open, the alternator may produce close to normal output, but the charge indicator light on the dash will be on dimly.

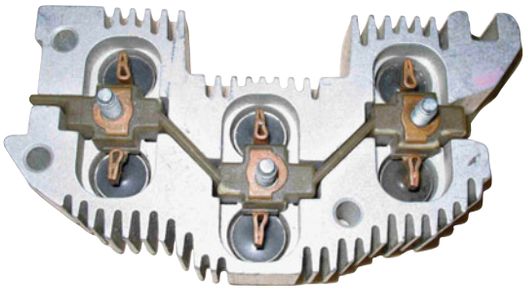

FIGURE 55–19 A typical rectifier bridge that contains all six diodes in one replaceable assembly.

A diode trio should be tested with a digital multimeter. The meter should be set to the diode-check position. The multimeter should indicate 0.5 to 0.7 V (500 to 700 mV) one way and OL (overlimit) after reversing the test leads and touching all three connectors of the diode trio.

TESTING THE RECTIFIER

TERMINOLOGY The rectifier assembly usually is equipped with six diodes including three positive diodes and three negative diodes (one positive and one negative for each winding of the stator).

METER SETUP The rectifier(s) (diodes) should be tested using a multimeter that is set to "diode check" position on the digital multimeter (DMM).

Because a diode (rectifier) should allow current to flow in only one direction, each diode should be tested to determine if the diode allows current flow in one direction and blocks current flow in the opposite direction. To test some alternator diodes, it may be necessary to unsolder the stator connections. ● **SEE FIGURE 55–19**.

Accurate testing is not possible unless the diodes are separated electrically from other alternator components.

TESTING PROCEDURE Connect the leads to the leads of the diode (pigtail and housing of the rectifier bridge). Read the meter.

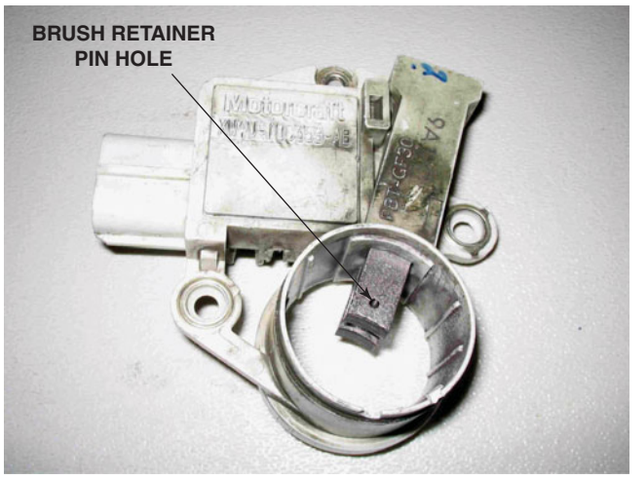

FIGURE 55–20 A brush holder assembly with new brushes installed. The holes in the brushes are used to hold the brushes up in the holder when it is installed in the alternator. After the rotor has been installed, the retaining pin is removed which allows the brushes to contact the slip rings of the rotor.

Reverse the test leads. A good diode should have high resistance (OL) one way (reverse bias) and low voltage drop of 0.5 to 0.7 V (500 to 700 mV) the other way (forward bias).

RESULTS Open or shorted diodes must be replaced. Most alternators group or combine all positive and all negative diodes in the one replaceable rectifier component.

REASSEMBLING THE ALTERNATOR

BRUSH HOLDER REPLACEMENT Alternator carbon brushes often last for many years and require no scheduled maintenance. The life of the alternator brushes is extended because they conduct only the field (rotor) current, which is normally only 2 to 5 amperes. The alternator brushes should be inspected when the alternator is disassembled and should be replaced when worn to less than 1/2 in. long. Brushes are commonly purchased assembled together in a brush holder. After the brushes are installed (usually retained by two or three screws) and the rotor is installed in the alternator housing, a brush retainer pin can be pulled out through an access hole in the rear of the alternator, allowing the brushes to be pressed against the slip rings by the brush springs. ● **SEE FIGURE 55–20**.

BEARING SERVICE AND REPLACEMENT The bearings of an alternator must be able to support the rotor and reduce friction. An alternator must be able to rotate at up to 15,000 RPM and withstand the forces created by the drive belt. The front bearing is usually a ball bearing type and the rear can be either a smaller roller or ball bearing.

The old or defective bearing can sometimes be pushed out of the front housing and the replacement pushed in by applying pressure with a socket or pipe against the outer edge of the bearing (outer race). Replacement bearings are usually prelubricated and seated. Many alternator front bearings must be removed from the rotor using a special puller.

REAL WORLD FIX

The Two-Minute Alternator Repair

A Chevrolet pickup truck was brought to a shop for routine service. The customer stated that the battery required a jump start after a weekend of sitting. The technician tested the battery and charging system voltage using a small handheld digital multimeter. The battery voltage was 12.4 volts (about 75% charged), but the charging voltage was also 12.4 volts at 2000 RPM. Because normal charging voltage should be 13.5 to 15 volts, it was obvious that the charging system was not operating correctly.

The technician checked the dash and found that the "charge" light was *not* on. Before removing the alternator for service, the technician checked the wiring connection on the alternator. When the connector was removed, it was discovered to be rusty. After the contacts were cleaned, the charging system was restored to normal operation. The technician had learned that the simple things should always be checked first before tearing into a big (or expensive) repair.

ALTERNATOR ASSEMBLY After testing or servicing, the alternator rectifier(s), regulator, stator, and brush holder must be reassembled using the following steps.

STEP 1 If the brushes are internally mounted, insert a wire through the holes in the brush holder to hold the brushes against the springs.

STEP 2 Install the rotor and front-end frame in proper alignment with the mark made on the outside of the alternator housing. Install the through bolts. Before removing the wire pin holding the brushes, spin the alternator pulley. If the alternator is noisy or not rotating freely, the alternator can easily be disassembled again to check for the cause. After making certain the alternator is free to rotate, remove the brush holder pin and spin the alternator again by hand. The noise level may be slightly higher with the brushes released onto the slip rings.

STEP 3 Alternators should be tested on a bench tester, if available, before they are reinstalled on a vehicle. When installing the alternator on the vehicle, be certain that all mounting bolts and nuts are tight. The battery terminal should be covered with a plastic or rubber protective cap to help prevent accidental shorting to ground, which could seriously damage the alternator.

REMANUFACTURED ALTERNATORS

Remanufactured or rebuilt alternators are totally disassembled and rebuilt. Even though there are many smaller rebuilders who may not replace all worn parts, the major national remanufacturers *totally* remanufacture the alternator. Old alternators (called **cores**) are totally disassembled and cleaned. Both bearings are replaced and all components are tested. Rotors are rewound to original specifications if required. The rotor windings are not counted but are rewound on the rotor "spool," using the correct-gauge copper wire, to the *weight* specified by the original manufacturer. New slip rings are replaced as required, soldered to the rotor spool windings, and machined. The rotors are also balanced and measured to ensure that the outside diameter of the rotor meets specifications. An undersized rotor will produce less alternator output because the field must be close to the stator windings for maximum output. Bridge rectifiers are replaced, if required. Every alternator is then assembled and tested for proper output, boxed, and shipped to a warehouse. Individual parts stores (called jobbers) purchase parts from various regional or local warehouses.

ALTERNATOR INSTALLATION

Before installing a replacement alternator, check service information for the exact procedure to follow for the vehicle being serviced. A typical installation procedure includes the following steps.

STEP 1 Verify that the replacement alternator is the correct unit for the vehicle.

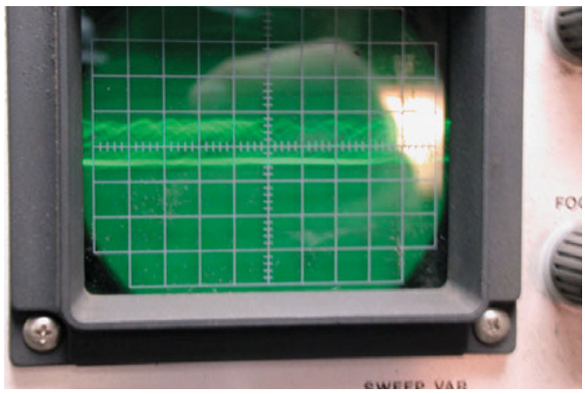
STEP 2 Install the alternator wiring on the alternator and install the alternator.

STEP 3 Check the condition of the drive belt and replace, if necessary. Install the drive belt over the drive pulley.

STEP 4 Properly tension the drive belt.

STEP 5 Tighten all fasteners to factory specifications.

STEP 6 Double-check that all fasteners are correctly tightened and remove all tools from the engine compartment area.



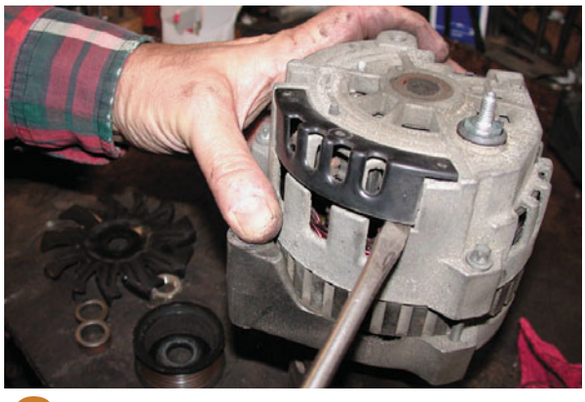
STEP 7 Reconnect the negative battery cable.

STEP 8 Start the engine and verify proper charging circuit operation.

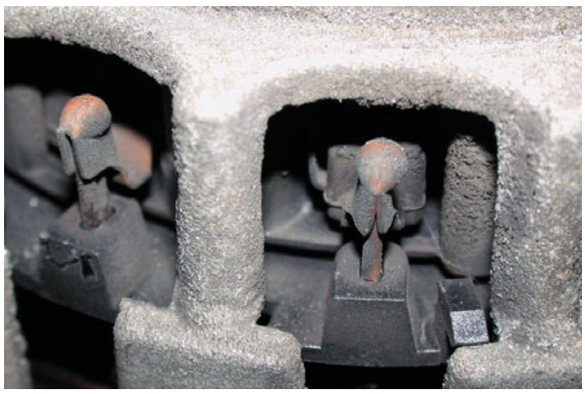
ALTERNATOR OVERHAUL

1 Before the alternator is disassembled, it is spin tested and connected to a scope to check for possible defective components.

2 The scope pattern shows that the voltage output is far from being a normal pattern. This pattern indicates serious faults in the rectifier diodes.



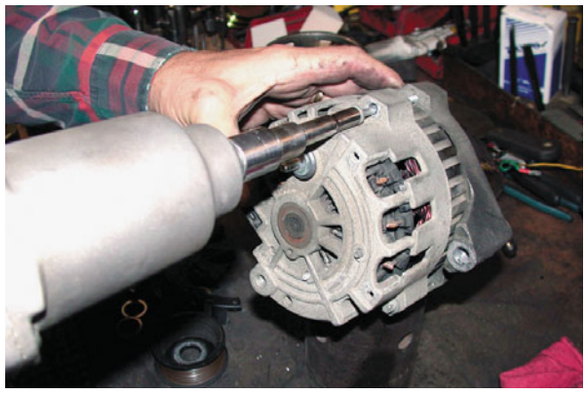
3 The first step is to remove the drive pulley. This rebuilder is using an electric impact wrench to accomplish the task.



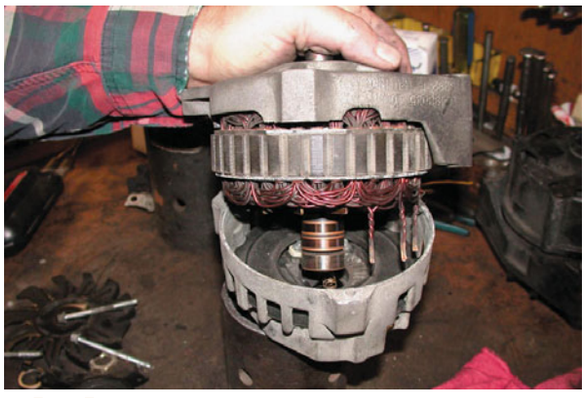
4 Carefully inspect the drive galley for damage of embedded rubber from the drive belt. The slightest fault can cause a vibration, noise, or possible damage to the alternator.

5 Remove the external fan (if equipped) and then the spacers as shown.

6 Next pop off the plastic cover (shield) covering the stator/rectifier connection.



7 After the cover has been removed, the stator connections to the rectifier can be seen.



8 Using a diagonal cutter, cut the weld to separate the stator from the rectifier.

9 Before separating the halves of the case, this technician uses a punch to mark both halves.

10 After the case has been marked, the through-bolts are removed.

11 The drive-end housing and the stator are being separated from the rear (slip-ring-end) housing.

12 The stator is checked by visual inspection for discoloration or other physical damage, and then checked with an ohmmeter to see if the windings are shorted-to-ground.

13 The front bearing is removed from the drive-end housing using a press.

14 A view of the slip-ring-end (SRE) housing showing the black plastic shield, which helps direct air flow across the rectifier.

15 A punch is used to dislodge the plastic shield retaining clips.

16 After the shield has been removed, the rectifier, regulator, and brush holder assembly can be removed by removing the retaining screws.

17 The hear transfer grease is visible when the rectifier assembly is lifted out of the rear housing.

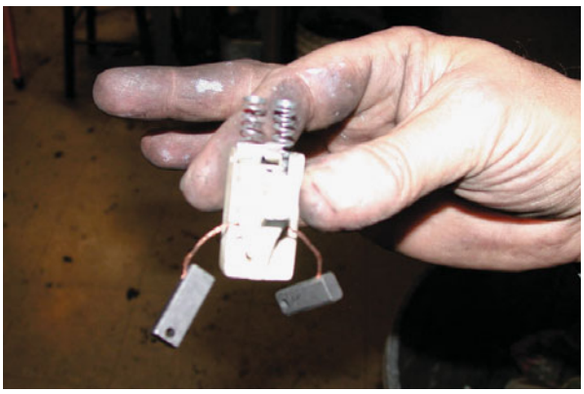
18 The parts are placed into a tumbler where ceramic stones and a water-based solvent are used to clean the parts.

19 This rebuilder is painting the housing using a high-quality industrial grade spray paint to make the rebuilt alternator look like new.

20 The slip rings on the rotor are being machined on a lathe.

21 The rotor is being tested using an ohmmeter. The specifications for the resistance between the slip rings on the CS-130 are 2.2 to 3.5 ohms.

22 The rotor is also tested between the slip ring and the rotor shaft. This reading should be infinity.



23 A new rectifier. This replacement unit is significantly different than the original but is designed to replace the original unit and meets the original factory specifications.

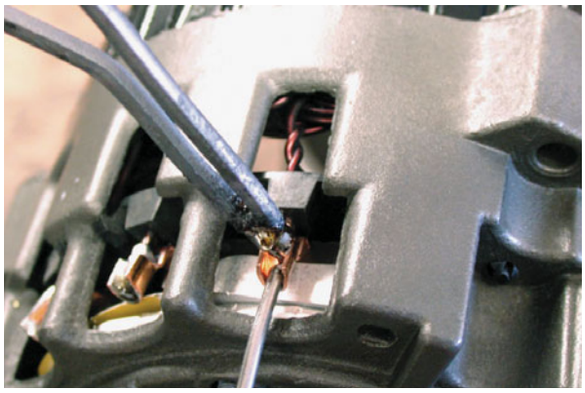
24 Silicone heat transfer compound is applied to the heat sink of the new rectifier.

CONTINUED ▶

25 Replacement brushes and springs are assembled into the brush holder.

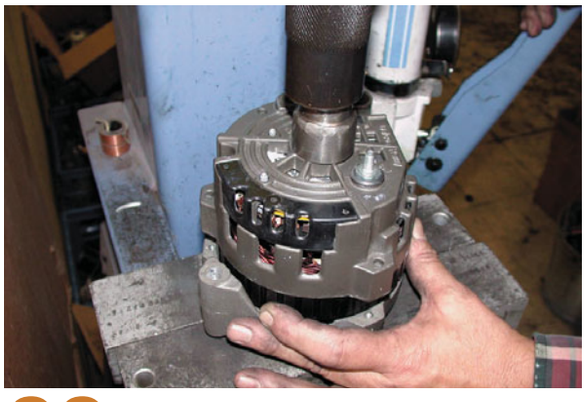
26 The brushes are pushed into the brush holder and retained by a straight wire, which extends through the rear housing of the alternator. This wire is then pulled out when the unit is assembled.

27 Here is what the CS alternator looks like after installing the new brush holder assembly, rectifier bridge, and voltage regulator.



28 The junction between the rectifier bridge and the voltage regulator is soldered.

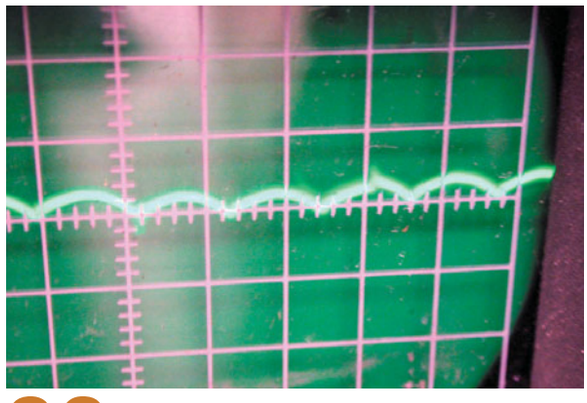
29 The plastic deflector shield is snapped back into location using a blunt chisel and a hammer. This shield directs the airflow from the fan over the rectifier bridge and voltage regulator.



30 Before the stator windings can be soldered to the rectifier bridge, the varnish insulation is removed from the ends of the leads.

31 After the stator has been inserted into the rear housing the stator leads are soldered to the copper lugs of the rectifier bridge.

32 New bearings are installed. A spacer is placed between the bearing and the slip rings to help prevent the possibility that the bearing could move on the shaft and short against the slip ring.



33 The slip-ring-end (SRE) housing is aligned with the marks made during disassembly and is pressed into the drive-end (DE) housing.

34 The retaining bolts, which are threaded into the drive-end housing from the back of the alternator are installed.

35 The external fan and drive pulley are installed and the retaining nut is tightened on the rotor shaft.

36 The scope pattern shows that the diodes and stator are functioning correctly and voltage check indicates that the voltage regulator is also functioning correctly.

FIGURE 56–1 Dual-filament (double-contact) bulbs contain both a low-intensity filament for taillights or parking lights and a high-intensity filament for brake lights and turn signals. Bulbs come in a variety of shapes and sizes. The numbers shown are the trade numbers.

EXTERIOR LIGHTING

HEADLIGHT SWITCH CONTROL Exterior lighting is controlled by the headlight switch, which is connected directly to the battery on most vehicles. Therefore, if the light switch is left on manually, the lights could drain the battery. Older headlight switches contained a built-in circuit breaker. If excessive current flows through the headlight circuit, the circuit breaker will momentarily open the circuit, then close it again. The result is headlights that flicker on and off rapidly. This feature allows the headlights to function, as a safety measure, in spite of current overload.

The headlight switch controls the following lights on most vehicles, usually through a module.

1. Headlights
2. Taillights
3. Side-marker lights
4. Front parking lights
5. Dash lights
6. Interior (dome) light(s)

COMPUTER-CONTROLLED LIGHTS Because these lights can easily drain the battery if accidentally left on, many newer vehicles control these lights through computer modules. The computer module keeps track of the time the lights are on and can turn them off if the time is excessive. The computer can control either the power side or the ground side of the circuit.

For example, a typical computer-controlled lighting system usually includes the following steps.

STEP 1 The driver depresses or rotates the headlight switch.

STEP 2 The signal from the headlight switch is sent to the nearest control module.

STEP 3 The control module then sends a request to the headlight control module to turn on the headlights as well as the front park and side-marker lights.
Through the data BUS, the rear control module receives the lights on signal and turns on the lights at the rear of the vehicle.

STEP 4 All modules monitor current flow through the circuit and will turn on a bulb failure warning light if it detects an open bulb or a fault in the circuit.

STEP 5 After the ignition has been turned off, the modules will turn off the lights after a time delay to prevent the battery from being drained.

BULB NUMBERS

TRADE NUMBER The number used on automotive bulbs is called the bulb **trade number,** as recorded with the American National Standards Institute (ANSI). The number is the same regardless of the manufacturer. ● **SEE FIGURE 56–1**.

CANDLEPOWER The trade number also identifies the size, shape, number of filaments, and amount of light produced, measured in **candlepower.** For example, the 1156 bulb, commonly used for backup lights, is 32 candlepower. A 194 bulb, commonly used for dash or side-marker lights, is rated at only 2 candlepower. The amount of light produced by a bulb is determined by the resistance of the filament wire, which also affects the amount of current (in amperes) required by the bulb.

It is important that the correct trade number of bulb always be used for replacement to prevent circuit or component damage. The correct replacement bulb for a vehicle is usually listed in the owner or service manual. ● **REFER TO CHART 56–1** for a listing of common bulbs and their specifications used in most vehicles.

BULB NUMBER SUFFIXES Many bulbs have suffixes that indicate some feature of the bulb, while keeping the same size and light output specifications.

Typical bulb suffixes include:

- NA: natural amber (amber glass)
- A: amber (painted glass)
- HD: heavy duty
- LL: long life
- IF: inside frosted

FIGURE 56–2 Bulbs that have the same trade number have the same operating voltage and wattage. The NA means that the bulb uses a natural amber glass ampoule with clear turn signal lenses.

- R: red
- B: blue
- G: green

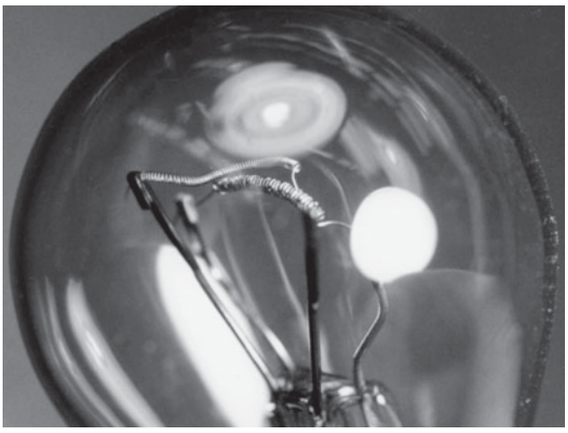

FIGURE 56–3 Close-up a 2057 dual-filament (double-contact) bulb that failed. Notice that the top filament broke from its mounting and melted onto the lower filament. This bulb caused the dash lights to come on whenever the brakes were applied.

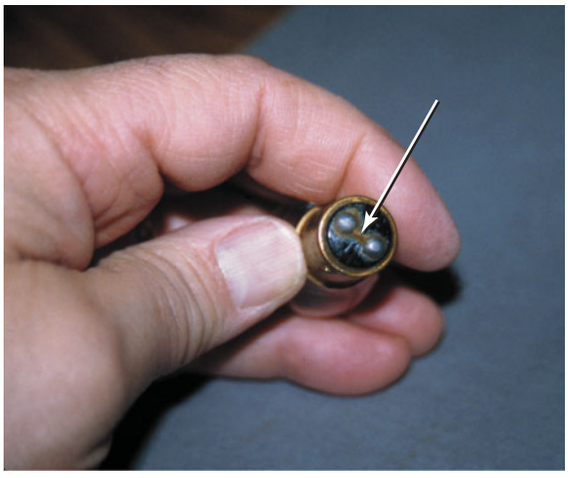

FIGURE 56–4 Corrosion caused the two terminals of this dual-filament bulb to be electrically connected.

FIGURE 56–5 Often the best diagnosis is a thorough visual inspection. This bulb was found to be filled with water, which caused weird problems.

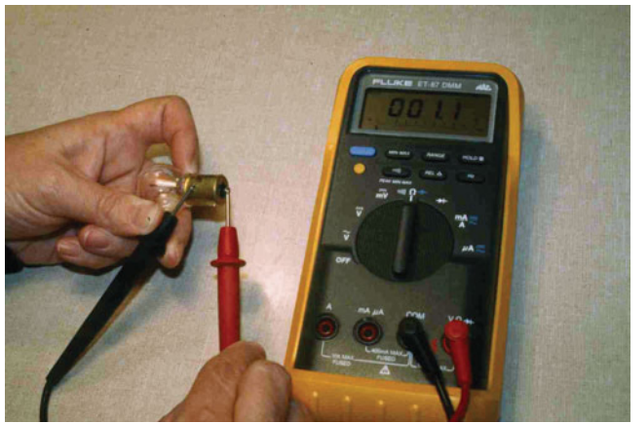

FIGURE 56–6 This single-filament bulb is being tested with a digital multimeter set to read resistance in ohms. The reading of 1.1 ohms is the resistance of the bulb when cold. As soon as current flows through the filament, the resistance increases about 10 times. It is the initial surge of current flowing through the filament when the bulb is cool that causes many bulbs to fail in cold weather as a result of the reduced resistance. As the temperature increases, the resistance increases.

REAL WORLD FIX

Weird Problem—Easy Solution

A General Motors minivan had the following electrical problems.

- The turn signals flashed rapidly on the left side.
- With the ignition key off, the lights-on warning chime sounded if the brake pedal was depressed.
- When the brake pedal was depressed, the dome light came on.

All of these problems were caused by *one* defective 2057 dual-filament bulb, as shown in ● **FIGURE 56–3.**

Apparently, the two filaments were electrically connected when one filament broke and then welded to the other filament. This caused the electrical current to feed back from the brake light filament into the taillight circuit, causing all the problems.

TESTING BULBS

Bulbs can be tested using two basic tests.

1. Perform a visual inspection of any bulb. Many faults, such as a shorted filament, corroded connector, or water, can cause weird problems that are often thought to be wiring issues.
   ● **SEE FIGURES 56–4 AND 56–5.**
2. Bulbs can be tested using an ohmmeter and checking the resistance of the filaments(s). Most bulbs will read low resistance at room temperature between 0.5 and 20 ohms depending on the bulb. Test results include:
   - **Normal resistance.** The bulb is good. Check both filaments if it is a two-filament bulb. ● **SEE FIGURE 56–6.**
   - **Zero ohms.** It is unlikely but possible for the bulb filament to be shorted.
   - **OL (electrically open).** The reading indicates that the bulb filament is broken.

BRAKE LIGHTS

OPERATION

Brake lights, also called stop lights, use the high-intensity filament of a double-filament bulb. (The low-intensity filament is for the taillights.) When the brakes are applied, the brake switch is closed and the brake lamps light. The brake switch receives current from a fuse that is hot all the time. The brake light switch is a normally open (N.O.) switch, but is closed when the driver depresses the brake

pedal. Since 1986, all vehicles sold in the United States have a third brake light commonly referred to as the **center high-mounted stop light (CHMSL).** ● **SEE FIGURE 56–7.**

? FREQUENTLY ASKED QUESTION

Why Are LEDs Used for Brake Lights?

Light-emitting diode (LED) brake lights are frequently used for high-mounted stop lamps (CHMSLs) for the following reasons.

1. **Faster illumination.** An LED will light up to 200 milliseconds faster than an incandescent bulb, which requires some time to heat the filament before it is hot enough to create light. This faster illumination can mean the difference in stopping distances at 60 mph (100 km/h) by about 18 ft (6 m) due to the reduced reaction time for the driver of the vehicle behind.
2. **Longer service life.** LEDs are solid-state devices that do not use a filament to create light. As a result, they are less susceptible to vibration and will often last the life of the vehicle.

NOTE: Aftermarket replacement LED bulbs that are used to replace conventional bulbs may require the use of a different type of flasher unit due to the reduced current draw of the LED bulbs. ● **SEE FIGURE 56–8.**

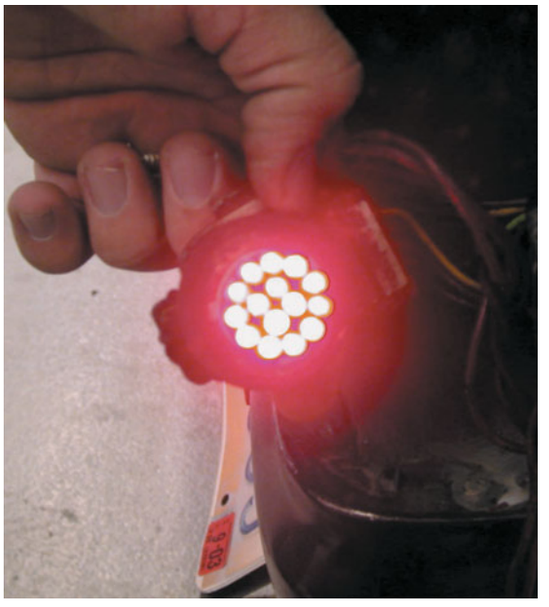

FIGURE 56–8 A replacement LED taillight bulb is constructed of many small, individual light-emitting diodes.

The brake switch is also used as an input switch (signal) for the following:

1. Cruise control (deactivates when the brake pedal is depressed)
2. Antilock brakes (ABS)
3. Brake shift interlock (prevents shifting from park position unless the brake pedal is depressed)

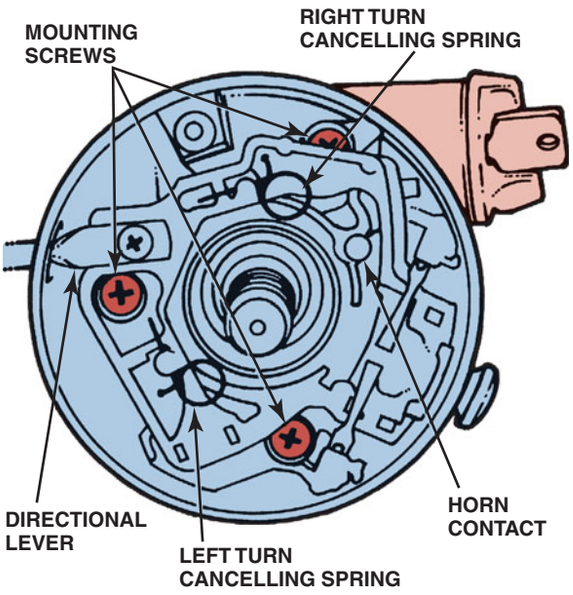

FIGURE 56–9 The typical turn signal switch includes various springs and cams to control the switch and to cause the switch to cancel after a turn has been completed.

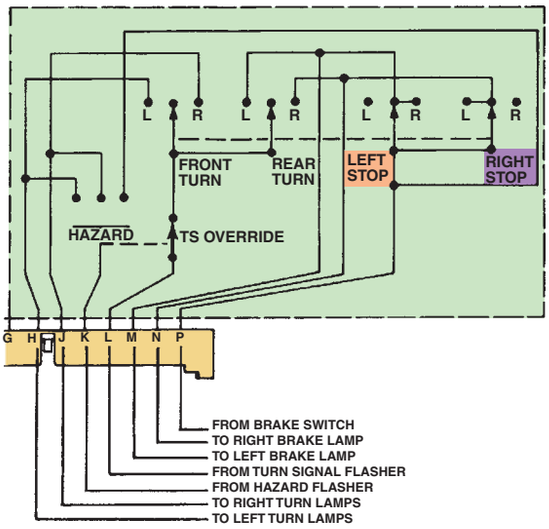

FIGURE 56–10 When the stop lamps and turn signals share a common bulb filament, stop light current flows through the turn signal switch.

TURN SIGNALS

OPERATION The turn signal circuit is supplied power from the ignition switch and operated by a lever and switch. ● **SEE FIGURE 56–9.**

When the turn signal switch is moved in either direction, the corresponding turn signal lamps receive current through the flasher unit. The flasher unit causes the current to start and stop as the turn signal lamp flashes on and off with the interrupted current.

ONE-FILAMENT STOP/TURN BULBS In many vehicles, the stop and turn signals are both provided by one filament. When the turn signal switch is turned on (closed), the filament receives interrupted current through the flasher unit. When the brakes are applied, the current first flows to the turn signal switch, except for the high-mounted stop, which is fed directly from the brake switch. If neither turn signal is on, then current through the turn signal switch flows to both rear brake lights. If the turn signal switch is operated (turned to either left or right), current flows through the flasher unit on the side that was selected and directly to the brake lamp on the opposite side. If the brake pedal is not depressed, then current flows through the flasher and only to one side. ● **SEE FIGURE 56–10.**

Moving the lever up or down completes the circuit through the flasher unit and to the appropriate turn signal lamps. A turn signal switch includes cams and springs that cancel the signal after the turn has been completed. As the steering wheel is turned in the signaled direction and then returns to its normal position, the cams and springs cause the turn signal switch contacts to open and break the circuit.

TWO-FILAMENT STOP/TURN BULBS In systems using separate filaments for the stop and turn lamps, the brake and turn signal switches are not connected. If the vehicle uses the same filament for both purposes, then brake switch current is routed through contacts within the turn signal switch. By linking certain contacts, the bulbs can receive either brake switch current or flasher current, depending upon which direction is being signaled. For example, ● **FIGURE 56–11** shows current flow through the switch when the brake switch is closed and a right turn is signaled.

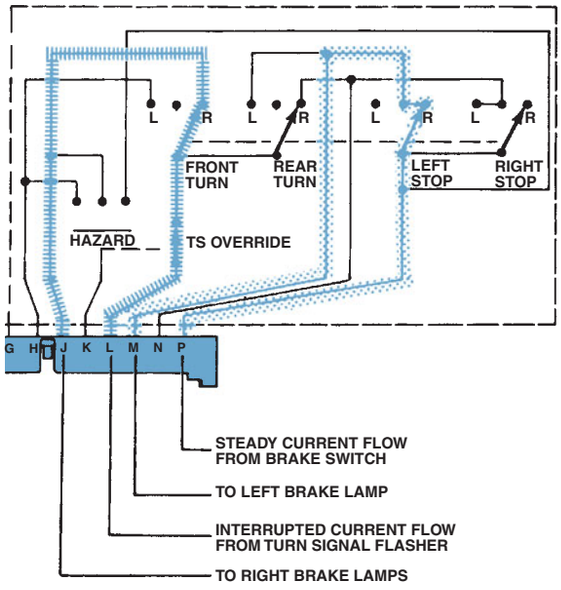

FIGURE 56–11 When a right turn in signaled, the turn signal switch contacts send flasher current to the right-hand filament and brake switch current to the left-hand filament.

Steady current through the brake switch is sent to the left brake lamp. Interrupted current from the turn signal is sent to the right turn lamps.

FLASHER UNITS A turn signal flasher unit is a metal or plastic can containing a switch that opens and closes the turn signal circuit. Vehicles can be equipped with many different types of flasher units. ● **SEE FIGURE 56–12.**

- **DOT flashers.** This turn signal flasher unit is often installed in a metal clip attached to the dash panel to allow the "clicking" noise of the flasher to be heard by the driver. The turn signal flasher is designed to transmit the current to light the front and rear bulbs on only one side at a time. The U.S. **Department of Transportation (DOT)** regulation requires that the driver be

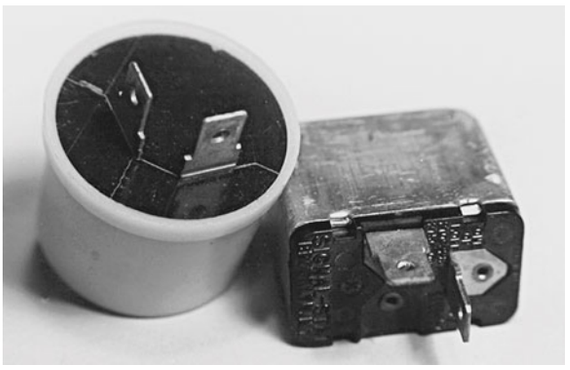

FIGURE 56–12 Two styles of two-prong flasher units.

alerted when a turn signal bulb is not working. This is achieved by using a series-type flasher unit. The flasher unit requires current flow through two bulbs (one in the front and one in the rear) in order to flash. If one bulb burns out, the current flow through only one bulb is not sufficient to make the unit flash; it will be a steady light. These turn signal units are often called DOT flashers.

- **Bimetal flashers.** The bimetal flashers have a lower cost and shorter life expectancy than hybrid or solid-state flashers. The operation of this flasher is current sensitive, which means that the flasher will stop flashing when one of the light bulbs is out and that it will flash at a faster rate when adding additional load, such as a trailer. The bimetal element is a sandwich of two different metals that distorts with temperature changes similar to a circuit breaker. The turn signal lamp current is passed through the bimetal element and causes heating. When the element is hot enough, the bimetal distorts, opening the contacts and turning off the lamps. After the bimetal cools, it returns to the original shape, closing the contacts and turning on the lamps again. This sequence is repeated until the load is removed. If one bulb burns out, the turn signal indicator lamp on the dash will remain lighted. The flasher will not flash because there is not enough current flow through the one remaining bulb to cause the flasher to become heated enough to open.
- **Hybrid flashers.** The **hybrid flashers** have an electronic flasher control circuit to operate the internal electromechanical relay and are commonly called a **flasher relay.** This type of flasher has a stable electronic timing circuitry that enables a wide operating voltage and temperature range with a reasonable cost. The life expectancy is considerably longer compared to bimetal units and is dependent on the load and relay used internally for switching the load. The hybrid flasher has a lamp current-sensing circuit which will cause the flash rate to double when a bulb is burned out.
- **Solid-state flashers.** The solid-state flashers have an internal electronic circuit for timing and solid-state power output devices for load switching. Life expectancy is longer than other flashers because there are no moving parts for mechanical breakdown. The biggest disadvantage of solid state is the higher cost. Solid-state units cause the turn indicator to flash rapidly if a bulb is burned out.

ELECTRONIC FLASHER REPLACEMENT UNITS Older vehicles (and a few newer ones) use thermal (bimetal) flashers that use heat to switch on and off. Most turn signal flasher units are mounted in a metal clip that is attached to the dash. The dash panel acts as a sounding board, increasing the sound of the flasher unit.

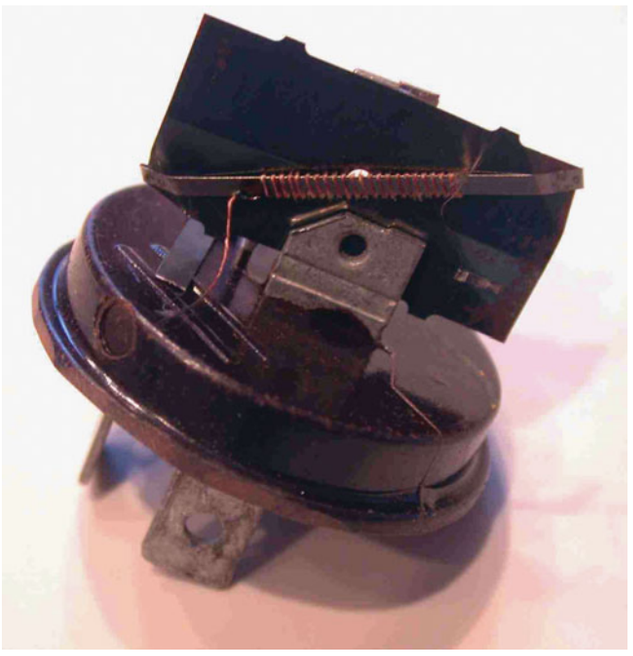

FIGURE 56–13 A hazard warning flasher uses a parallel resistor across the contacts to provide a constant flashing rate regardless of the number of bulbs used in the circuit.

Most four-way hazard flasher units are plugged into the fuse panel. Some turn signal flasher units are plugged into the fuse panel. How do you know for sure where the flasher unit is located? With both the turn signal and the ignition on, listen and/or feel for the clicking of the flasher unit. Some service manuals also give general locations for the placement of flasher units.

Newer vehicles have electronic flashers that use microchips to control the on/off function. Electronic flashers are compatible with older systems and are wise to use for the following reasons.

1. Electronic flashers do not burn out, and they provide a faster "flash" of the turn signals.
2. If upgrading to LED tail lamps, or lights, the LED bulbs only work with electronic flashers unless a resistor is added in the circuit.

HAZARD WARNING FLASHER The **hazard warning** flasher is a device installed in a vehicle lighting system with the primary function of causing both the left and right turn signal lamps to flash when the hazard warning switch is activated. Secondary functions may include visible dash indicators for the hazard system and an audible signal to indicate when the flasher is operating. A typical hazard warning flasher is also called a *parallel* or *variable-load* flasher because there is a resistor in parallel with the contacts to provide a control load and, therefore, a constant flash rate, regardless of the number of bulbs being flashed. ● **SEE FIGURE 56–13.**

COMBINATION TURN SIGNAL AND HAZARD WARNING FLASHER The combination flasher is a device that combines the functions of a turn signal flasher and a hazard warning flasher into one package, which often uses three electrical terminals.

HEADLIGHTS

HEADLIGHT SWITCHES The headlight switch operates the exterior and interior lights of most vehicles. On noncomputer-controlled lighting systems, the headlight switch is connected directly to the

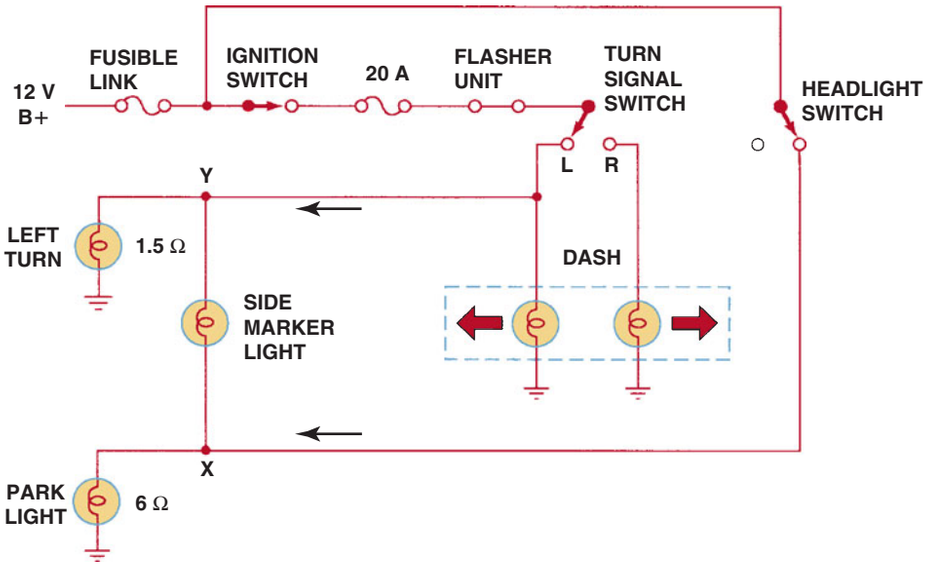

FIGURE 56–14 The side-marker light goes out whenever there is voltage at both points X and Y. These opposing voltages stop current flow through the side-marker light. The left turn light and left park light are actually the same bulb (usually 2057) and are shown separately to help explain how the side-marker light works on many vehicles.

FREQUENTLY ASKED QUESTION

How Do You Tell What Type of Flasher Is Being Used?

The easiest way to know which type of flasher can be used is to look at the type of bulb used in the tail lamps and turn signals. If it is a "wedge" style (plastic base, flat and rectangular), the vehicle has an electronic flasher. If it is a "twist and turn" bayonet-style (brass base) bulb, then either type of flasher can be used.

FREQUENTLY ASKED QUESTION

Why Does the Side-Marker Light Alternately Flash?

A question that service technicians are asked frequently is why the side-marker light alternately goes out when the turn signal is on, and is on when the turn signal is off. Some vehicle owners think that there is a fault with the vehicle, but this is normal operation. The side-marker light goes out when the lights are on and the turn signal is flashing because there are 12 volts on both sides of the bulb (see points X and Y in ● **FIGURE 56–14**).

Normally, the side-marker light gets its ground through the turn signal bulb.

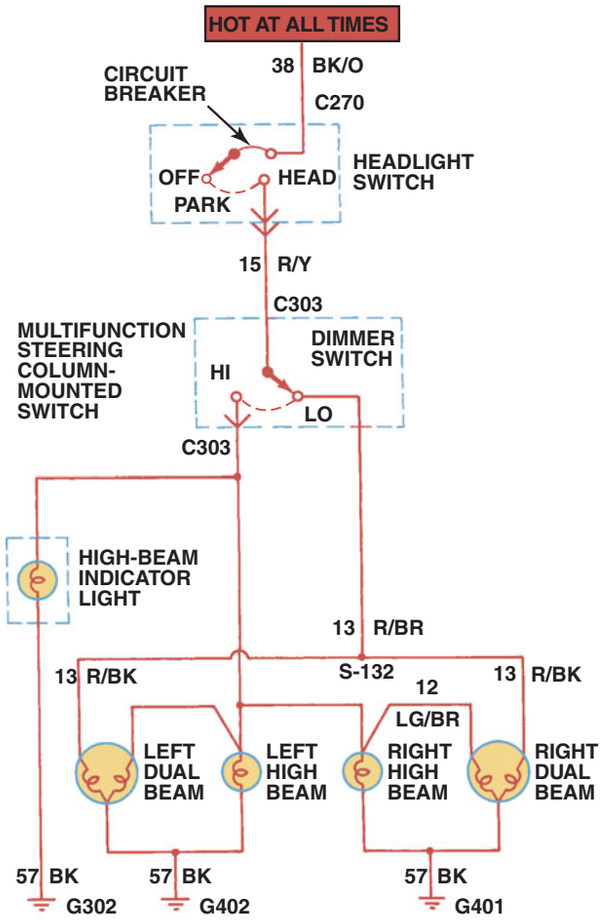

FIGURE 56–15 Typical headlight circuit diagram. Note that the headlight switch is represented by a dotted outline indicating that other circuits (such as dash lights) also operate from the switch.

battery through a fusible link, and has continuous power or is "hot" all the time. A circuit breaker is built into most older model headlight switches to protect the headlight circuit. ● **SEE FIGURE 56–15.**

The headlight switch may include the following:

- The interior dash lights can often be dimmed manually by rotating the headlight switch knob or by another rotary knob that controls a variable resistor (called a **rheostat**). The rheostat drops the voltage sent to the dash lights. Whenever there is a voltage drop (increased resistance), there is heat. A coiled resistance wire is built into a ceramic housing that is designed to insulate the rest of the switch from the heat and allow heat to escape.
- The headlight switch also contains a built-in circuit breaker that will rapidly turn the headlights on and off in the event of a short circuit. This prevents a total loss of headlights. If the headlights are rapidly flashing on and off, check the entire headlight circuit for possible shorts. The circuit breaker controls only the headlights. The other lights controlled by the headlight switch (taillights, dash lights, and parking lights) are fused separately. Flashing headlights also may be caused by a failure in the built-in circuit breaker, requiring replacement of the switch assembly.

FIGURE 56–17 A typical composite headlamp assembly. The lens, housing, and bulb sockets are usually included as a complete assembly.

FIGURE 56–18 Handle a halogen bulb by the base to prevent the skin's oil from getting on the glass.

AUTOMATIC HEADLIGHTS

Computer-controlled lights use a light sensor that signals when to have the computer turn on the headlights. The sensor is mounted on the dashboard or mirror. Often these systems have a driver-adjusted sensitivity control that allows for the lights to be turned on at various levels of light. Most systems also have a computer module control over the time that the lights remain on after the ignition has been turned off and the last door has been closed. A scan tool is often needed to change this time delay.

SEALED BEAM HEADLIGHTS

A sealed beam headlight consists of a sealed glass or plastic assembly containing the bulb, reflective surface, and prism lenses to properly focus the light beam. Low-beam headlights contain two filaments and three electrical terminals.

- One for low beam
- One for high beam
- Common ground

High-beam headlights contain only one filament and two terminals. Because low-beam headlights also contain a high-beam filament, the entire headlight assembly must be replaced if either filament is defective. ● **SEE FIGURE 56–16.**

A sealed beam headlight can be tested with an ohmmeter. A good bulb should indicate low ohms between the ground terminal and both power-side (hot) terminals. If either the high-beam or the low-beam filament is burned out, the ohmmeter will indicate infinity (OL).

HALOGEN SEALED BEAM HEADLIGHTS

Halogen sealed beam headlights are brighter and more expensive than normal headlights. Because of their extra brightness, it is common practice to have only two headlights on at any one time, because the candlepower output would exceed the maximum U.S. federal standards if all four halogen headlights were on. Therefore, before trying to repair the problem that only two of the four lamps are on, check the owner or shop manual for proper operation.

CAUTION: Do not attempt to wire all headlights together. The extra current flow could overheat the wiring from the headlight switch through the dimmer switch and to the headlights. The overloaded circuit could cause a fire.

COMPOSITE HEADLIGHTS

Composite headlights are constructed using a replaceable bulb and a fixed lens cover that is part of the vehicle. Composite headlights are the result of changes in the aerodynamic styling of vehicles where sealed beam lamps could no longer be used. ● **SEE FIGURE 56–17.**

TECH TIP

Diagnose Bulb Failure

Halogen bulbs can fail for various reasons. Some causes for halogen bulb failure and their indications are as follows:

- **Gray color.** Low voltage to bulb (check for corroded socket or connector)
- **White (cloudy) color.** Indication of an air leak
- **Broken filament.** Usually caused by excessive vibration
- **Blistered glass.** Indication that someone has touched the glass

NOTE: *Never touch the glass (called the ampoule) of any halogen bulb.* The oils from your fingers can cause unequal heating of the glass during operation, leading to a shorter-than-normal service life. ● **SEE FIGURE 56–18.**

The replaceable bulbs are usually bright halogen bulbs. Halogen bulbs get very hot during operation, between 500°F and 1,300°F (260°C and 700°C). It is important never to touch the glass of any halogen bulb with bare fingers because the natural oils of the skin on the glass bulb can cause the bulb to break when it heats during normal operation.

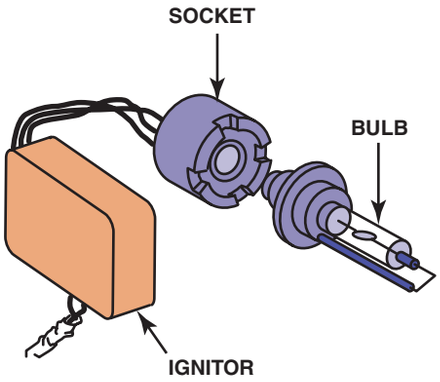

FIGURE 56–19 The igniter contains the ballast and transformer needed to provide high-voltage pulses to the arc tube bulb.

FREQUENTLY ASKED QUESTION

What Is the Difference Between the Temperature of the Light and the Brightness of the Light?

The temperature of the light indicates the color of the light. The brightness of the light is measured in lumens. A standard 100 watt incandescent light bulb emits about 1,700 lumens. A typical halogen headlight bulb produces about 2,000 lumens, and a typical HID bulb produces about 2,800 lumens.

HIGH-INTENSITY DISCHARGE HEADLIGHTS

PARTS AND OPERATION **High-intensity discharge (HID)** headlights produce a distinctive blue-white light that is crisper, clearer, and brighter than light produced by a halogen headlight.

High-intensity discharge lamps do not use a filament like conventional electrical bulbs, but contain two electrodes about 0.2 in. (5 mm) apart. A high-voltage pulse is sent to the bulb which arcs across the tips of electrodes producing light.

It creates light from an electrical discharge between two electrodes in a gas-filled arc tube. It produces twice the light with less electrical input than conventional halogen bulbs.

The HID lighting system consists of the discharge arc source, igniter, ballast, and headlight assembly. ● **SEE FIGURE 56–19.**

The two electrodes are contained in a tiny quartz capsule filled with xenon gas, mercury, and metal halide salts. HID headlights are also called **xenon headlights.** The lights and support electronics are expensive, but they should last the life of the vehicle unless physically damaged.

HID headlights produce a white light giving the lamp a blue-white color. The color of light is expressed in temperature using the Kelvin scale. **Kelvin (K)** temperature is the Celsius temperature plus 273 degrees. Typical color temperatures include:

- Daylight: 5,400°K
- HID: 4,100°K
- Halogen: 3,200°K
- Incandescent (tungsten): 2,800°K

● **SEE FIGURE 56–20.**

FIGURE 56–20 HID (xenon) headlights emit a whiter light than halogen headlights and usually look blue compared to halogen bulbs.

The HID ballast is powered by 12 volts from the headlight switch on the body control module. The HID headlights operate in three stages or states.

1. Start-up or stroke state
2. Run-up state
3. Steady state

START-UP OR STROKE STATE When the headlight switch is turned to the on position, the ballast may draw up to 20 amperes at 12 volts. The ballast sends multiple high-voltage pulses to the arc tube to start the arc inside the bulb. The voltage provided by the ballast during the start-up state ranges from −600 volts to +600 volts, which is increased by a transformer to about 25,000 volts. The increased voltage is used to create an arc between the electrodes in the bulb.

RUN-UP STATE After the arc is established, the ballast provides a higher than steady state voltage to the arc tube to keep the bulb illuminated. On a cold bulb, this state could last as long as 40 seconds. On a hot bulb, the run-up state may last only 15 seconds. The current requirements during the run-up state are about 360 volts from the ballast and a power level of about 75 watts.

STEADY STATE The steady state phase begins when the power requirement of the bulb drops to 35 watts. The ballast provides a minimum of 55 volts to the bulb during steady state operation.

BI-XENON HEADLIGHTS Some vehicles are equipped with bi-xenon headlights, which use a shutter to block some of the light during low-beam operation and then mechanically move to expose more of the light from the bulb for high-beam operation. Because xenon lights are relatively slow to start working, vehicles equipped with bi-xenon headlights use two halogen lights for the “flash-to-pass” feature.

FAILURE SYMPTOMS The following symptoms indicate bulb failure.

- A light flickers
- Lights go out (caused when the ballast assembly detects repeated bulb restrikes)
- Color changes to a dim pink glow

Bulb failures are often intermittent and difficult to repeat. However, bulb failure is likely if the symptoms get worse over time. Always follow the vehicle manufacturer’s recommended testing and service procedures.

DIAGNOSIS AND SERVICE High-intensity discharge headlights will change slightly in color with age. This **color shift** is usually not noticeable unless one headlight arc tube assembly has been replaced due to a collision repair, and then the difference in color may be noticeable. The difference in color will gradually change as

the arc tube ages and should not be too noticeable by most customers. If the arc tube assembly is near the end of its life, it may not light immediately if it is turned off and then back on immediately. This test is called a "hot restrike" and if it fails, a replacement arc tube assembly may be needed or there is another fault, such as a poor electrical connection, that should be checked.

WARNING

Always adhere to all warnings because the high-voltage output of the ballast assembly can cause personal injury or death.

LED HEADLIGHTS

Some vehicles, including several Lexus models, use LED headlights either as standard equipment (Lexus LS600h) or optional. ● **SEE FIGURE 56–21.**

Advantages include:

- Long service life
- Reduced electrical power required

Disadvantages include:

- High cost
- Many small LEDs required to create the necessary light output

HEADLIGHT AIMING

According to U.S. federal law, all headlights, regardless of shape, must be able to be aimed using headlight aiming equipment. Older vehicles equipped with sealed beam headlights used a headlight aiming system that attached to the headlight itself. ● **SEE FIGURES 56–22 AND 56–23**. Also see the photo sequence on headlight aiming at the end of the chapter.

FIGURE 56–21 LED headlights usually require multiple units to provide the needed light as seen on this Lexus LS600h.

FIGURE 56–23 Many composite headlights have a built-in bubble level to make aiming easy and accurate.

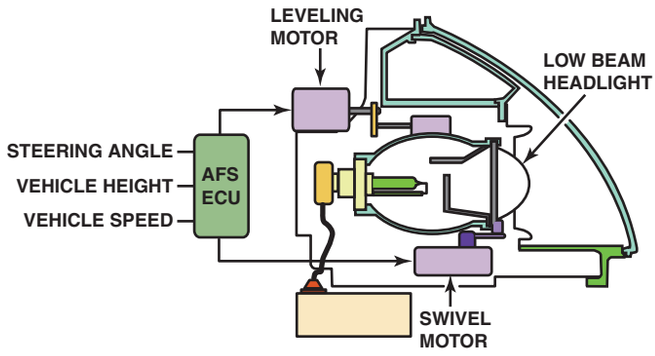

FIGURE 56–25 A typical adaptive front lighting system uses two motors: one for the up and down movement and the other for rotating the low-beam headlight to the left and right.

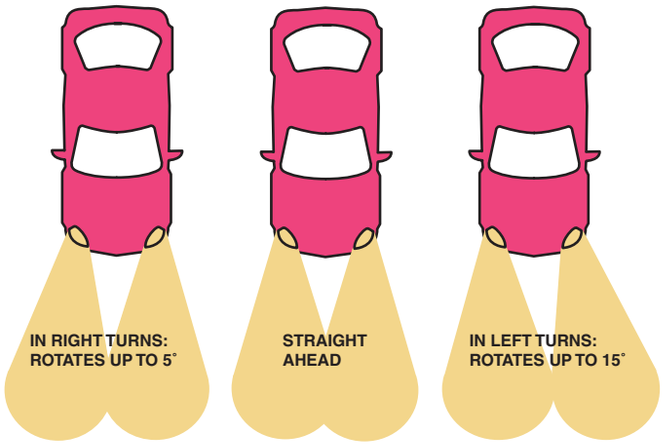

FIGURE 56–24 Adaptive front lighting systems rotate the low-beam headlight in the direction of travel.

FIGURE 56–26 Typical dash-mounted switch that allows the driver to disable the front lighting system.

ADAPTIVE FRONT LIGHTING SYSTEM

PARTS AND OPERATION A system that mechanically moves the headlights to follow the direction of the front wheels is called **adaptive** (or **advanced**) **front light system,** or **AFS.** The AFS provides a wide range of visibility during cornering. The headlights are usually capable of rotating 15 degrees to the left and 5 degrees to the right (some systems rotate 14 degrees and 9 degrees, respectively). Vehicles that use AFS include Lexus, Mercedes, and certain domestic models, usually as an extra cost option. ● **SEE FIGURE 56–24.**

NOTE: These angles are reversed on vehicles sold in countries that drive on the left side of the road, such as Great Britain, Japan, Australia, and New Zealand.

The vehicle has to be moving above a predetermined speed, usually above 20 mph (30 km/h) and the lights stop moving when the speed drops below about 3 mph (5 km/h).

AFS is often used in addition to self-leveling motors so that the headlights remain properly aimed regardless of how the vehicle is loaded. Without self-leveling, headlights would shine higher than normal if the rear of the vehicle is heavily loaded. ● **SEE FIGURE 56–25.**

When a vehicle is equipped with an adaptive front lighting system, the lights are moved by the headlight controller outward, and then inward as well as up and down as a test of the system. This action is quite noticeable to the driver, and is normal operation of the system.

DIAGNOSIS AND SERVICE The first step when diagnosing an AFS fault is to perform the following visual inspection.

- Start by checking that the AFS is switched on. Most AFS headlights are equipped with a switch that allows the driver to turn the system on and off. ● **SEE FIGURE 56–26.**
- Check that the system performs a self-test during start-up.
- Verify that both low-beam and high-beam lights function correctly. The system may be disabled if a fault with one of the headlights is detected.
- Use a scan tool to test for any AFS-related diagnostic trouble codes. Some systems allow the AFS to be checked and operated using a scan tool.

Always follow the recommended testing and service procedures as specified by the vehicle manufacturer in service information.

TECH TIP

Checking a Dome Light Can Be Confusing

If a technician checks a dome light with a test light, both sides of the bulb will "turn on the light" if the bulb is good. This will be true if the system's "ground switched" doors are closed and the bulb is good. This confuses many technicians because they do not realize that the ground will not be sensed unless the door is open.

DAYTIME RUNNING LIGHTS

PURPOSE AND FUNCTION **Daytime running lights (DRLs)** involve operation of the following:

- Front parking lights
- Separate DRL lamps
- Headlights (usually at reduced current and voltage) when the vehicle is running

Canada has required daytime running lights on all new vehicles since 1990. Studies have shown that DRLs have reduced accidents where used.

Daytime running lights primarily use a control module that turns on either the low or high-beam headlights or separate daytime running lights. The lights on some vehicles come on when the engine starts. Other vehicles will turn on the lamps when the engine is running but delay their operation until a signal from the vehicle speed sensor indicates that the vehicle is moving.

To avoid having the lights on during servicing, some systems will turn off the headlights when the parking brake is applied and the ignition switch is cycled off then back on. Others will only light the headlights when the vehicle is in a drive gear. ● **SEE FIGURE 56–27.**

CAUTION: Most factory daytime running lights operate the headlights at reduced intensity. These are *not* designed to be used at night. Normal intensity of the headlights (and operation of the other external lamps) is actuated by turning on the headlights as usual.

DIMMER SWITCHES

The headlight switch controls the power or hot side of the headlight circuit. The current is then sent to the dimmer switch, which allows current to flow to either the high-beam or the low-beam filament of the headlight bulb, as shown in ● **FIGURE 56–28.**

An indicator light illuminates on the dash when the high beams are selected.

The dimmer switch is usually hand operated by a lever on the steering column. Some steering column switches are actually attached to the *outside* of the steering column and are spring loaded. To replace these types of dimmer switches, the steering column needs to be lowered slightly to gain access to the switch itself.

COURTESY LIGHTS

Courtesy light is a generic term primarily used for interior lights, including overhead (dome) and under-the-dash (courtesy) lights. These interior lights are controlled by operating switches located in the doorjambs of the vehicle doors or by a switch on the dash. ● **SEE FIGURE 56–29.**

Many Ford vehicles use the door switches to open and close the power side of the circuit. Many newer vehicles operate the interior lights through the vehicle computer or through an electronic module. Because the exact wiring and operation of these units differ, consult the service information for the exact model of the vehicle being serviced.

ILLUMINATED ENTRY

Some vehicles are equipped with illuminated entry, meaning the interior lights are turned on for a given amount of time when the outside door handle is operated while the doors are locked. Most vehicles equipped with illuminated entry also light the exterior door keyhole. Vehicles equipped with body computers use the input from the key fob remote to "wake up" the power supply for the body computer.

FIBER OPTICS

Fiber optics is the transmission of light through special plastic (polymethyl methacrylate) that keeps the light rays parallel even if the plastic is tied in a knot. These strands of plastic are commonly used in automotive applications as indicators for the driver that certain lights are functioning. For example, some vehicles are equipped with fender-mounted units that light when the lights or turn signals are operating. Plastic fiber-optic strands, which often look like standard electrical wire, transmit the light at the bulb to the indicator on top of the fender so that the driver can determine if a certain light is operating. Fiber-optic strands also can be run like wires to indicate the operation of all lights on the dash or console. Fiber-optic strands are also commonly used to light ashtrays, outside door locks, and other areas where a small amount of light is required. The source of the light can be any normally operating light bulb, which means that one bulb can be used to illuminate many areas. A special bulb clip is normally used to retain the fiber-optic plastic tube near the bulb.

AUTOMATIC DIMMING MIRRORS

PARTS AND OPERATION Automatic dimming mirrors use electrochromic technology to dim the mirror in proportion to the amount of headlight glare from other vehicles at the rear. The electrochromic technology developed by Gentex Corporation uses a gel that changes with light between two pieces of glass. One piece of glass acts as a reflector and the other has a transparent (clear) electrically conductive coating. The inside rearview mirror also has

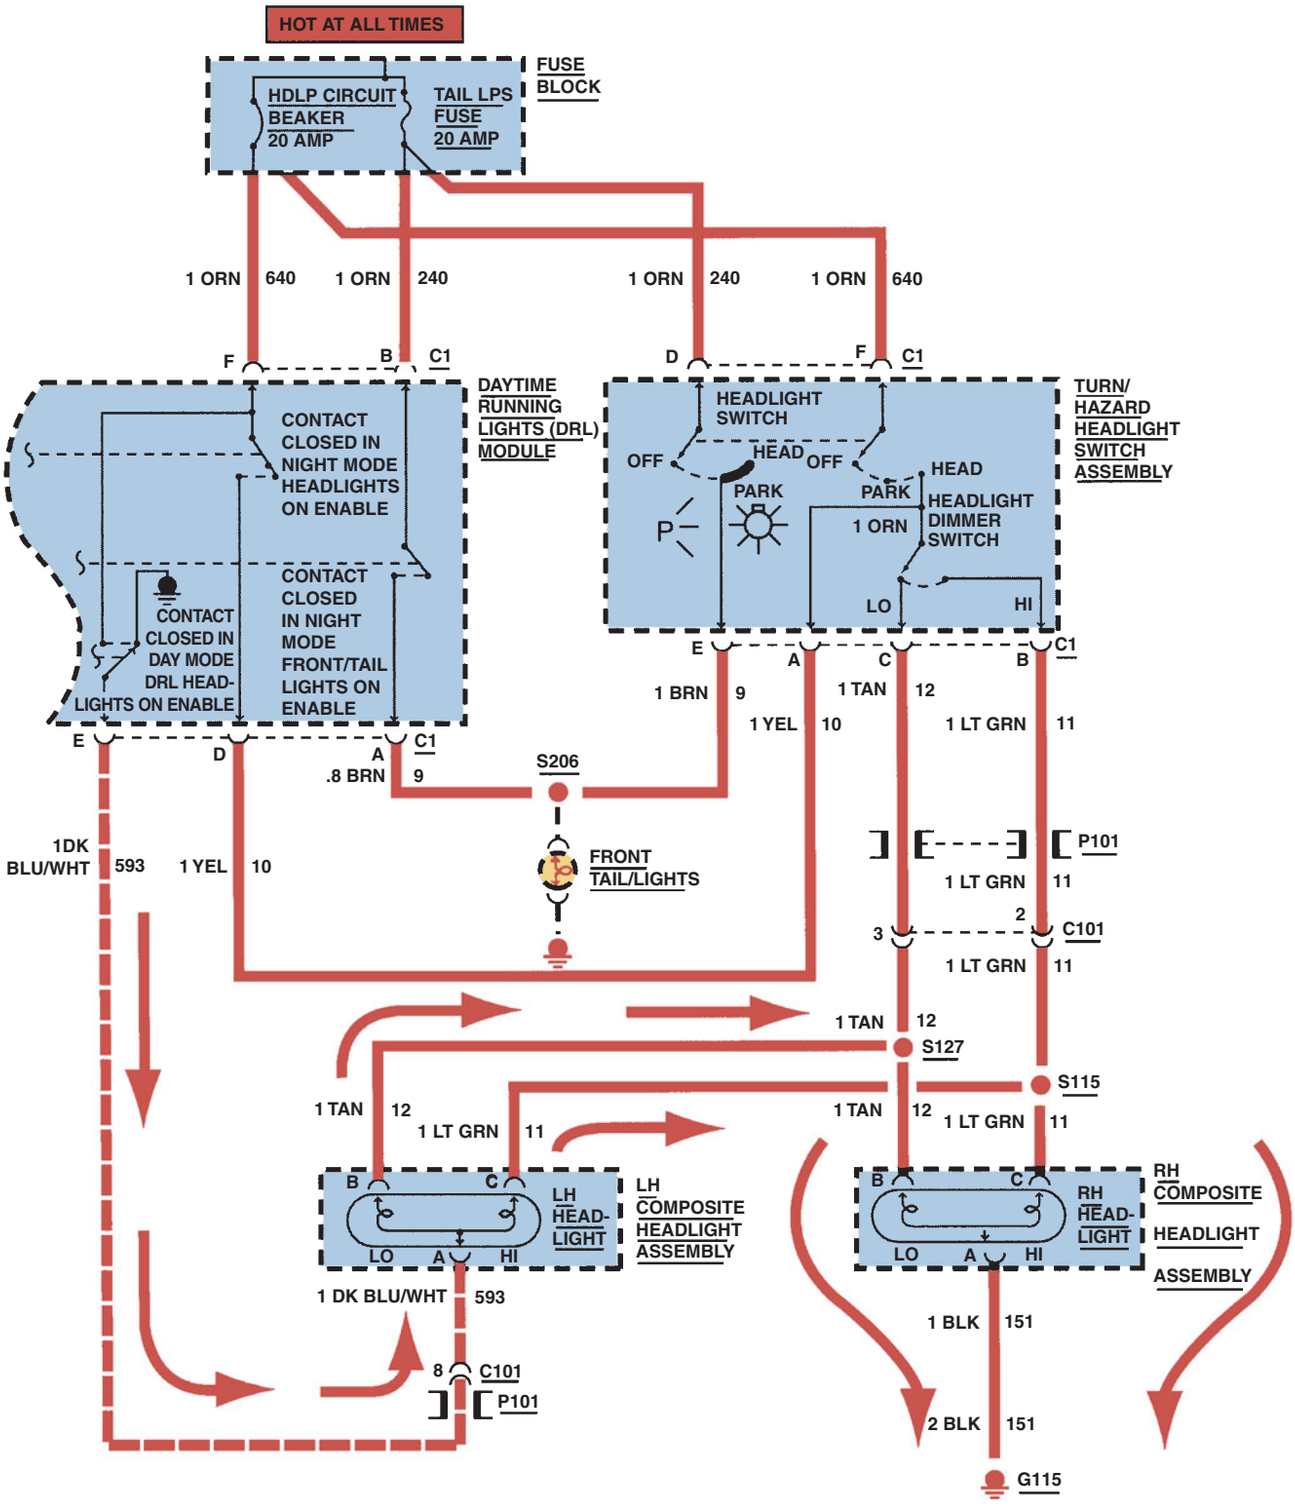

FIGURE 56–27 Typical daytime running light (DRL) circuit. Follow the arrows from the DRL module through both headlights. Notice that the left and right headlights are connected in series, resulting in increased resistance, less current flow, and dimmer than normal lighting. When the normal headlights are turned on, both headlights receive full battery voltage, with the left headlight grounding through the DRL module.

a forward-facing light sensor that is used to detect darkness and signal the rearward-facing sensor to begin to check for excessive glare from headlights behind the vehicle. The rearward-facing sensor sends a voltage to the electrochromic gel in the mirror that is in proportion to the amount of glare detected. The mirror dims in proportion to the glare and then becomes like a standard rearview mirror when the glare is no longer detected. If automatic dimming mirrors are used on the exterior, the sensors in the interior mirror and electronics are used to control both the interior and exterior mirrors. ● **SEE FIGURE 56–30.**

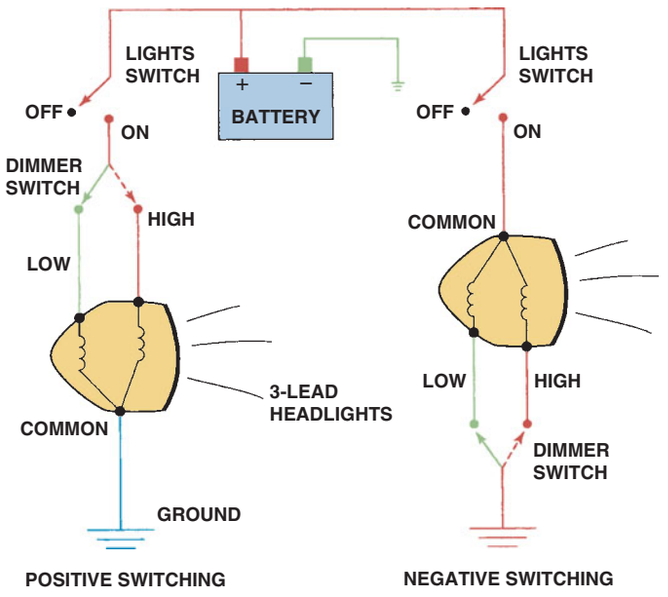

FIGURE 56–28 Most vehicles use positive switching of the high- and low-beam headlights. Notice that both filaments share the same ground connection. Some vehicles use negative switching and place the dimmer switch between the filaments and the ground.

FIGURE 56–29 A typical courtesy light doorjamb switch. Newer vehicles use the door switch as an input to the vehicle computer and the computer turns the interior lights on or off. By placing the lights under the control of the computer, the vehicle engineers have the opportunity to delay the lights after the door is closed and to shut them off after a period of time to avoid draining the battery.

DIAGNOSIS AND SERVICE

If a customer concern states that the mirrors do not dim when exposed to bright headlights from the vehicle behind, the cause could be sensors or the mirror itself. Be sure that the mirror is getting electrical power. Most automotive dimming mirrors have a green light to indicate the presence of electrical power. If no voltage is found at the mirror, follow standard troubleshooting procedures to find the cause. If the mirror is getting voltage, start the diagnosis by placing a strip of tape over the forward-facing light sensor. Turn the ignition key on, engine off (KOEO), and observe the operation of the mirror when a flashlight or trouble light is directed onto the mirror. If the mirror reacts and dims, the forward-facing sensor is defective. Most often, the entire mirror assembly has to be replaced if any sensor or mirror faults are found.

One typical fault with automatic dimming mirrors is a crack can occur in the mirror assembly, allowing the gel to escape from between the two layers of glass. This gel can drip onto the dash or center console and harm these surfaces. The mirror should be replaced at the first sign of any gel leakage.

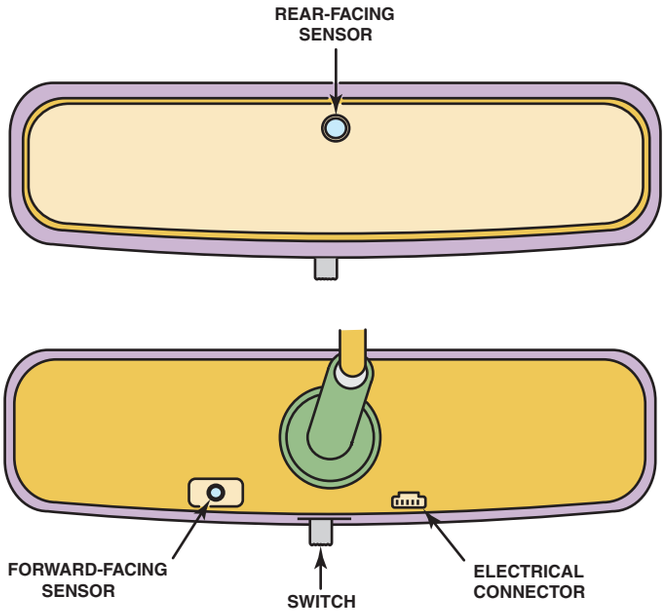

FIGURE 56–30 An automatic dimming mirror compares the amount of light toward the front of the vehicle to the rear of the vehicle and allies a voltage to cause the gel to darken the mirror.

FREQUENTLY ASKED QUESTION

What Is the Troxler Effect?

The **Troxler effect,** also called *Troxler fading,* is a visual effect where an image remains on the retina of the eye for a short time after the image has been removed. The effect was discovered in 1804 by Igney Paul Vital Troxler (1780–1866), a Swiss physician. Because of the Troxler effect, headlight glare can remain on the retina of the eye and create a blind spot. At night, this fading away of the bright lights from the vehicle in the rear reflected by the rearview mirror can cause a hazard.

TECH TIP

The Weirder the Problem, the More Likely It Is a Poor Ground Connection

Bad grounds are often the cause for feedback or lamps operating at full or partial brilliance. At first the problem looks weird because often the switch for the lights that are on dimly is not even turned on. When an electrical device is operating and it lacks a proper ground connection, the current will try to find ground and will often cause other circuits to work. Check all grounds before replacing parts.

FEEDBACK

DEFINITION When current that lacks a good ground goes backward along the power side of the circuit in search of a return path (ground) to the battery, this reverse flow is called **feedback,** or *reverse-bias* current flow. Feedback can cause other lights or gauges that should not be working to actually turn on.

FEEDBACK EXAMPLE A customer complained that when the headlights were on, the left turn signal indicator light on the dash remained on. The cause was found to be a poor ground connection for the left front parking light socket. The front parking light bulb is a dual filament: one filament for the parking light (dim) and one filament for the turn signal operation (bright). A corroded socket did not provide a good enough ground to conduct all current required to light the dim filament of the bulb.

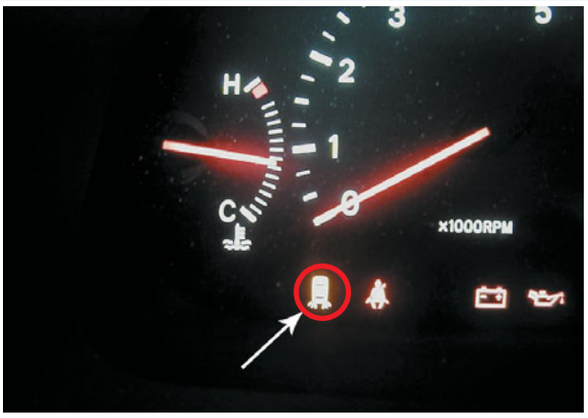
The two filaments of the bulb share the same ground connection and are electrically connected. When all the current could not flow through the bulb's ground in the socket, it caused a feedback or reversed its flow through the other filament, looking for ground. The turn signal filament is electrically connected to the dash indicator light; therefore, the reversed current on its path toward ground could light the turn signal indicator light. Cleaning or replacing the socket usually solves the problem if the ground wire for the socket is making a secure chassis ground connection.

LIGHTING SYSTEM DIAGNOSIS

Diagnosing any faults in the lighting and signaling systems usually includes the following steps.

STEP 1 Verify the customer concern.

STEP 2 Perform a visual inspection, checking for collision damage or other possible causes that would affect the operation of the lighting circuit.



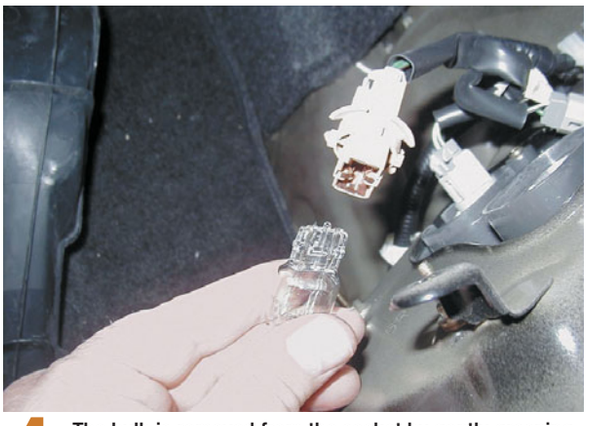
STEP 3 Connect a factory or enhanced scan tool with bidirectional control of the computer modules to check for proper operation of the affected lighting circuit.

STEP 4 Follow the diagnostic procedure as found in service information to determine the root cause of the problem.

LIGHTING SYSTEM SYMPTOM GUIDE

The following list will assist technicians in troubleshooting lighting systems.

Problem	Possible Causes and/or Solutions
One headlight dim	1. Poor ground connection on body 2. Corroded connector
One headlight out (low or high beam)	1. Burned out headlight filament (Check the headlight with an ohmmeter. There should be a low-ohm reading between the power-side connection and the ground terminal of the bulb.) 2. Open circuit (no 12 volts to the bulb)
Both high and low-beam headlights out	1. Burned out bulbs (Check for voltage at the wiring connector to the headlights for a possible open circuit to the headlights or open [defective] dimmer switch.) 2. Open circuit (no 12 volts to the bulb)
All headlights inoperative	1. Burned out filaments in all headlights (Check for excessive charging system voltage.) 2. Defective dimmer switch 3. Defective headlight switch
Slow turn signal operation	1. Defective flasher unit 2. High resistance in sockets or ground wire connections 3. Incorrect bulb numbers
Turn signals operating on one side only	1. Burned out bulb on affected side 2. Poor ground connection or defective socket on affected side 3. Incorrect bulb number on affected side 4. Defective turn signal switch
Interior light(s) inoperative	1. Burned out bulb(s) 2. Open in the power-side circuit (blown fuse) 3. Open in doorjamb switch(es)
Interior lights on all the time	1. Shorted doorjamb switch 2. Shorted control switch
Brake lights inoperative	1. Defective brake switch 2. Defective turn signal switch 3. Burned out brake light bulbs 4. Open circuit or poor ground connection 5. Blown fuse
Hazard warning lights inoperative	1. Defective hazard flasher unit 2. Open in hazard circuit 3. Blown fuse 4. Defective hazard switch
Hazard warning lights blinking too rapidly	1. Incorrect flasher unit 2. Shorted wiring to front or rear lights 3. Incorrect bulb numbers



1 The driver noticed that the taillight fault indicator (icon) on the dash was on any time the lights were on.

2 A visual inspection at the rear of the vehicle indicated that the right rear taillight bulb did not light. Removing a few screws from the plastic cover revealed the taillight assembly.

3 The bulb socket is removed from the taillight assembly by gently twisting the base of the bulb counterclockwise.

4 The bulb is removed from the socket by gently grasping the bulb and pulling the bulb straight out of the socket. Many bulbs required that you rotate the bulb 90° (1/4 turn) to release the retaining bulbs.

5 The new 7443 replacement bulb is being checked with an ohmmeter to be sure that it is okay before it is installed in the vehicle.

6 The replacement bulb in inserted into the taillight socket and the lights are turned on to verify proper operation before putting the components back together.

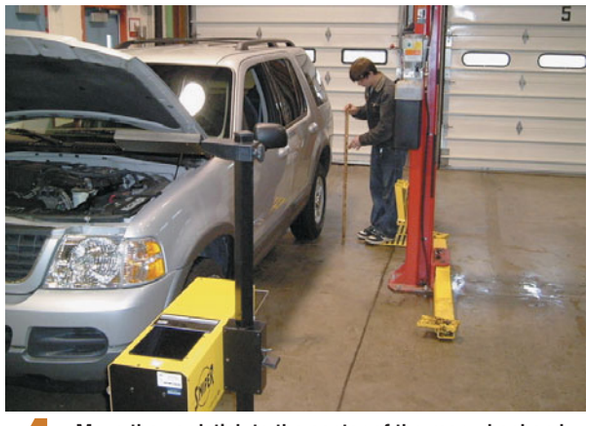
OPTICAL HEADLIGHT AIMING



1 Before checking the vehicle for headlight aim, be sure that all the tires are at the correct inflation pressure, and that the suspension is in good working condition.

2 The headlight aim equipment will have to be adjusted for the slope of the floor in the service bay. Start the process by turning on the laser light generator on the side of the aimer body.

3 Place a yardstick or measuring tape vertically in front of the center of the front wheel, noting the height of the laser beam.

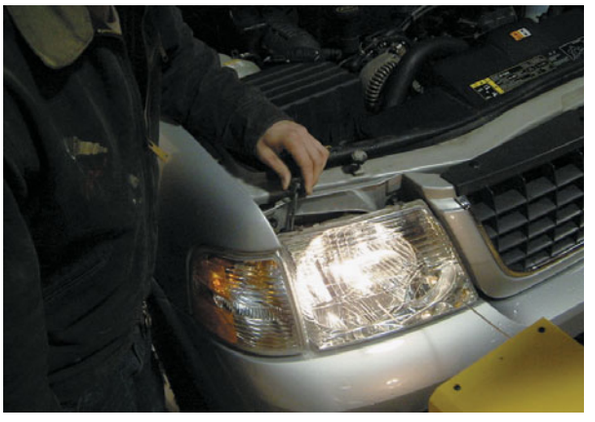
4 Move the yardstick to the center of the rear wheel and measure the height of the laser beam at this point. The height at the front and rear wheels should be the same.

5 If the laser beam height measurements are not the same, the floor slope of the aiming equipment must be adjusted. Turn the floor slope knob until the measurements are equal.

6 Place the aimer in front of the headlight to be checked, at a distance of 10 to 14 inches (25 to 35 cm). Use the aiming pointer to adjust the height of the aimer to the middle of the headlight.

7 Align the aimer horizontally, using the pointer to place the aimer at the center of the headlight.

8 Lateral alignment (aligning the body of the aimer with the body of the vehicle) is done by looking through the upper visor. The line in the upper visor is aligned with symmetrical points on the vehicle body.



9 Turn on the vehicle headlights, being sure to select the correct beam position for the headlight to be aimed.

10 View the light beam through the aimer window. The position of the light pattern will be different for high and low beams.

11 If the first headlight is aimed adequately, move the aimer to the headlight on the opposite side of the vehicle. Follow the previous steps to position the aimer accurately.

12 If adjustment is required, move the headlight adjusting screws using a special tool or a 1/4-in. drive ratchet/socket combination. Watch the light beam through the aimer window to verify the adjustment.

DASH WARNING SYMBOLS

PURPOSE AND FUNCTION All vehicles are equipped with warning lights that are often confusing to drivers. Because many vehicles are sold throughout the world, symbols instead of words are being used as warning lights. The dash warning lights are often called *telltale* lights as they are used to notify the driver of a situation or fault.

BULB TEST When the ignition is first turned on, all of the warning lights come on as part of a self-test and to help the driver or technician spot any warning light that may be burned out. Technicians or drivers who are familiar with what lights should light may be able to determine if one or more warning lights are not on when the ignition is first turned on. Most factory scan tools can be used to command all of the warning lights on to help determine if one is not working.

ENGINE FAULT WARNING Engine fault warning lights include the following:

- **Engine coolant temperature.** This warning lamp should come on when the ignition is first turned on as a bulb check and if the coolant temperature reaches 248°F to 258°F (120°C to 126°C), depending on the make and model of the vehicle. **SEE FIGURE 57–1.**

  If the engine coolant temperature warning lamp comes on while driving, perform the following in an attempt to reduce the temperature.

  1. Turn off the air conditioning.
  2. Turn on the heater.
  3. If the hot light remains on, drive to a safe location and shut off the engine and allow it to cool to help avoid serious engine damage.

- **Engine oil pressure.** This warning lamp should light when the ignition is first turned on as a bulb check; or if the engine oil pressure light comes on when driving, perform the following:

  1. Pull off the road as soon as possible.
  2. Shut off the engine.
  3. Check the oil level.
  4. Do not drive the vehicle with the engine oil light on or severe engine damage can occur.

  SEE FIGURE 57–2.

- **Water in diesel fuel warning.** This warning lamp will light when the ignition is first turned on as a bulb check and if water is detected in the diesel fuel. This lamp is only used or operational in vehicles equipped with a diesel engine. If the water in diesel fuel warning lamp comes on, do the following:

  1. Remove the water using the built-in drain, usually part of the fuel filter.
  2. Check service information for the exact procedure to follow.

  SEE FIGURE 57–3.

- **Maintenance required warning.** The maintenance required lamp comes on when the ignition is first turned on as a bulb check and if the vehicle requires service. The service required could include:

  1. Oil and oil filter change
  2. Tire rotation
  3. Inspection

FIGURE 57–1 Engine coolant temperature is too high.

FIGURE 57–2 Engine oil pressure too low.

FIGURE 57–3 Water detected in fuel. Notice to drain the water from the fuel filter assembly on a vehicle equipped with a diesel engine.

FIGURE 57–6 Charging system fault detected.

Check service information for the exact service required. ● **SEE FIGURE 57–4.**

- **Malfunction indicator lamp (MIL), also called a check engine or service engine soon (SES) light.** This warning lamp comes on when the ignition is first turned on as a bulb test and then only if a fault in the powertrain control module (PCM) has been detected. If the MIL comes on when driving, it is not necessary to stop the vehicle, but the cause for why the warning lamp came on should be determined as soon as possible to avoid harming the engine or engine control systems. The MIL could come on if any of the following has been detected.
  1. A sensor or actuator is electrically open or shorted.
  2. A sensor is out of range for expected values.
  3. An emission control system failure occurs, such as a loose gas cap.

  If the MIL is on, a diagnostic trouble code has been set. Use a scan tool to retrieve the code(s) and follow service information for the exact procedure to follow. ● **SEE FIGURE 57–5.**

ELECTRICAL SYSTEM–RELATED WARNING LIGHTS

- **Charging system fault.** This warning lamp will come on when the ignition is first turned on as a bulb check and if a fault in the charging system has been detected. The lamp could include a fault with any of the following:
  1. Battery state of charge (SOC), electrical connections, or the battery itself
  2. Alternator or related wiring

  ● **SEE FIGURE 57–6.**

  If the charge system warning lamp comes on, continue to drive until it is safe to pull over. The vehicle can usually be driven for several miles using battery power alone.

  Check the following by visible inspection.
  1. Alternator drive belt
  2. Loose or corroded electrical connections at the battery
  3. Loose or corroded wiring to the alternator
  4. Defective alternator

SAFETY-RELATED WARNING LAMPS

Safety-related warning lamps include the following:

- **Safety belt warning lamp.** The safety belt warning lamp will light and sound an alarm to notify the driver if the driver's side or passenger's side safety belt is not fastened. It is also used to indicate a fault in the safety belt circuit. Check service information for the exact procedure to follow if the safety belt warning light remains on even when the belts are fastened. ● **SEE FIGURE 57–7.**

FIGURE 57–8 Fault detected in the supplemental restraint (airbag) system.

FIGURE 57–9 Fault detected in base brake system.

FIGURE 57–10 Brake light bulb failure detected.

FIGURE 57–11 Exterior light bulb failure detected.

- **Airbag warning lamp.** The airbag warning lamp comes on and flashes when the ignition is first turned on as part of a self-test of the system. If the airbag warning lamp remains on after the self-test, then the airbag controller has detected a fault. Check service information for the exact procedure to follow if the airbag warning lamp is on. ● **SEE FIGURE 57–8.**

  NOTE: The passenger side airbag light may indicate that it is on or off, depending if there is a passenger or an object heavy enough to trigger the seat sensor.

- **Red brake fault warning light.** All vehicles are equipped with a red brake warning (RBW) lamp that lights if a fault in the base (hydraulic) brake system is detected. Three types of sensors are used to light this warning light.
  1. A brake fluid level sensor located in the master cylinder brake fluid reservoir
  2. A pressure switch located in the pressure differential switch, which detects a difference in pressure between the front and rear or diagonal brake systems
  3. The parking brake could be applied. ● **SEE FIGURE 57–9.**

  If the red brake warning light comes on, do not drive the vehicle until the cause is determined and corrected.
- **Brake light bulb failure.** Some vehicles are able to detect if a brake light is burned out. The warning lamp will warn the driver when a situation like this occurs. ● **SEE FIGURE 57–10.**
- **Exterior light bulb failure.** Many vehicles use the body control module (BCM) to monitor current flow through all of the exterior lights and therefore can detect if a bulb is not working. ● **SEE FIGURE 57–11.**

TECH TIP

Check the Spare

Some vehicles that are equipped with a full-size spare tire also have a sensor in the spare. If the warning lamp is on and all four tires are properly inflated, check the spare.

- **Worn brake pads.** Some vehicles are equipped with sensors built into the disc brake pads that are used to trigger a dash warning light. The warning light often comes on when the ignition is first turned on as a bulb check and then goes out. If the brake pad warning lamp is on, check service information for the exact service procedure to follow. ● **SEE FIGURE 57–12.**
- **Antilock brake system (ABS) fault.** The amber antilock brake system warning light comes on if the ABS controller detects a fault in the antilock braking system. Examples of what could trigger the warning light include:
  1. Defective wheel speed sensor
  2. Low brake fluid level in the hydraulic control unit assembly
  3. Electrical fault detected anywhere in the system

  ● **SEE FIGURE 57–13.**

  If the amber ABS warning lamp is on, it is safe to drive the vehicle, but the antilock portion may not function.
- **Low tire pressure warning.** A tire pressure monitoring system (TPMS) warns if the inflation pressure of a tire has decreased by 25% (about 8 psi). If the warning lamp or message of a low tire is displayed, check the tire pressures before driving. If the inflation pressure is low, repair or replace the tire. ● **SEE FIGURE 57–14.**

DRIVER INFORMATION SYSTEM

- **Door open or ajar warning light.** If a door is open or ajar, a warning light is used to notify the driver. Check and close all doors and tailgates before driving. ● **SEE FIGURE 57–15.**
- **Windshield washer fluid low.** A sensor in the windshield washer fluid reservoir is used to turn on the low washer fluid warning lamp. ● **SEE FIGURE 57–16.**

FIGURE 57–20 Vehicle stability control system either off or working if flashing.

FIGURE 57–21 Traction control system has been turned off.

- **Low fuel warning.** A low fuel indicator light is used to warn the driver that the fuel level is low. In most vehicles, the light comes on when there is between 1 and 3 gallons (3.8 and 11 liters) of fuel remaining. ● **SEE FIGURE 57–17.**
- **Headlights on light.** This dash indicator lights whenever the headlights are on. ● **SEE FIGURE 57–18.**

  NOTE: This light may or may not indicate that the headlights are on if the headlight switch is set to the automatic position.
- **Low traction detected.** On a vehicle equipped with a traction control system (TCS), a dash indicator light is flashed whenever the system is working to restore traction. If the low traction warning light is flashing, reduce the rate of acceleration to help the system restore traction of the drive wheels with the road surface. ● **SEE FIGURE 57–19.**
- **Electronic stability control.** If a vehicle is equipped with electronic stability control (ESC), also called vehicle stability control (VSC), the dash indicator lamp will flash if the system is trying to restore vehicle stability. ● **SEE FIGURE 57–20.**
- **Traction off.** If the traction control system (TCS) is turned off by the driver, an indicator lamp lights to help remind the driver that this system has been turned off and will not be able to restore traction when lost. The system reverts to on, when the ignition is turned off, and then back on as the traction off button is depressed. ● **SEE FIGURE 57–21.**

CRUISE

FIGURE 57–22 Indicates that the cruise control is on and able to maintain vehicle speed if set. Some vehicles use a symbol that looks like a small speedometer to indicate that the cruise control is on.

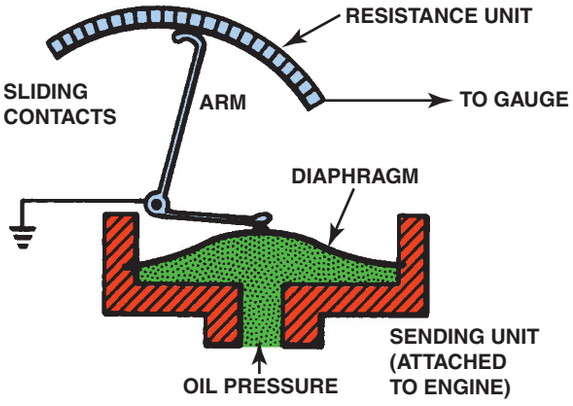

FIGURE 57–23 A typical oil pressure sending unit provides a varying amount of resistance as engine oil pressure changes. The output from the sensor is a variable voltage.

- **Cruise indicator lamp.** Most vehicles are equipped with a switch that turns on the cruise control. The cruise (speed) control system does not work unless it has been turned on to help prevent accidental engagement. When the cruise control has been turned on, the cruise indicator light is on. ● **SEE FIGURE 57–22.**

OIL PRESSURE WARNING DEVICES

OPERATION The oil pressure lamp operates through use of an oil pressure sensor unit, which is screwed into the engine block, and grounds the electrical circuit and lights the dash warning lamp in the event of low oil pressure, that is, 3 to 7 psi (20 to 50 kilopascals [kPa]). Normal oil pressure is generally between 10 and 60 psi (70 and 400 kPa). Some vehicles are equipped with a variable voltage oil pressure sensors rather than a simple pressure switch. ● **SEE FIGURE 57–23.**

OIL PRESSURE LAMP DIAGNOSIS To test the operation of the oil pressure warning circuit, unplug the wire from the oil pressure sending unit, usually located near the oil filter, with the ignition switch on. With the wire disconnected from the sending unit, the warning lamp should be off. If the wire is touched to a ground, the warning lamp should be on. If there is *any* doubt of the operation of the oil pressure warning lamp, always check the actual engine oil pressure using a gauge that can be screwed into the opening that is left after unscrewing the oil pressure sending unit. For removing the sending unit, special sockets are available at most auto parts stores, or a 1 in. or 1 1/16 in. 6-point socket may be used for most units.

TEMPERATURE LAMP DIAGNOSIS

The "hot" lamp, or engine coolant overheat warning lamp, warns the driver whenever the engine coolant temperature is between 248°F and 258°F (120°C and 126°C). This temperature is slightly below the boiling point of the coolant in a properly operating cooling system. The temperature sensor on older models was separate from the sensor used by the engine computer. However, most vehicles now use the engine coolant temperature (ECT) sensor for engine temperature gauge operation. To test this sensor, use a scan tool to verify proper engine temperature and follow the vehicle manufacturer's recommended testing procedures. ● **SEE FIGURE 57–24.**

FIGURE 57–24 A temperature gauge showing normal operating temperature between 180°F and 215°F, depending on the specific vehicle and engine.

REAL WORLD FIX

The Low Oil Pressure Story

After replacing valve cover gaskets on a Chevrolet V-8, the technician discovered that the oil pressure warning lamp was on. After checking the oil level and finding everything else okay, the technician discovered a wire pinched under the valve cover.

The wire went to the oil pressure sending unit. The edge of the valve cover had cut through the insulation and caused the current from the oil lamp to go to ground through the engine. Normally the oil lamp comes on when the sending unit grounds the wire from the lamp.

The technician freed the pinched wire and covered the cut with silicone sealant to prevent corrosion damage.

BRAKE WARNING LAMP

All vehicles sold in the United States after 1967 must be equipped with a dual braking system and a dash-mounted warning lamp to signal the driver of a failure in one part of the hydraulic brake system. The switch that operates the warning lamp is called a **pressure differential switch.** This switch is usually the center portion of a multipurpose brake part called a **combination valve.** If there is unequal hydraulic pressure in the braking system, the switch usually provides a ground path for the brake warning lamp, and the lamp comes on. ● **SEE FIGURE 57–25.**

Unfortunately, the dash warning lamp is often the same lamp as that used to warn the driver that the parking brake is on. The warning lamp is usually operated by using the parking brake lever

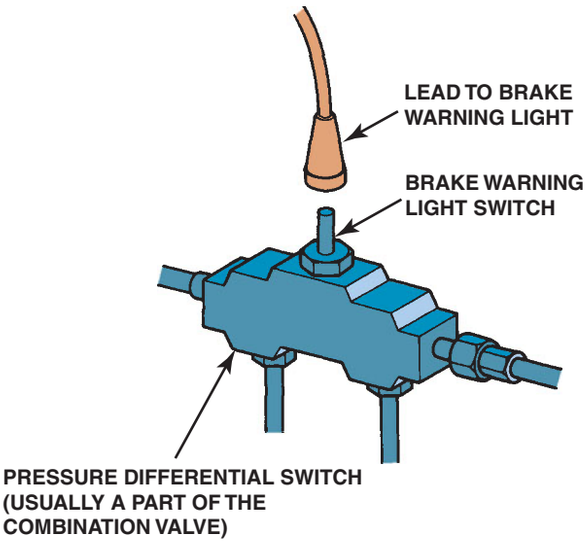

FIGURE 57–25 Typical brake warning light switch located on or near the master brake cylinder.

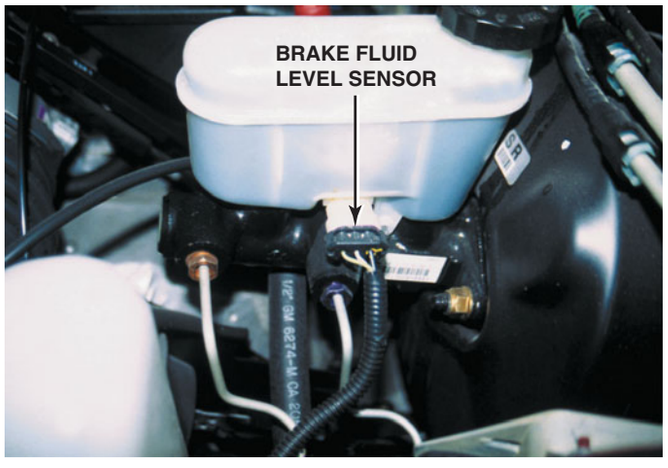

FIGURE 57–26 The red brake warning lamp can be turned on if the brake fluid level is low.

or brake hydraulic pressure switch to complete the ground for the warning lamp circuit. If the warning lamp is on, first check if the parking brake is fully released. If the parking brake is fully released, the problem could be a defective parking brake switch or a hydraulic brake problem. To test for which system is causing the lamp to remain on, simply unplug the wire from the valve or switch. If the wire on the pressure differential switch is disconnected and the warning lamp remains on, then the problem is due to a defective or misadjusted parking brake switch. If, however, the warning lamp goes out when the wire is removed from the brake switch, then the problem is due to a hydraulic brake fault that caused the pressure differential switch to complete the warning lamp circuit. The red brake warning lamp also can be turned on if the brake fluid is low. ● **SEE FIGURE 57–26** for an example of a brake fluid level sensor.

ANALOG DASH INSTRUMENTS

An analog display uses a needle to show the value, whereas a digital display uses numbers. Analog electromagnetic dash instruments use small electromagnetic coils that are connected to a sending unit for such things as fuel level, water temperature, and oil pressure. The sensors are the same regardless of the type of display used. The resistance of the sensor varies with what is being measured. ● **SEE FIGURE 57–27** for typical electromagnetic fuel gauge operation.

NETWORK COMMUNICATION

DESCRIPTION Many instrument panels are operated by electronic control units that communicate with the engine control computer for engine data such as revolutions per minute (rpm) and engine temperature. These electronic **instrument panels (IPs)** use the voltage changes from variable-resistance sensors, such as that of the fuel gauge, to determine fuel level. Therefore, even though the sensor in the fuel tank is the same, the display itself may be computer controlled. The data is transmitted to the instrument cluster as well as to the powertrain control module through serial data lines. Because all sensor inputs are interconnected, the technician should always follow the factory recommended diagnostic procedures. ● **SEE FIGURE 57–28.**

STEPPER MOTOR ANALOG GAUGES

DESCRIPTION Most analog dash displays use a stepper motor to move the needle. A **stepper motor** is a type of electric motor that is designed to rotate in small steps based on the signal from a computer. This type of gauge is very accurate.

OPERATION A digital output is used to control stepper motors. Stepper motors are direct current motors that move in fixed steps or increments from de-energized (no voltage) to fully energized (full voltage). A stepper motor often has as many as 120 steps of motion. When using a stepper motor that is controlled by the PCM, it is very easy for the PCM to keep track of the stepper motor's position. By counting the number of steps that have been sent to the stepper motor, the PCM can determine its relative position. While the PCM does not actually receive a feedback signal from the stepper motor, it knows how many steps forward or backward the motor should have moved.

A typical stepper motor uses a permanent magnet and two electromagnets. Each of the two electromagnetic windings is controlled by the computer. The computer pulses the windings and changes the polarity of the windings to cause the armature of the stepper motor to rotate 90 degrees at a time. Each 90-degree pulse is recorded by the computer as a "count" or "step," which explains the name given to this type of motor. ● **SEE FIGURE 57–29.**

NOTE: Many electronic gauge clusters are checked at key on where the dash display needles will be commanded to 1/4, 1/2, 3/4, and full positions before returning to their normal readings. This self-test allows the service technician to check the operation of each individual gauge, even though replacing the entire instrument panel cluster is usually necessary to repair an inoperative gauge.

DIAGNOSIS The dash electronic circuits are often too complex to show on a wiring diagram. Instead, all related electronic circuits are simply indicated as a solid box with "electronic module" printed

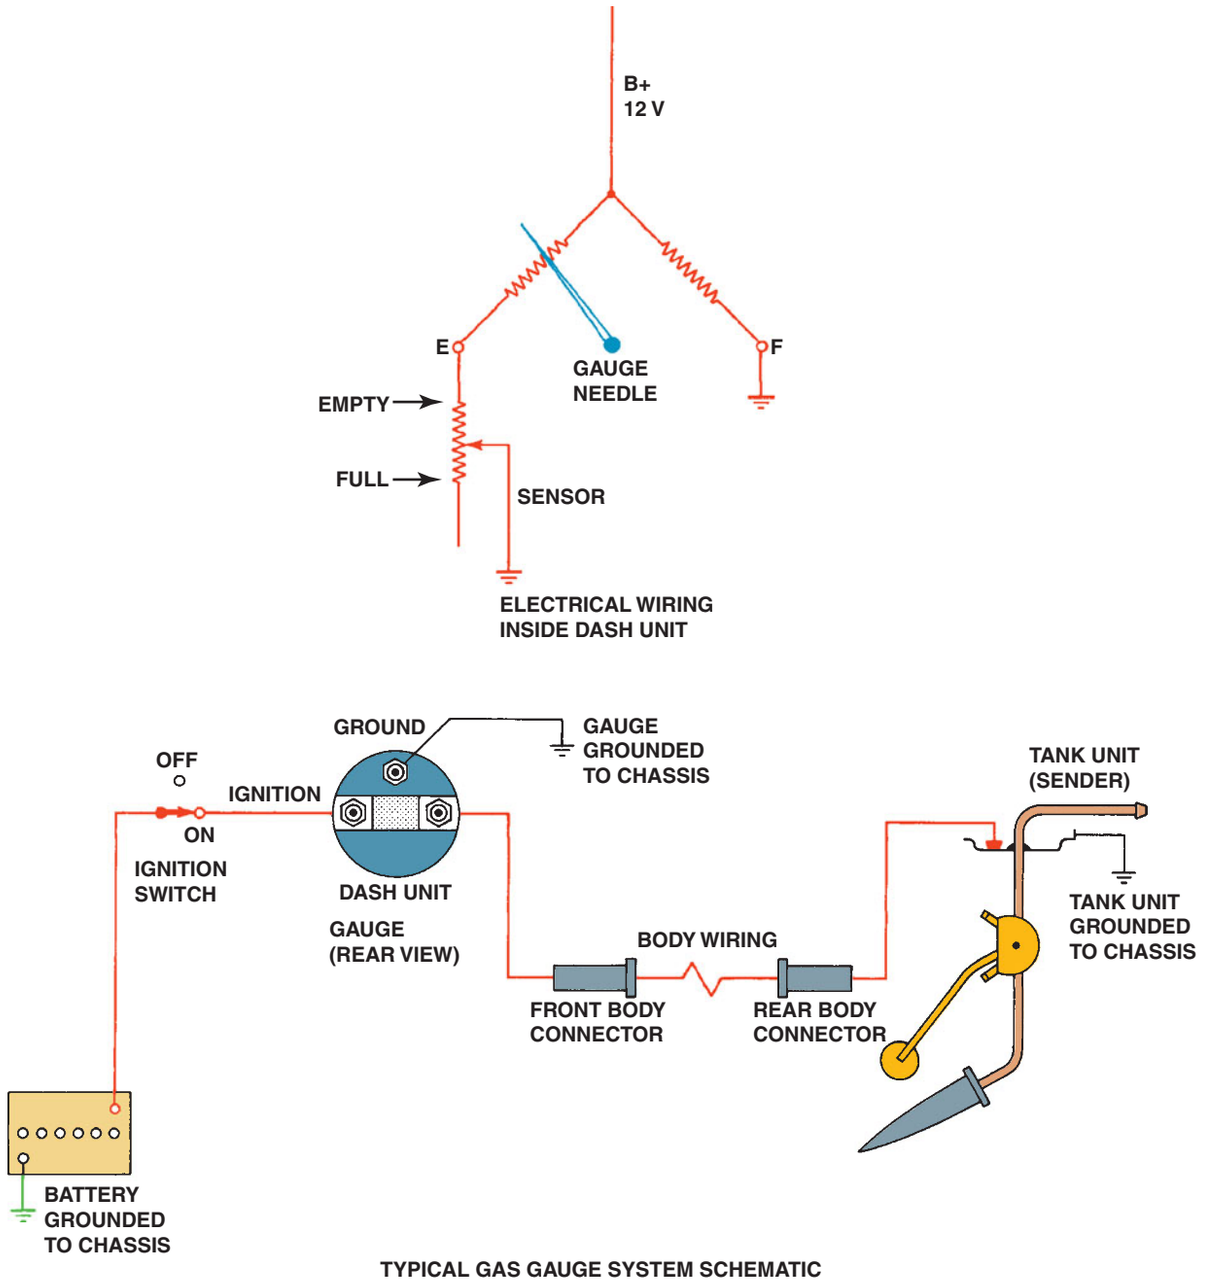

FIGURE 57–27 Electromagnetic fuel gauge wiring. If the sensor wire is unplugged and grounded, the needle should point to "E" (empty). If the sensor wire is unplugged and held away from ground, the needle should point to "F" (full).

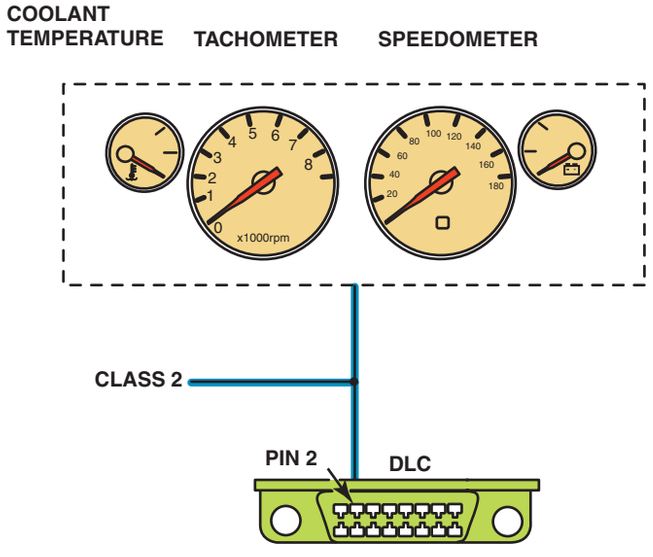

FIGURE 57–28 A typical instrument display uses data from the sensors over serial data lines to the individual gauges.

on the diagram. Even if all the electronic circuits were shown on the wiring diagram, it would require the skill of an electronics engineer to determine exactly how the circuit was designed to work. ● **SEE FIGURE 57–30.**

Note that the grounding for the "check oil" dash indicator lamp is accomplished through an electronic buffer. The exact conditions, such as amount of time since the ignition was shut off, are unknown to the technician. To correctly diagnose problems with this type of circuit, technicians must read, understand, and follow the written diagnostic procedures specified by the vehicle manufacturer.

HEAD-UP DISPLAY

The **head-up display (HUD)** is a supplemental display that projects the vehicle speed and sometimes other data, such as turn signal information, onto the windshield. The projected image looks as if it

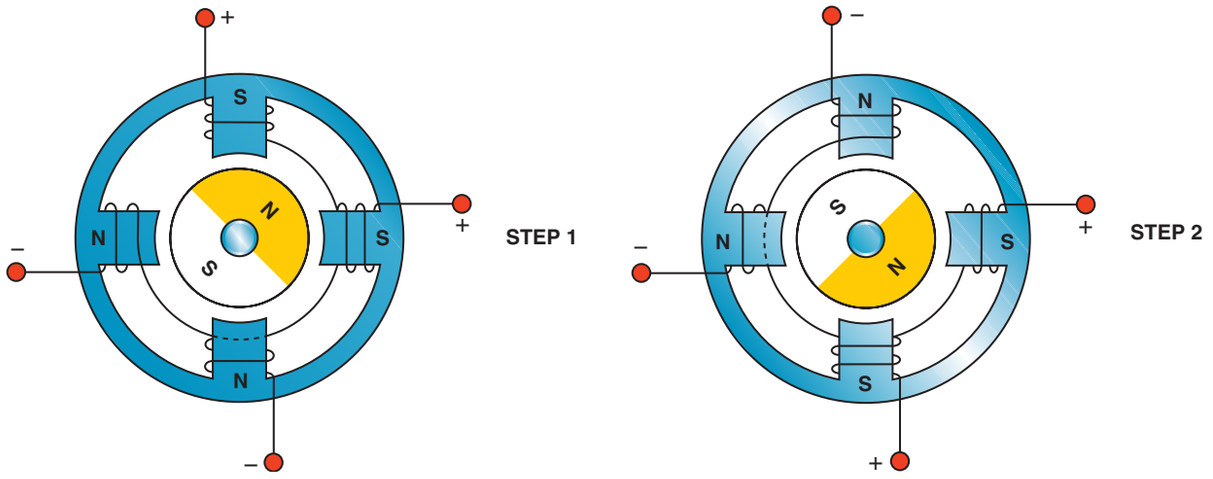

FIGURE 57–29 Most stepper motors use four wires which are pulsed by the computer to rotate the armature in steps.

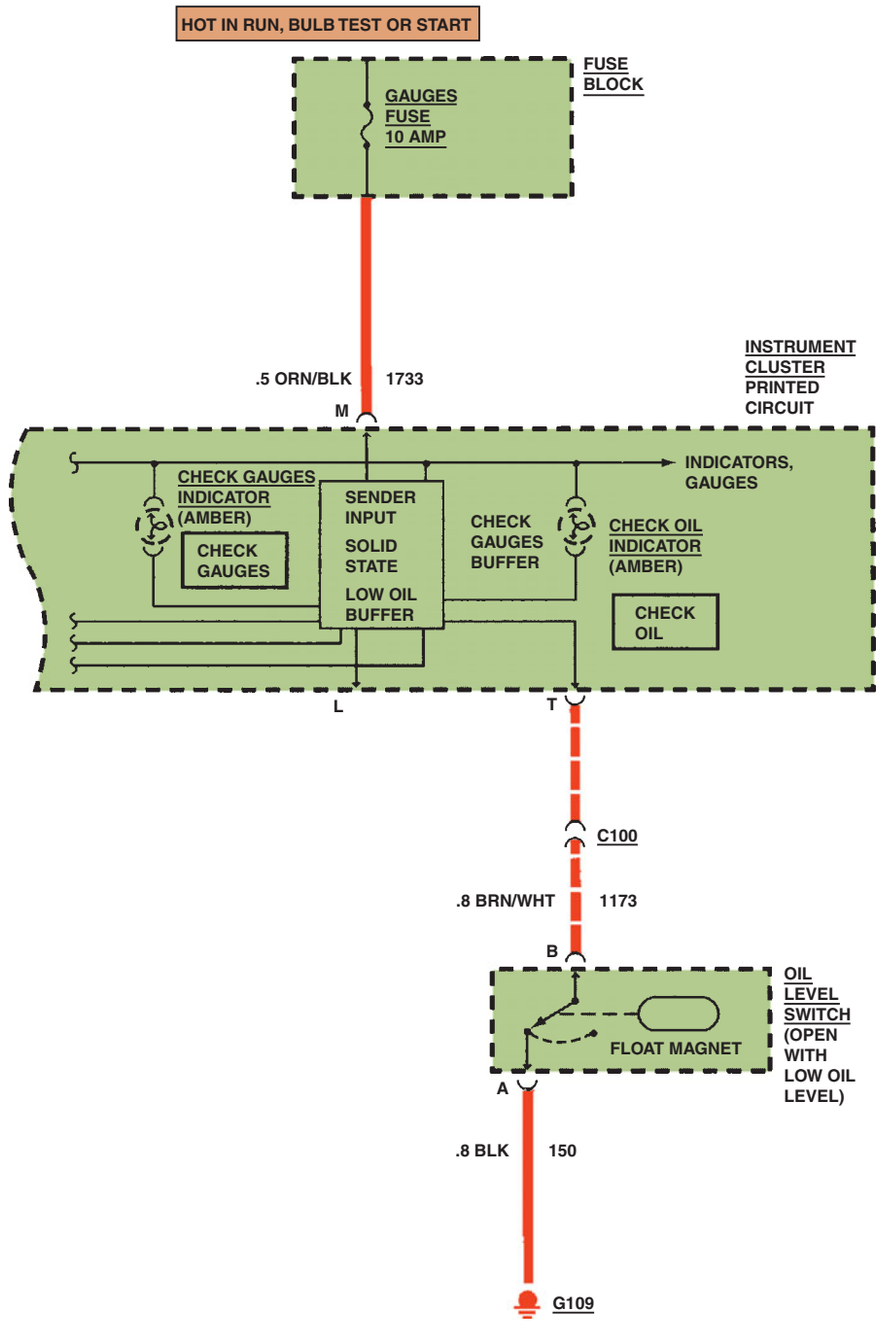

FIGURE 57–30 The ground for the "check oil" indicator lamp is controlled by the electronic low-oil buffer. Even though this buffer is connected to an oil level sensor, the buffer also takes into consideration the amount of time the engine has been stopped and the temperature of the engine. The only way to properly diagnose a problem with this circuit is to use the procedures specified by the vehicle manufacturer. Besides, only the engineer who designed the circuit knows for sure how it is supposed to work.

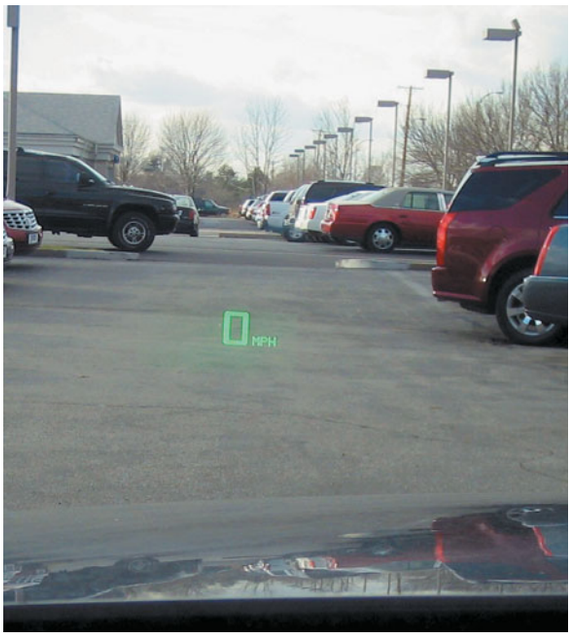

FIGURE 57–31 A typical head-up display showing zero miles per hour, which is actually projected on the windshield from the head-up display in the dash.

FIGURE 57–32 The dash-mounted control for the head-up display on this Cadillac allows the driver to move the image up and down on the windshield for best viewing.

is some distance ahead, making it easy for the driver to see without having to refocus on a closer dash display. ● **SEE FIGURES 57–31 AND 57–32.**

The head-up display can also have the brightness controlled on most vehicles that use this type of display. The HUD unit is installed in the instrument panel (IP) and uses a mirror to project vehicle information onto the inside surface of the windshield. ● **SEE FIGURE 57–33.**

Follow the vehicle manufacturer's recommended diagnostic and testing procedures if any faults are found with the head-up display.

NIGHT VISION

PARTS AND OPERATION Night vision systems use a camera that is capable of observing objects in the dark to assist the driver while driving at night. The primary night viewing illumination devices

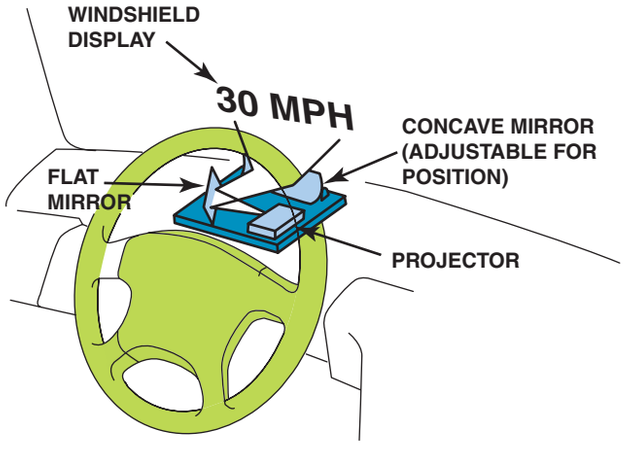

FIGURE 57–33 A typical head-up display (HUD) unit.

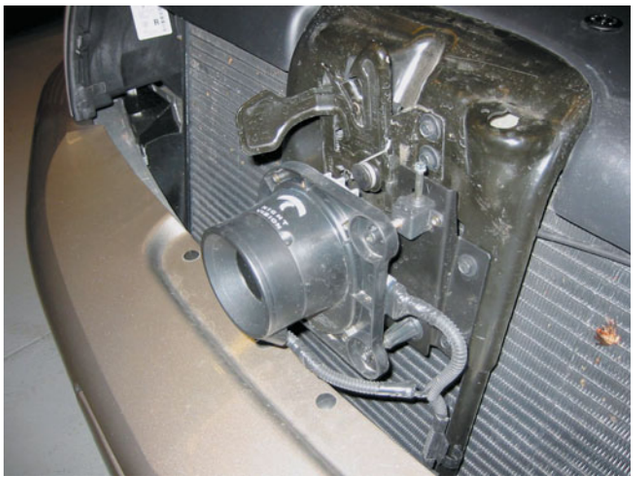

FIGURE 57–34 A night vision camera behind the grille of a Cadillac.

are the headlights. The night vision option uses a head-up display (HUD) to improve the vision of the driver beyond the scope of the headlights. Using a HUD display allows the driver to keep eyes on the road and hands on the wheel for maximum safety.

Besides the head-up display, the night vision camera uses a special thermal imaging or infrared technology. The camera is mounted behind the grille in the front of the vehicle. ● **SEE FIGURE 57–34.**

The camera creates pictures based on the heat energy emitted by objects rather than from light reflected on an object as in a normal optical camera. The image looks like a black and white photo negative when hot objects (higher thermal energy) appear light or white, and cool objects appear dark or black. Other parts of the night vision system include:

- **On/off and dimming switch.** This allows the driver to adjust the brightness of the display and to turn it on or off as needed.
- **Up/down switch.** The night vision HUD system has an electric tilt adjust motor that allows the driver to adjust the image up or down on the windshield within a certain image.

CAUTION: Becoming accustomed to night vision can be difficult and may take several nights to get used to looking at the head-up display.

DIAGNOSIS AND SERVICE The first step when diagnosing a fault with the night vision system is to verify the concern. Check the owner manual or service information for proper operation. For

example, the Cadillac night vision system requires the following actions to function.

1. The ignition has to be in the on (run) position.
2. The Twilight Sentinel photo cell must indicate that it is dark.
3. The headlights must be on.
4. The switch for the night vision system must be on and the brightness adjusted so the image is properly displayed.

The night vision system uses a camera in the front of the vehicle that is protected from road debris by a grille. However, small stones or other debris can get past the grille and damage the lens of the camera. If the camera is damaged, it must be replaced as an assembly because no separate parts are available. Always follow the vehicle manufacturer's recommended testing and servicing procedures.

DIGITAL ELECTRONIC DISPLAY OPERATION

TYPES

- Mechanical or electromechanical dash instruments use cables, mechanical transducers, and sensors to operate a particular dash instrument.
- Digital dash instruments use various electric and electronic sensors that activate segments or sections of an electronic display. Most electronic dash clusters use a computer chip and various electronic circuits to operate and control the internal power supply, sensor voltages, and display voltages.
- Electronic dash display systems may use one or more of several types of displays: light-emitting diode (LED), liquid crystal display (LCD), vacuum tube fluorescent (VTF), and cathode ray tube (CRT).

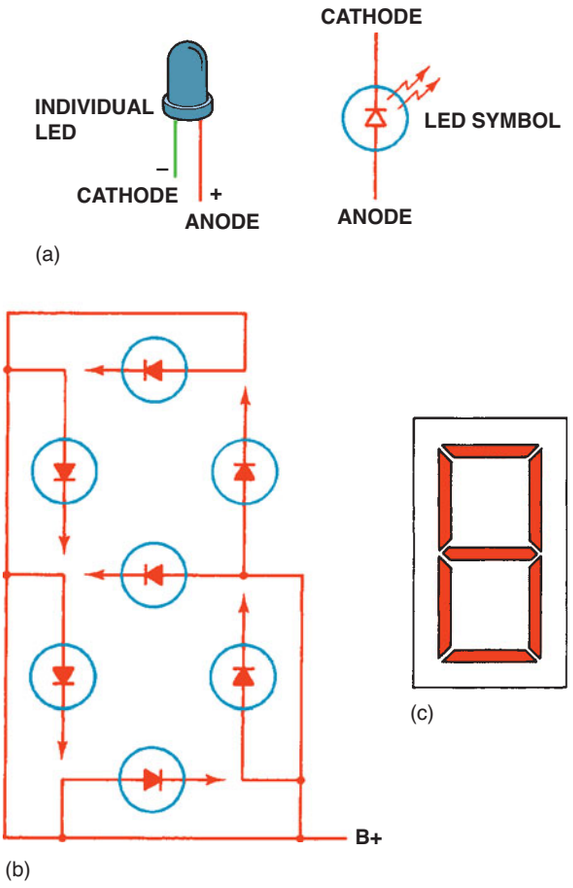

FIGURE 57–35 (a) Symbol and line drawing of a typical light-emitting diode (LED). (b) Grouped in seven segments, this array is called a seven-segment LED display with a common anode (positive connection). The dash computer toggles the cathode (negative) side of each individual segment to display numbers and letters. (c) When all segments are turned on, the number 8 is displayed.

LED DIGITAL DISPLAYS All diodes emit some form of energy during operation; the **light-emitting diode (LED)** is a semiconductor that is constructed to release energy in the form of light. Many colors of LEDs can be constructed, but the most popular are red, green, and yellow. Red is difficult to see in direct sunlight; therefore, if an LED is used, most vehicle manufacturers use yellow. Light-emitting diodes can be arranged in a group of seven, which then can be used to display both numbers and letters. ● **SEE FIGURE 57–35.**

An LED display requires more electrical power than other types of electronic displays. A typical LED display requires 30 mA for each *segment;* therefore, each number or letter displayed could require 210 mA (0.210 A).

LIQUID CRYSTAL DISPLAYS **Liquid crystal displays (LCDs)** can be arranged into a variety of forms, letters, numbers, and bar graph displays.

- LCD construction consists of a special fluid sandwiched between two sheets of polarized glass. The special fluid between the glass plates will permit light to pass if a small voltage is applied to the fluid through a conductive film laminated to the glass plates.
- The light from a very bright halogen bulb behind the LCD shines through those segments of the LCD that have been polarized to let the light through, which then show numbers or letters. Color filters can be placed in front of the display to change the color of certain segments of the display, such as the maximum engine speed on a digital tachometer.

CAUTION: Be careful, when cleaning an LCD, not to push on the glass plate covering the special fluid. If excessive pressure is exerted on the glass, the display may be permanently distorted. If the glass breaks, the fluid will escape and could damage other components in the vehicle as a result of its strong alkaline nature. Use only a soft, damp cloth to clean these displays.

- The major disadvantage of an LCD digital dash is that the numbers or letters are slow to react or change at low temperatures. ● **SEE FIGURE 57–36.**

VACUUM TUBE FLUORESCENT DISPLAYS The **vacuum tube fluorescent (VTF)** display is a popular automotive and household appliance display because it is very bright and can easily be viewed in strong sunlight. The usual VTF display is green, but white is often used for home appliances.

- The VTF display generates its bright light in a manner similar to that of a TV screen, where a chemical-coated light-emitting element called a **phosphor** is hit with high-speed electrons.

FIGURE 57–36 A typical navigation system. This Honda/Acura system uses some of the climate control functions as well as the trip information on the display. This particular unit uses a DVD unit in the trunk along with a global positioning satellite (GPS) to display a map and your exact location for the entire country.

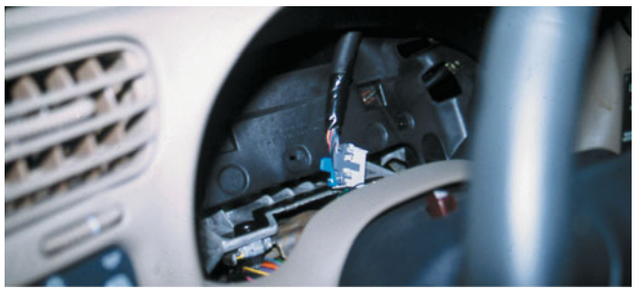
- VTF displays are very bright and must be dimmed by use of dense filters or by controlling the voltage applied to the display. A typical VTF dash is dimmed to 75% brightness whenever the parking lights or headlights are turned on. Some displays use a photocell to monitor and adjust the intensity of the display during daylight viewing. Most VTF displays are green for best viewing under most lighting conditions.

CATHODE RAY TUBE

A **cathode ray tube (CRT)** dash display, which is similar to a television tube or LCD display, permits the display of hundreds of controls and diagnostic messages in one convenient location.

Using the touch-sensitive cathode ray tube, the driver or technician can select from many different displays, including those of radio, climate, trip, and dash instrument information. The driver can readily access all of these functions. Further diagnostic information can be displayed on the CRT if the proper combination of air-conditioning controls is touched. The diagnostic procedures for these displays involve pushing two or more buttons at the same time to access the diagnostic menu. Always follow the factory service manual recommendations.

COLD CATHODE FLUORESCENT DISPLAYS



Cold **cathode fluorescent lighting (CFL)** models are used by many vehicle manufacturers for backlighting. Current consumption ranges from 3 to 5 mA (0.003 to 0.005 A) with an average life of 40,000 hours. CFL is replacing conventional incandescent light bulbs.

ELECTRONIC ANALOG DISPLAYS

Most analog dash displays since the early 1990s are electronically or computer controlled. The sensors may be the same, but the sensor information is sent to the body or vehicle computer through a data BUS, and then the computer controls current through small electromagnets that move the needle of the gauge. ● **SEE FIGURE 57–37.** A scan tool often is needed to diagnosis the operation of a computer-controlled analog dash instrument display.

WOW DISPLAY

When a vehicle equipped with a digital dash is started, all segments of the electronic display are turned on at full brilliance for 1 or 2 seconds. This is commonly called the **WOW display,** and is used to show off the brilliance of the display. If numbers are part of the display, the number 8 is shown, because this number uses all segments of a number display. Technicians can also use the WOW display to determine if all segments of the electronic display are functioning correctly.

(c) The rear view of the dash display showing that there are a few bulbs that can be serviced, but otherwise the unit is serviced as an assembly.

TECH TIP

The Bulb Test

Many ignition switches have six positions. Notice the *bulb test* position (between "on" and "start"). When the ignition is turned to "on" (run), some dash warning lamps are illuminated. When the bulb test position is reached, additional dash warning lamps often are lighted. Technicians use this ignition switch position to check the operation of fuses that protect various circuits. Dash warning lamps are not all powered by the same fuses. If an electrical component or circuit does not work, the power side (fuse) can be quickly checked by observing the operation of the dash lamps that have a common fuse with the problem circuit. Consult a wiring diagram for fuse information on the exact circuit being tested. ● **SEE FIGURES 57–38 AND 57–39.**

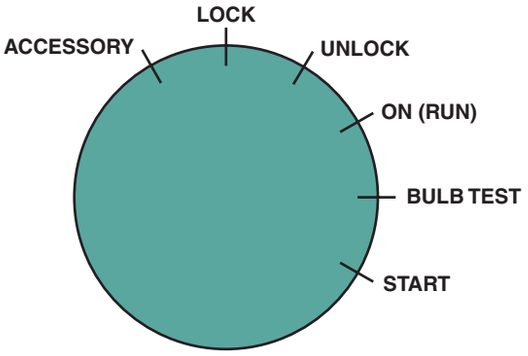

FIGURE 57–38 Typical ignition switch positions. Notice the bulb check position between "on" (run) and "start." These inputs are often just voltage signal to the body control module and can be checked using a scan tool.

FIGURE 57–39 Many newer vehicles place the ignition switch on the dash and incorporate antitheft controls. Note the location of the accessory position.

REAL WORLD FIX

The Speedometer Works as if It Is a Tachometer

The owner of a Lincoln Town Car complained that all of a sudden the speedometer needle went up and down with engine speed rather than vehicle speed. In fact, the speedometer needle went up and down with engine speed even though the gear selector was in "park" and the vehicle was not moving. After hours of troubleshooting, the service technician went back and started checking the basics and discovered that the alternator had a bad diode. The technician measured over 1 volt AC and over 10 amperes AC ripple current using a clamp-on AC/DC ammeter. Replacing the alternator restored the proper operation of the speedometer.

ELECTRONIC SPEEDOMETERS

OPERATION Electronic dash displays ordinarily use an electric vehicle speed sensor driven by a small gear on the output shaft of the transmission. These speed sensors contain a permanent magnet and generate a voltage in proportion to the vehicle speed. These speed sensors are commonly called **permanent magnet (PM) generators.** ● **SEE FIGURE 57–40.**

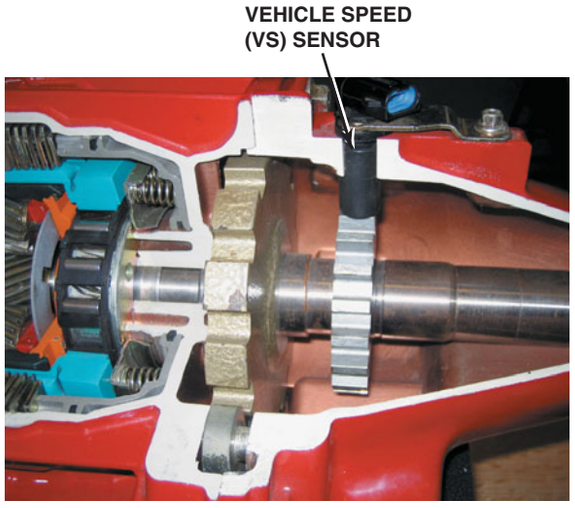

FIGURE 57–40 A vehicle speed sensor located in the extension housing of the transmission. Some vehicles use the wheel speed sensors for vehicle speed information.

TECH TIP

The Soldering Gun Trick

Diagnosing problems with digital or electronic dash instruments can be difficult. Replacement parts generally are expensive and usually not returnable if installed in the vehicle. A popular trick that helps isolate the problem is to use a soldering gun near the PM generator.

A PM generator contains a coil of wire. As the magnet inside revolves, a voltage is produced. It is the *frequency* of this voltage that the dash (or engine) computer uses to calculate vehicle speed.

A soldering gun plugged into 110 volts AC will provide a strong *varying* magnetic field around the soldering gun. This magnetic field is constantly changing at the rate of 60 cycles per second. This frequency of the magnetic field induces a voltage in the windings of the PM generator. This induced voltage at 60 hertz (Hz) is converted by the computer circuits to a miles per hour (mph) reading on the dash.

To test the electronic speedometer, turn the ignition to "on" (engine off) and hold a soldering gun near the PM generator.

CAUTION: The soldering gun tip can get hot, so hold it away from wiring or other components that may be damaged by the hot tip.

If the PM generator, wiring, computer, and dash are okay, the speedometer should register a speed, usually 54 mph (87 km/h). If the speedometer does not work when the vehicle is driven, the problem is in the PM generator drive.

If the speedometer does not register a speed when the soldering gun is used, the problem could be caused by the following:

1. Defective PM generator (check the windings with an ohmmeter)
2. Defective (open or shorted) wiring from the PM generator to the computer
3. Defective computer or dash circuit

REAL WORLD FIX

The Toyota Truck Story

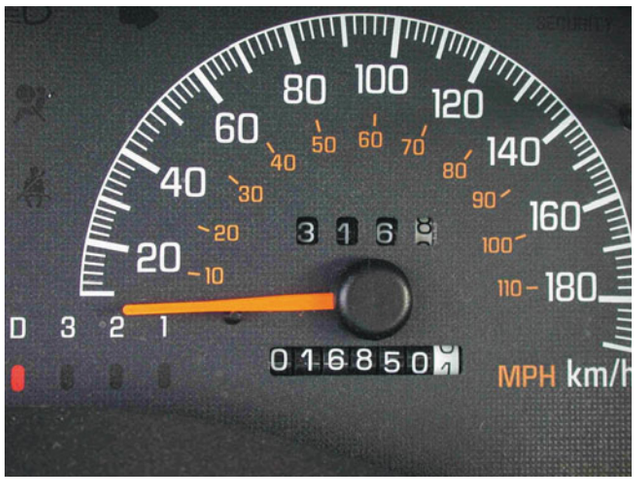
The owner of a Toyota truck complained that several electrical problems plagued the truck, including the following:

1. The cruise (speed) control would kick out intermittently.
2. The red brake warning lamp would come on, especially during cold weather.

The owner had replaced the parking brake switch, thinking that was the cause of the red brake warning lamp coming on.

An experienced technician checked the wiring diagram in service information. Checking the warning lamp circuit, the technician noticed that the same wire went to the brake fluid level sensor. The brake fluid was at the minimum level. Filling the master cylinder to the maximum level with clean brake fluid solved both problems. The electronics of the cruise control stopped operation when the red brake warning lamp was on as a safety measure.

REAL WORLD FIX



Look for Previous Repairs

A technician was asked to fix the speedometer on a Pontiac Grand Am that showed approximately double the actual speed. Previous repairs had included a new vehicle speed (VS) sensor and computer. Nothing made any difference. The customer stated that the problem happened all of a sudden. After hours of troubleshooting, the customer just happened to mention that the automatic transaxle had been repaired shortly before the speedometer problem. The root cause of the problem was discovered when the technician learned that a final drive assembly from a 4T60-E transaxle had been installed on the 3T-40 transaxle. The 4T60-E final drive assembly has 13 reluctor teeth whereas the 3T-40 has 7 teeth. This difference in the number of teeth caused the speedometer to read almost double the actual vehicle speed. After the correct part was installed, the speedometer worked correctly. The technician now always asks if there has been any recent work performed in the vehicle prior to any diagnosis.

The output of a PM generator speed sensor is an AC voltage that varies in frequency and amplitude with increasing vehicle speed. The PM generator speed signal is sent to the instrument cluster electronic circuits. These specialized electronic circuits include a buffer amplifier circuit that converts the variable sine wave voltage from the speed sensor to an on/off signal that can be used by other electronic circuits to indicate a vehicle's speed. The vehicle speed is then displayed by either an electronic needle-type speedometer or by numbers on a digital display.

ELECTRONIC ODOMETERS

PURPOSE AND FUNCTION An odometer is a dash display that indicates the total miles traveled by the vehicle. Some dash displays also include a trip odometer that can be reset and used to record total miles traveled on a trip or the distance traveled between fuel stops. Electronic dash displays can use either an electrically driven mechanical odometer or a digital display odometer to indicate miles traveled. On mechanical type odometers, a small electric motor, called a stepper motor, is used to turn the number wheels of a mechanical-style odometer. A pulsed voltage is fed to this stepper motor, which moves in relation to the miles traveled. ● **SEE FIGURE 57–41.**

(a)

(b)

FIGURE 57–41 (a) Some odometers are mechanical and are operated by a stepper motor. (b) Many vehicles are equipped with an electronic odometer.

REAL WORLD FIX

Electronic Devices Cannot Swim

The owner of a Dodge minivan complained that after the vehicle was cleaned inside and outside, the temperature gauge, fuel gauge, and speedometer stopped working. The vehicle speed sensor was checked and found to be supplying a square wave signal that changed with vehicle speed. A scan tool indicated a speed, yet the speedometer displayed zero all the time. Finally, the service technician checked the body computer to the right of the accelerator pedal and noticed that it had been wet, from the interior cleaning. Drying the computer did not fix the problem, but a replacement body computer fixed all the problems. The owner discovered that electronic devices do not like water and that computers cannot swim.

Digital odometers use LED, LCD, or VTF displays to indicate miles traveled. Because total miles must be retained when the ignition is turned off or the battery is disconnected, a special electronic chip must be used that will retain the miles traveled.

These special chips are called **nonvolatile random-access memory (NVRAM).** *Nonvolatile* means that the information stored in the electronic chip is not lost when electrical power is removed. Some vehicles use a chip called **electronically erasable programmable read-only memory (EEPROM).** Most digital odometers can read up to 999,999.9 miles or kilometers (km), and then the display indicates error. If the chip is damaged or exposed to static electricity, it may fail to operate and "error" may appear.

SPEEDOMETER/ODOMETER SERVICE If the speedometer and odometer fail to operate, check the following:

- The speed sensor should be the first item checked. With the vehicle safely raised off the ground and supported, check vehicle speed using a scan tool. If a scan tool is not available, disconnect the wires from the speed sensor near the output shaft of the transmission. Connect a multimeter set on AC volts to the terminals of the speed sensor and rotate the drive wheels with the transmission in neutral. A good speed sensor should indicate approximately 2 volts AC if the drive wheels are rotated by hand.
- If the speed sensor is working, check the wiring from the speed sensor to the dash cluster. If the wiring is good, the instrument panel (IP) should be sent to a specialty repair facility.
- If the speedometer operates correctly but the mechanical odometer does not work, the odometer stepper motor, the number wheel assembly, or the circuit controlling the stepper motor is defective. If the digital odometer does not operate but the speedometer operates correctly, then the dash cluster must be removed and sent to a specialized repair facility. A replacement chip is available only through authorized sources; if the odometer chip is defective, the original number of miles must be programmed into the replacement chip.

ELECTRONIC FUEL LEVEL GAUGES

OPERATION Electronic fuel level gauges ordinarily use the same fuel tank sending unit as that used on conventional fuel gauges. The tank unit consists of a float attached to a variable resistor. As the fuel level changes, the resistance of the sending unit changes. As the resistance of the tank unit changes, the dash-mounted gauge also changes. The only difference between a digital fuel level gauge and a conventional needle type is in the display. Digital fuel level gauges can be either numerical (indicating gallons or liters remaining in the tank) or a bar graph display. ● **SEE FIGURE 57–42.**

The diagnosis of a problem is the same as that described earlier for conventional fuel gauges. If the tests indicate that the dash unit is defective, usually the *entire* dash gauge assembly must be replaced.

NAVIGATION AND GPS

PURPOSE AND FUNCTION The **global positioning system (GPS)** uses 24 satellites in orbit around the earth to provide signals for navigation devices. GPS is funded and controlled by the U.S. Department of Defense (DOD). While the system can be used by anyone with a GPS receiver, it was designed for and is operated by the U.S. military. ● **SEE FIGURE 57–43.**

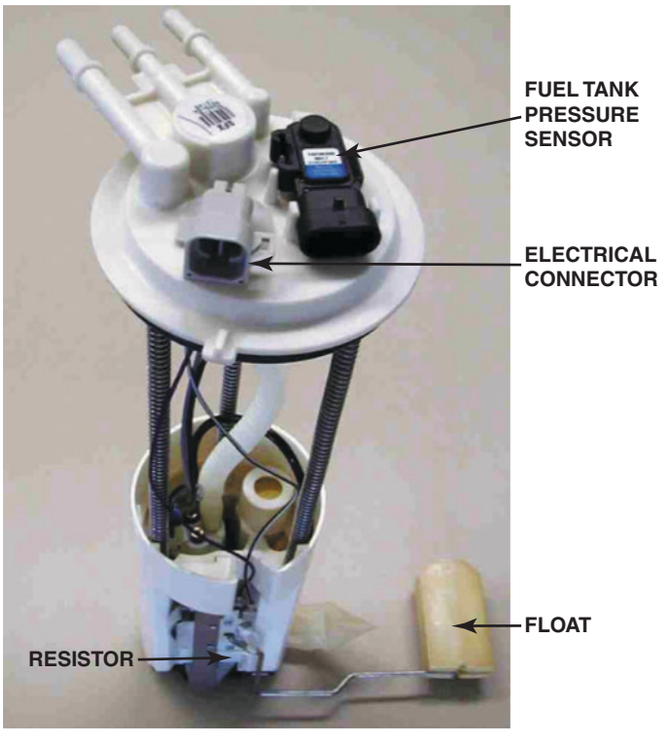


FIGURE 57–42 A fuel tank module assembly that contains the fuel pump and fuel level sensor in one assembly.

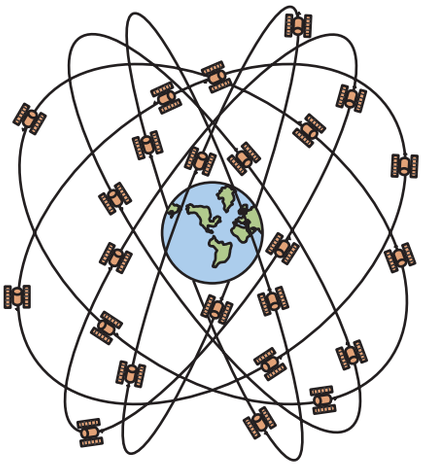

FIGURE 57–43 Global positioning systems use 24 satellites in high earth orbit whose signals are picked up by navigation systems. The navigation system computer then calculates the location based on the position of the satellite overhead.

BACKGROUND The current global positioning system was developed after a civilian airplane from Korean Airlines, Flight 007, was shot down as it flew over Soviet territory in 1983. The system became fully operational in 1991. Civilians were granted use of GPS that same year, but with less accuracy than the system used by the military.

Until 2000, the nonmilitary use of GPS was purposely degraded by a computer program called selection availability (S/A) built into the satellite transmission signals. After 2000, the S/A has been officially turned off, allowing nonmilitary users more accurate position information from the GPS receivers.

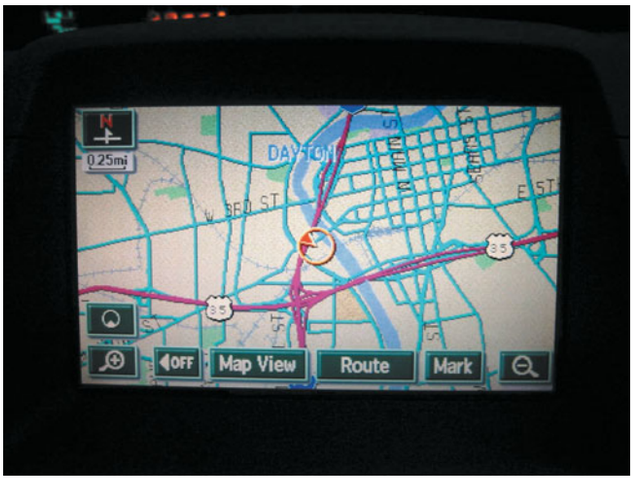

FIGURE 57–44 A typical GPS display screen showing the location of the vehicle.

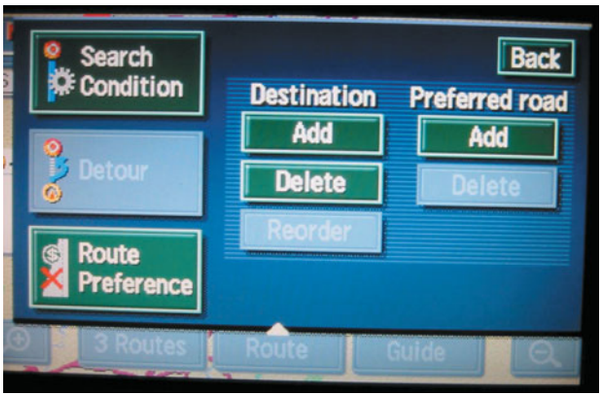

FIGURE 57–45 A typical navigation display showing various options. Some systems do not allow access to these functions if the vehicle is in gear and/or moving.

FREQUENTLY ASKED QUESTION

Does the Government Know Where I Am?

No. The navigation system uses signals from the satellites and uses the signals from three or more to determine position. If the vehicle is equipped with OnStar, then the vehicle position can be monitored by the use of the cellular telephone link to OnStar call centers. Unless the vehicle has a cellular phone connection to the outside world, the only people who will know the location of the vehicle are the persons inside the vehicle viewing the navigation screen.

TECH TIP

Window Tinting Can Hurt GPS Reception

Most factory-installed navigation systems use a GPS antenna inside the rear back glass or under the rear package shelf. If a metalized window tint is applied to the rear glass, the signal strength from the GPS satellites can be reduced. If the customer concern includes inaccurate or nonfunctioning navigation, check for window tint.

TECH TIP

Touch Screen Tip

Most vehicle navigation systems use a touch screen for use by the driver (or passenger) to input information or other on-screen prompts. Most touch screens use infrared beams projected from the top and bottom plus across the screen to form a grid. The system detects where on the screen a finger is located by the location of the beams that are cut. Do not push harder on the display if the unit does not respond, or damage to the display unit may occur. If no response is detected when lightly depressing the screen, rotate the finger to cause the infrared beams to be cut.

NAVIGATION SYSTEM PARTS AND OPERATION

Navigation systems use the GPS satellites for basic location information. The navigation controller located in the rear of the vehicle uses other sensors, including a digitized map to display the location of the vehicle.

- **GPS satellite signals.** These signals from at least three satellites are needed to locate the vehicle.
- **Yaw sensor.** This sensor is often used inside the navigation unit to detect movement of the vehicle during cornering. This sensor is also called a "g" sensor because it measures force; 1 g is the force of gravity.
- **Vehicle speed sensor.** This sensor input is used by the navigation controller to determine the speed and distance the vehicle travels. This information is compiled and compared to the digital map and GPS satellite inputs to locate the vehicle.
- **Audio output/input.** Voice-activated factory units use a built-in microphone at the center top of the windshield and the audio speakers speech output.

Navigation systems include the following components.

1. Screen display ● **SEE FIGURE 57–44.**
2. GPS antenna
3. Navigation control unit, usually with map information on a DVD

The DVD includes street names and the following information.

1. Points of interest (POI), including automated teller machines (ATMs), restaurants, schools, colleges, museums, shopping, and airports, as well as vehicle dealer locations.
2. Business addresses and telephone numbers, including hotels and restaurants (If the telephone number is listed in the business telephone book, it can usually be displayed on the navigation screen. If the telephone number of the business is known, the location can be displayed.)

NOTE: Private residences or cellular telephone numbers are not included in the database of telephone numbers stored on the navigation system DVD.

3. Turn-by-turn directions to addresses that are selected by:
   - Points of interest (POI)
   - Typed in using a keyboard shown on the display

The navigation unit then often allows the user to select the fastest way to the destination, as well as the shortest way, or how to avoid toll roads. ● **SEE FIGURE 57–45.**

DIAGNOSIS AND SERVICE

For the correct functioning of the navigation system, three inputs are needed.

- Location
- Direction
- Speed

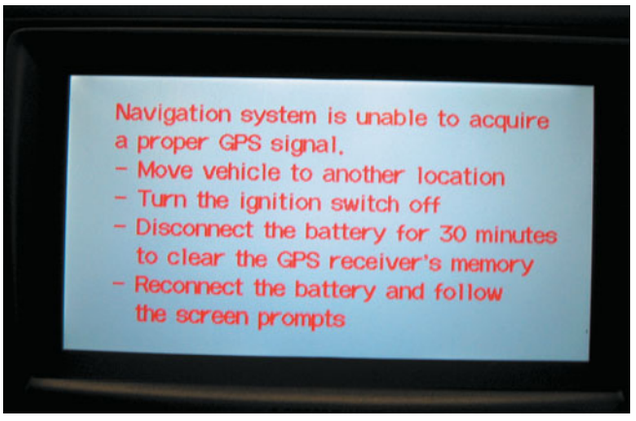

FIGURE 57–46 A screen display of a navigation system that is unable to acquire usable signals from GPS satellites.

The navigation system uses the GPS satellite and map data to determine a location. Direction and speed are determined by the navigation computer from inputs from the satellite, plus the yaw sensor and vehicle speed sensor. The following symptoms may occur and be a customer complaint. Knowing how the system malfunctions helps to determine the most likely cause.

- If the vehicle icon jumps down the road, a fault with the vehicle speed (VS) sensor input is usually indicated.
- If the icon rotates on the screen, but the vehicle is not being driven in circles, a fault with the yaw sensor or yaw sensor input to the navigation controller is likely.
- If the icon goes off course and shows the vehicle on a road that it is not on, a fault with the GPS antenna is the most common reason for this situation.

Sometimes the navigation system itself will display a warning that views from the satellite are not being received. Always follow the displayed instructions. ● **SEE FIGURE 57–46.**

ONSTAR

PARTS AND OPERATION

OnStar is a system that includes the following functions.

1. Cellular telephone
2. Global positioning antenna and computer

OnStar is standard or optional on most General Motors vehicles and selected other brands and models, to help the driver in an emergency or to provide other services. The cellular telephone is used to communicate with the driver from advisors at service centers. The advisor at the service center is able to see the location of the vehicle as transmitted from the GPS antenna and computer system in the vehicle on a display. OnStar does not display the location of the vehicle to the driver unless the vehicle is also equipped with a navigation system.

Unlike most navigation systems, the OnStar system requires a monthly fee. OnStar was first introduced in 1996 as an option on some Cadillac models. Early versions used a handheld cellular telephone while later units used a group of three buttons mounted on the inside rearview mirror and a hands-free cellular telephone. ● **SEE FIGURE 57–47.**

The first version used analog cellular service while later versions used a dual mode (analog and digital) service until 2007. Since 2007, all OnStar systems use digital cellular service, which means that older systems that were analog only need to be upgraded.

FIGURE 57–47 The three-button OnStar control is located on the inside rearview mirror. The left button (telephone handset icon) is pushed if a hands-free cellular call is to be made. The center button is depressed to contact an OnStar advisor and the right emergency button is used to request that help be sent to the vehicle's location.

? FREQUENTLY ASKED QUESTION

What Is Navigation Enhanced Climate Control?

Some vehicles, such as the Acura RL, use data from the navigation system to help control the automatic climate control system. Data about the location of the vehicle includes:

- **Time and date.** This information allows the automatic climate control system to determine where the sun is located.
- **Direction of travel.** The navigation system can also help the climate control system determine the direction of travel.

As a result of the input from the navigation system, the automatic climate control system can control cabin temperature in addition to various other sensors in the vehicle. For example, if the vehicle was traveling south in the late afternoon in July, the climate control system could assume that the passenger side of the vehicle would be warmed more by the sun than the driver's side and could increase the airflow to the passenger side to help compensate for the additional solar heating.

The OnStar system includes the following features, which can vary depending on the level of service desired and cost per month.

- **Automatic notification of airbag deployment.** If the airbag is deployed, the advisor is notified immediately and attempts to call the vehicle. If there is no reply, or if the occupants report an emergency, the advisor will contact emergency services and give them the location of the vehicle.
- **Emergency services.** If the red button is pushed, OnStar immediately locates the vehicle and contacts the nearest emergency service agency.
- **Stolen vehicle location assistance.** If a vehicle is reported stolen, a call center advisor can track the vehicle.
- **Remote door unlock.** An OnStar advisor can send a cellular telephone message to the vehicle to unlock the vehicle if needed.
- **Roadside assistance.** When called, an OnStar advisor can locate a towing company or locate a provider who can bring gasoline or change a flat tire.

- **Accident assistance.** An OnStar advisor is able to help with the best way to handle an accident. The advisor can supply a step-by-step checklist of the things that should be done plus call the insurance company, if desired.
- **Remote horn and lights.** The OnStar system is tied into the lights and horn circuits so an advisor can activate them if requested to help the owner locate the vehicle in a parking lot or garage.
- **Vehicle diagnosis.** Because the OnStar system is tied to the PCM, an OnStar advisor can help with diagnosis if there is a fault detected. The system works as follows:
  - The malfunction indicator light (MIL) (check engine) comes on to warn the driver that a fault has been detected.
  - The driver can depress the OnStar button to talk to an advisor and ask for a diagnosis.
  - The OnStar advisor will send a signal to the vehicle requesting the status from the powertrain control module (PCM), as well as the controller for the antilock brakes and the airbag module.
  - The vehicle then sends any diagnostic trouble codes to the advisor. The advisor can then inform the driver about the importance of the problem and give advice as to how to resolve the problem.

DIAGNOSIS AND SERVICE The OnStar system can fail to meet the needs of the customer if any of the following conditions occur.

1. Lack of cellular telephone service in the area
2. Poor global positioning system (GPS) signals, which can prevent an OnStar advisor from determining the position of the vehicle
3. Transport of the vehicle by truck or ferry so that it is out of contact with the GPS satellite in order for an advisor to properly track the vehicle

If all of the above are okay and the problem still exists, follow service information diagnostic and repair procedures. If a new vehicle communication interface module (VCIM) is installed in the vehicle, the electronic serial number (ESN) must be tied to the vehicle. Follow service information instructions for the exact procedures to follow.

BACKUP CAMERA

PARTS AND OPERATION A **backup camera** is used to display the area at the rear of the vehicle in a screen display on the dash when the gear selector is placed in reverse. Backup cameras are also called *reversing cameras* or *rearview cameras.*

Backup cameras are different from normal cameras because the image displayed on the dash is flipped so it is a mirror image of the scene at the rear of the vehicle. This reversing of the image is needed because the driver and the camera are facing in opposite directions. Backup cameras were first used in large vehicles with limited rearward visibility, such as motor homes. Many vehicles equipped with navigation systems today include a backup camera for added safety while backing. ● **SEE FIGURE 57–48.**

The backup camera contains a wide-angle or fisheye lens to give the largest viewing area. Most backup cameras are pointed downward so that objects on the ground, as well as walls, are displayed. ● **SEE FIGURE 57–49.**

DIAGNOSIS AND SERVICE Faults in the backup camera system can be related to the camera itself, the display, or the connecting wiring. The main input to the display unit comes from the transmission range switch which signals the backup camera when the transmission is shifted into reverse.

FIGURE 57–48 A typical view displayed on the navigation screen from the backup camera.

FIGURE 57–49 A typical fisheye-type backup camera usually located near the center on the rear of the vehicle near the license plate.

TECH TIP

Check for Repainted Bumper

The ultrasonic sensors embedded in the bumper are sensitive to paint thickness because the paint covers the sensors. If the system does not seem to be responding to objects, and if the bumper has been repainted, measure the paint thickness using a nonferrous paint thickness gauge. The maximum allowable paint thickness is 6 mils (0.006 inch or 0.15 mm).

To check the transmission range switch, perform the following:

1. Check if the backup (reverse) lights function when the gear selector is placed in reverse with the key on, engine off (KOEO).
2. Check that the transmission/transaxle is fully engaged in reverse when the selector is placed in reverse.

Most of the other diagnosis involves visual inspection, including:

1. Check the backup camera for damage.
2. Check the screen display for proper operation.
3. Check that the wiring from the rear camera to the body is not cut or damaged.

Always follow the vehicle manufacturer's recommended diagnosis and repair procedures.

FIGURE 57–50 A typical backup sensor display located above the rear window inside the vehicle. The warning lights are visible in the inside rearview mirror.

FIGURE 57–51 The small round buttons in the rear bumper are ultrasonic sensors used to sense distance to an object.

BACKUP SENSORS

COMPONENTS Backup sensors are used to warn the driver if there is an object behind the vehicle while backing. The system used in General Motors vehicles is called **rear park assist (RPA),** and includes the following components.

- Ultrasonic object sensors built into the rear bumper assembly
- A display with three lights usually located inside the vehicle above the rear window and visible to the driver in the rearview mirror
- An electronic control module that uses an input from the transmission range switch and lights the warning lamps needed when the vehicle gear selector is in reverse

OPERATION The three-light display includes two amber lights and one red light. The following lights are displayed depending on the distance from the rear bumper.

- One amber lamp will light when the vehicle is in reverse and traveling at less than 3 mph (5 km/h) and the sensors detect an object 40 to 60 in. (102 to 152 cm) from the rear bumper. A chime also sounds once when an object is detected, to warn the driver to look at the rear parking assist display. ● **SEE FIGURE 57–50.**
- Two amber lamps light when the distance between the rear bumper and an object is between 20 and 40 in. (50 and 100 cm) and the chime will sound again.
- Two amber lamps and the red lamp light and the chime sounds continuously when the distance between the rear bumper and the object is between 11 and 20 in. (28 and 50 cm).

If the distance between the rear bumper and the object is less than 11 in. (28 cm), all indicator lamps flash and the chime will sound continuously.

The ultrasonic sensors embedded in the rear bumper "fire" individually every 150 milliseconds (27 times per second). ● **SEE FIGURE 57–51.**

The sensors fire and then receive a return signal and arm to fire again in sequence from the left sensor to the right sensor.

Each sensor has the following three wires.

1. An 8 volt supply wire from the RPA module, used to power the sensor
2. A reference low or ground wire
3. A signal line, used to send and receive commands to and from the RPA module

DIAGNOSIS The rear parking assist control module is capable of detecting faults and storing diagnostic trouble codes (DTCs). If a fault has been detected by the control module, the red lamp flashes and the system is disabled. Follow service information diagnostic procedures because the rear parking assist module cannot usually be accessed using a scan tool. Most systems use the warning lights to indicate trouble codes.

LANE DEPARTURE WARNING SYSTEM

PARTS AND OPERATION The **lane departure warning system (LDWS)** uses cameras to detect if the vehicle is crossing over lane marking lines on the pavement. Some systems use two cameras, one mounted on each outside rearview mirror. Some systems use infrared sensors located under the front bumper to monitor the lane markings on the road surface.

The system names also vary according to vehicle manufacturer, including:

Honda/Acura: lane keep assist system (LKAS)

Toyota/Lexus: lane monitoring system (LMS)

General Motors: lane departure warning (LDW)

Ford: lane departure warning (LDW)

Nissan/Infinity: lane departure prevention (LDP) system

If the cameras detect that the vehicle is starting to cross over a lane dividing line, a warning chime will sound or a vibrating mechanism mounted in the driver's seat cushion is triggered on the side where the departure is being detected. This warning will not occur if the turn signal is on in the same direction as detected. ● **SEE FIGURE 57–52.**

DIAGNOSIS AND SERVICE Before attempting to service or repair a lane departure warning system fault, check service information for an explanation on how the system is supposed to work. If the system is not working as designed, perform a visual inspection of the sensors or cameras, checking for damage from road debris or evidence of body damage, which could affect the sensors. After a visual inspection, follow the vehicle manufacturer's recommended diagnosis procedures to locate and repair the fault in the system.

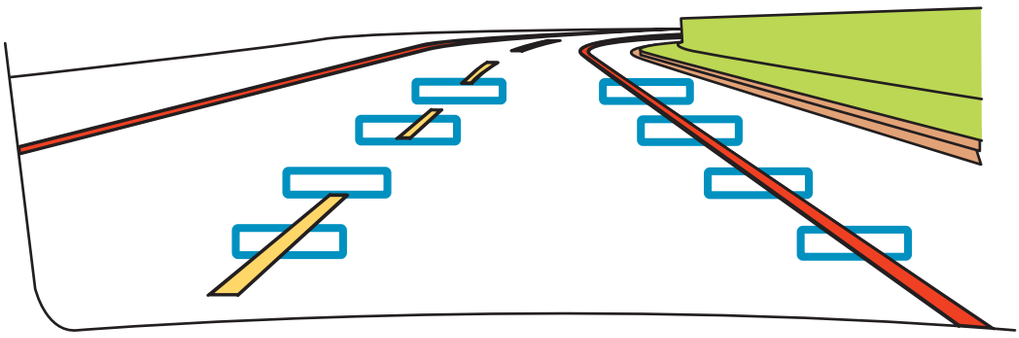

FIGURE 57–52 A lane departure warning system often uses cameras to sense the road lines and warns the driver if the vehicle is not staying within the lane, unless the turn signal is on.

ELECTRONIC DASH INSTRUMENT DIAGNOSIS AND TROUBLESHOOTING

If one or more electronic dash gauges do not work correctly, first check the WOW display that lights all segments to full brilliance whenever the ignition switch is first switched on. If *all* segments of the display do *not* operate, then the entire electronic cluster must be replaced in most cases. If all segments operate during the WOW display but do not function correctly afterwards, the problem is most often a defective sensor or defective wiring to the sensor.

All dash instruments except the voltmeter use a variable-resistance unit as a sensor for the system being monitored. Most new-vehicle dealers are required to purchase essential test equipment, including a test unit that permits the technician to insert various fixed-resistance values in the suspected circuit. For example, if a 45 ohm resistance is put into the fuel gauge circuit that reads from 0 to 90 ohms, a properly operating dash unit should indicate one-half tank. The same tester can produce a fixed signal to test the operation of the speedometer and tachometer. If this type of special test equipment is not available, the electronic dash instruments can be tested using the following procedure.

1. With the ignition switched off, unplug the wire(s) from the sensor for the function being tested. For example, if the oil pressure gauge is not functioning correctly, unplug the wire connector at the oil pressure sending unit.
2. With the sensor wire unplugged, turn the ignition switch on and wait until the WOW display stops. The display for the affected unit should show either fully lighted segments or no lighted segments, depending on the make of the vehicle and the type of sensor.
3. Turn the ignition switch off. Connect the sensor wire lead to ground and turn the ignition switch on. After the WOW display, the display should be the opposite (either fully on or fully off) of the results in step 2.

TESTING RESULTS If the electronic display functions fully on and fully off with the sensor unplugged and then grounded, the problem is a defective sensor. If the electronic display fails to function fully on and fully off when the sensor wire(s) are opened and grounded, the problem is usually in the wiring from the sensor to the electronic dash or it is a defective electronic cluster.

CAUTION: Whenever working on or *near* any type of electronic dash display, always wear a wire attached to your wrist (wrist strap) connected to a good body ground to prevent damaging the electronic dash with static electricity.

TECH TIP

Keep Stock Overall Tire Diameter

Whenever larger (or smaller) wheels or tires are installed, the speedometer and odometer calibration are also thrown off. This can be summarized as follows:

- **Larger diameter tires.** The speed showing on the speedometer is slower than the actual speed. The odometer reading will show fewer miles than actual.
- **Smaller diameter tires.** The speed showing on the speedometer is faster than the actual speed. The odometer reading will show more miles than actual.

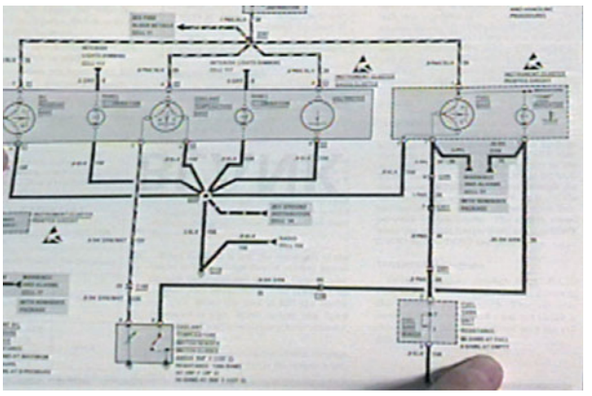
General Motors trucks can be recalibrated with a recalibration kit (1988–1991) or with a replacement controller assembly called a digital ratio adapter controller (DRAC) located under the dash. It may be possible to recalibrate the speedometer and odometer on earlier models, before 1988, or vehicles that use speedometer cables by replacing the drive gear in the transmission. Check service information for the procedure on the vehicle being serviced.

MAINTENANCE REMINDER LAMPS

Maintenance reminder lamps indicate that the oil should be changed or that other service is required. There are numerous ways to extinguish a maintenance reminder lamp. Some require the use of a special tool. Always check the owner manual or service information for the exact procedure for the vehicle being serviced. For example, to reset the oil service reminder light on many General Motors vehicles, you have to perform the following:

STEP 1 Turn the ignition key on (engine off).

STEP 2 Depress the accelerator pedal three times and hold it down on the fourth.

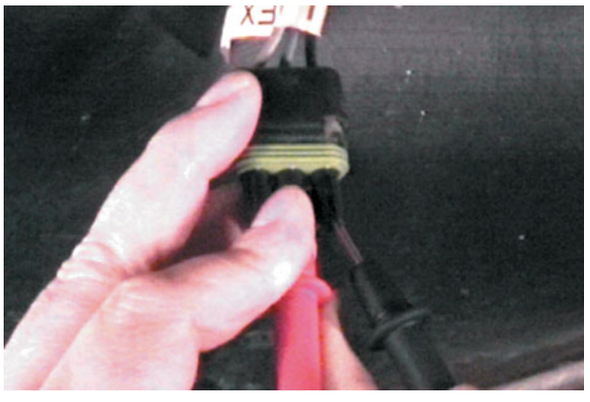


STEP 3 When the reminder light flashes, release the accelerator pedal.

STEP 4 Turn the ignition key to the off position.

STEP 5 Start the engine and the light should be off.

1 Observe the fuel gauge. This General Motors vehicle shows an indicated reading of slightly above one-half tank.



2 Consult the factory service manual for the specifications, wire color, and recommended test procedure.

3 From the service manual, the connector for the fuel gauge-sending unit was located under the vehicle near the rear. A visual inspection indicated that the electrical wiring and connector were not damaged or corroded.

4 To test resistance of the sending unit (tank unit) use a digital multimeter and select ohms (Ω).

5 Following the schematic in the service manual the sending unit resistance can be measured between the pink and the black wires in the connector.

6 The meter displays 50 ohms or slightly above the middle of the normal resistance value for the vehicle of 0 Ω (empty) to 90 Ω (full).

CONTINUED ▶

STEP BY STEP

7 To check if the dash unit can move, the connector is unplugged with the ignition key on (engine off).

8 As the connector is disconnected, the needle of the dash unit moves toward full.

9 After a couple of seconds, the needle disappears above the full reading. The open connector represented infinity ohms and normal maximum reading occurs when the tank unit reads 90 ohms. If the technician does not realize that the needle could disappear, an incorrect diagnosis could be made.

10 To check if the dash unit is capable of reading empty, a fuse jumper wire is connected between the signal wire at the dash end of the connector and a good chassis ground.

11 A check of a dash unit indicated that the needle does accurately read empty.

12 After testing, reconnect the electrical connectors and verify for proper operation of the fuel level gauge.

HORN, WIPER, AND BLOWER MOTOR CIRCUITS

OBJECTIVES: **After studying Chapter 58, the reader will be able to:** • Prepare for ASE Electrical/Electronic Systems (A6) certification test content area "G" (Horn and Wiper/Washer Diagnosis and Repair) and content area "H" (Accessories Diagnosis and Repair). • Describe how the horn operates. • List the components of a wiper circuit. • Explain how the blower motor can run at different speeds. • Discuss how to diagnosis faults in the horn, wiper, and blower motor circuits.

KEY TERMS: Horns 646 • Pulse wipers 649 • Rain sense wipers 653 • Series-wound field 649 • Shunt field 649 • Variable-delay wipers 649 • Windshield wipers 648

HORNS

PURPOSE AND FUNCTION

Horns are electric devices that emit a loud sound used to alert other drivers or persons in the area. Horns are manufactured in several different tones ranging from 1,800 to 3,550 Hz. Vehicle manufacturers select from various horn tones for a particular vehicle sound. ● **SEE FIGURE 58–1.**

When two horns are used, each has a different tone when operated separately, yet the sound combines when both are operated.

FIGURE 58–1 Two horns are used on this vehicle. Many vehicles use only one horn, often hidden underneath the vehicle.

HORN CIRCUITS

Automotive horns usually operate on full battery voltage wired from the battery, through a fuse, switch, and then to the horns. Most vehicles use a horn *relay.* With a relay, the horn button on the steering wheel or column completes a circuit to ground that closes a relay, and the heavy current flow required by the horn then travels from the relay to the horn. Without a horn relay, the high current of the horns must flow through the steering wheel horn switch. ● **SEE FIGURE 58–2.**

The horn relay is also connected to the body control module, which "beeps" the horn when the vehicle is locked or unlocked, using the key fob remote.

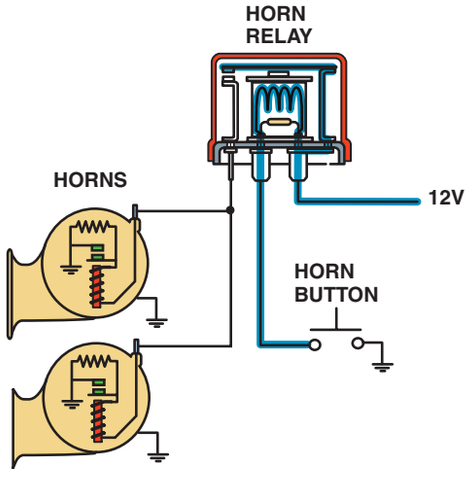

FIGURE 58–2 A typical horn circuit. Note that the horn button completes the ground circuit for the relay.

HORN OPERATION

A vehicle horn is an actuator that converts an electrical signal to sound. The horn circuit includes an armature (a coil of wire) and contacts that are attached to a diaphragm. When energized, the armature causes the diaphragm to move up which then opens a set of contact points that de-energize the armature circuit. As the diaphragm moves down, the contact points close, re-energize the armature circuit, and the diaphragm moves up again. This rapid opening and closing of the contact points causes the diaphragm to vibrate at an audible frequency. The sound created by the diaphragm is magnified as it travels through a trumpet attached to the diaphragm chamber. Most horn systems typically use one or two horns, but some have up to four. Those with multiple horns use both high- and low-pitch units to achieve a harmonious tone. Only a high-pitched unit is used in single-horn applications. The horn assembly is marked with an "H" or "L" for pitch identification.

HORN SYSTEM DIAGNOSIS There are three types of horn failure.

- No horn operation
- Intermittent operation
- Constant operation
- Weak or low volume sound

If a horn does not operate at all, check for the following:

- Burned fuse or fusible link
- Open circuit
- Defective horn
- Faulty relay
- Defective horn switch
- Poor ground (horn mounting)
- Corroded or rusted electrical connector

If a horn operates intermittently, check for the following:

- Loose contact at the switch
- Loose, frayed, or broken wires
- Defective relay

HORN SOUNDS CONTINUOUSLY A horn that sounds continuously and cannot be shut off is caused by horn switch contacts that are stuck closed, or a short-to-ground on the control circuit. This may be the result of a defective horn switch or a faulty relay. Stuck relay contacts keep the circuit complete so the horn sounds constantly. Disconnect the horn and check continuity through the horn switch and relay to locate the source of the problem.

INOPERATIVE HORN To help determine the cause of an inoperative horn, use a fused jumper wire and connect one end to the positive post of the battery and the other end to the wire terminal of the horn itself. Also use a fused jumper wire to substitute a ground path to test or confirm a potential bad ground circuit. If the horn works with jumper wires connected, check ground wires and connections.

- If the horn works, the problem is in the circuit supplying current to the horn.
- If the horn does not work, the horn itself could be defective or the mounting bracket may not be providing a good ground.

HORN SERVICE When a horn malfunctions, circuit tests are made to determine if the horn, relay, switch, or wiring is the source of the failure. Typically, a digital multimeter (DMM) is used to perform voltage drop and continuity checks to isolate the failure.

- **Switch and relay.** A momentary contact switch is used to sound the horn. The horn switch is mounted to the steering wheel in the center of the steering column on some models, and is part of a multifunction switch installed on the steering column.

  CAUTION: If steering wheel removal is required for diagnosis or repair of the horn circuit, follow service information procedures for disarming the airbag circuit prior to steering wheel removal, and for the specified test equipment to use.

  On most late-model vehicles, the horn relay is located in a centralized power distribution center along with other relays, circuit breakers, and fuses. The horn relay bolts onto an inner fender or the bulkhead in the engine compartment of older vehicles. Check the relay to determine if the coil is being energized and if current passes through the power circuit when the horn switch is depressed.

  Obtain an electrical schematic of the horn circuit and use a voltmeter to test input, output, and control voltage.

- **Circuit testing.** Circuit testing involves the following steps.

  STEP 1 Make sure the fuse or fusible link is good before attempting to troubleshoot the circuit.

  STEP 2 Check that the ground connections for the horn are clean and tight. Most horns ground to the chassis through the mounting bolts. High ground circuit resistance due to corrosion, road dirt, or loose fasteners may cause no, or intermittent, horn operation.

  STEP 3 On a system with a relay, test the power output circuit and the control circuit. Check for voltage available at the horn, voltage available at the relay, and continuity through the switch. When no relay is used, there are two wires leading to the horn switch, and a connection to the steering wheel is made with a double contact slip ring. Test points on this system are similar to those of a system with a relay, but there is no control circuit.

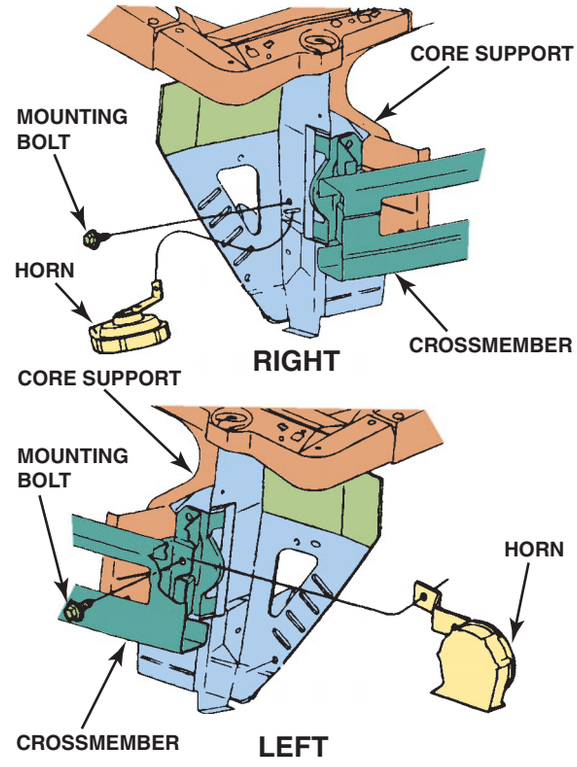

FIGURE 58–3 Horns typically mount to the radiator core support or bracket at the front of the vehicle.

HORN REPLACEMENT Horns are generally mounted on the radiator core support by bolts and nuts or sheet metal screws. It may be necessary to remove the grille or other parts to access the horn mounting screws. If a replacement horn is required, attempt to use a horn of the same tone as the original. The tone is usually indicated by a number or letter stamped on the body of the horn. To replace a horn, simply remove the fasteners and lift the old horn from its mounting bracket.

Clean the attachment area on the mounting bracket and chassis before installing the new horn. Some models use a corrosion-resistant mounting bolt to ensure a ground connection. ● **SEE FIGURE 58–3.**

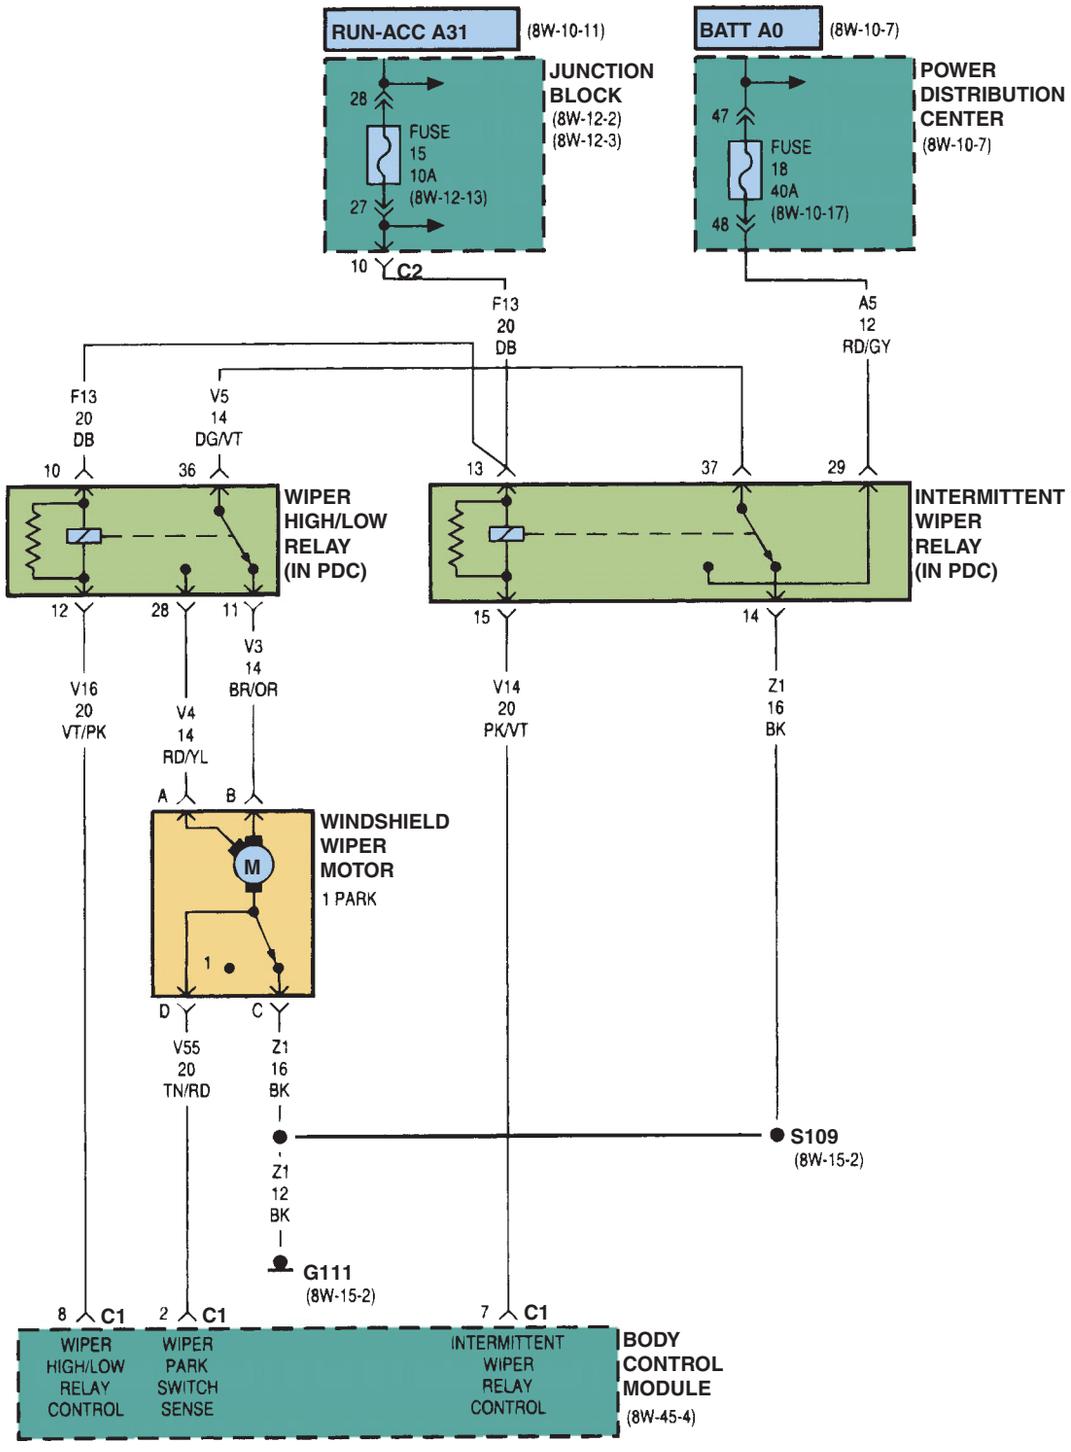

FIGURE 58–4 A circuit diagram is necessary to troubleshoot a windshield wiper problem.

WINDSHIELD WIPER AND WASHER SYSTEM

PURPOSE AND FUNCTION

Windshield wipers are used to keep the viewing area of the windshield clean of rain. Windshield wiper systems and circuits vary greatly between manufacturers as well as between models. Some vehicles combine the windshield wiper and windshield washer functions into a single system. Many minivans and sport utility vehicles (SUVs) also have a rear window wiper and washer system that works independently of the windshield system. In spite of the design differences, all windshield and rear window wiper and washer systems operate in a similar fashion.

COMPUTER CONTROLLED

Most wipers since the 1990s have used the body computer to control the actual operation of the wiper. The wiper controls are simply a command to the computer. The computer may also turn on the headlights whenever the wipers are on, which is the law in some states. ● **SEE FIGURE 58–4.**

WIPER AND WASHER COMPONENTS

A typical combination wiper and washer system consists of the following:

- Wiper motor
- Gearbox

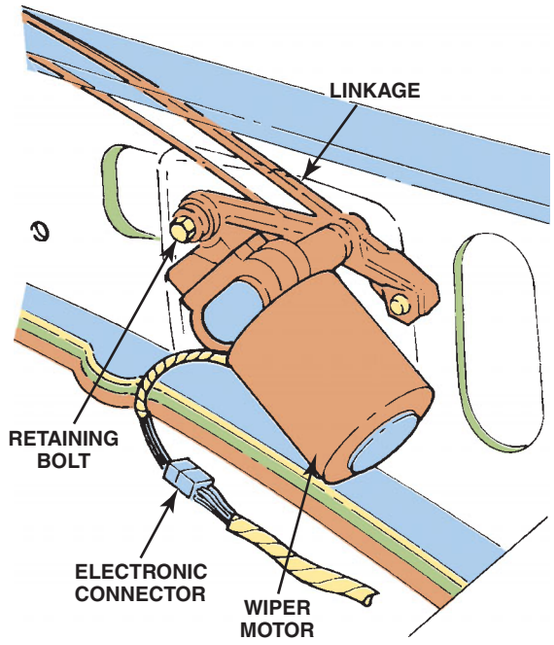

FIGURE 58–5 The motor and linkage bolt to the body and connect to the switch with a wiring harness.

- Wiper arms and linkage
- Washer pump
- Hoses and jets (nozzles)
- Fluid reservoir
- Combination switch
- Wiring and electrical connectors
- Electronic control module

The motor and gearbox assembly is wired to the wiper switch on the instrument panel or steering column or to the wiper control module. ● **SEE FIGURE 58–5.**

Some systems use either a one- or two-speed wiper motor, whereas others have a variable-speed motor.

WINDSHIELD WIPER MOTORS

The windshield wipers ordinarily use a special two-speed electric motor. Most are compound-wound motors, a motor type, which provides for two different speeds.

- **Series-wound field**
- **Shunt field**

One speed is achieved in the series wound field and the other speed in the shunt wound field. The wiper switch provides the necessary electrical connections for either motor speed. Switches in the mechanical wiper motor assembly provide the necessary operation for "parking" and "concealing" of the wipers. ● **SEE FIGURE 58–6** for a typical wiper motor assembly.

- **Wiper motor operation.** Most wiper motors use a permanent magnet motor with a low speed + brush and a high speed + brush. The brushes connect the battery to the internal windings of the motor, and the two brushes provide for two different motor speeds.

  The ground brush is directly opposite the low-speed brush. The high-speed brush is off to the side of the low-speed brush. When current flows through the high-speed brush, there are fewer turns on the armature between the hot and ground brushes, and therefore the resistance is less. With less resistance, more current flows and the armature revolves faster. ● **SEE FIGURES 58–7 AND 58–8.**

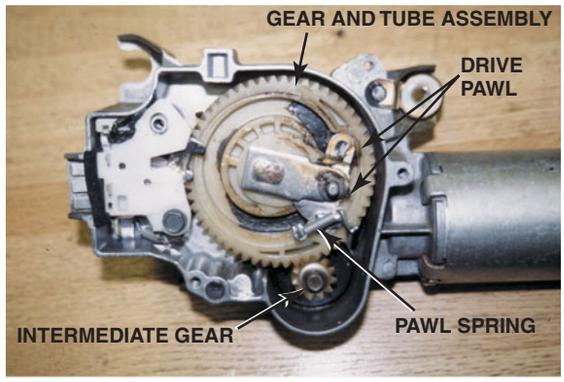

FIGURE 58–6 A typical wiper motor with the housing cover removed. The motor itself has a worm gear on the shaft that turns the small intermediate gear, which then rotates the gear and tube assembly, which rotates the crank arm (not shown) that connects to the wiper linkage.

- **Variable wipers.** The **variable-delay wipers** (also called **pulse wipers**) use an electronic circuit with a variable resistor that controls the time of the charge and discharge of a capacitor. The charging and discharging of the capacitor controls the circuit for the operation of the wiper motor. ● **SEE FIGURE 58–9.**

HIDDEN WIPERS

Some vehicles are equipped with wipers that become hidden when turned off. These wipers are also called *depressed wipers.* The gearbox has an additional linkage arm to provide depressed parking for hidden wipers. This link extends to move the wipers into the park position when the motor turns in reverse of operating direction. With depressed park, the motor assembly includes an internal park switch. The park switch completes a circuit to reverse armature polarity in the motor when the windshield wiper switch is turned off. The park circuit opens once the wiper arms are in the park position. Instead of a depressed park feature, some systems simply extend the cleaning arc below the level of the hood line.

WINDSHIELD WIPER DIAGNOSIS

Windshield wiper failure may be the result of an electrical fault or a mechanical problem, such as binding linkage. Generally, if the wipers operate at one speed setting but not another, the problem is electrical.

To determine if there is an electrical or mechanical problem, access the motor assembly and disconnect the wiper arm linkage from the motor and gearbox. Depending on the type of vehicle, this procedure may involve:

- Removing body trim panels from the covered areas at the base of the windshield to gain access to the linkage connectors
- Switching the motor on to each speed (If the motor operates at all speeds, the problem is mechanical. If the motor still does not operate, the problem is electrical.)

If the wiper motor does not run at all, check for the following:

- Grounded or inoperative switch
- Defective motor
- Circuit wiring fault
- Poor electrical ground connection

If the motor operates but the wipers do not, check for the following:

- Stripped gears in the gearbox or stripped linkage connection
- Loose or separated motor-to-gearbox connection
- Loose linkage to the motor connection

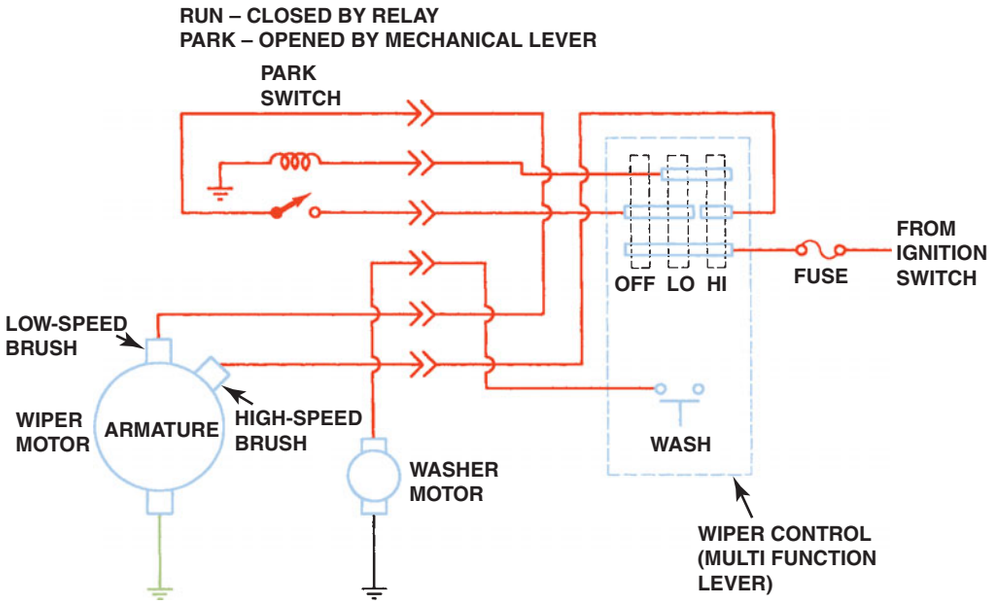

FIGURE 58–7 A wiring diagram of a two-speed windshield wiper circuit using a three-brush, two-speed motor. The dashed line for the multifunction lever indicates that the circuit shown is only part of the total function of the steering column lever.

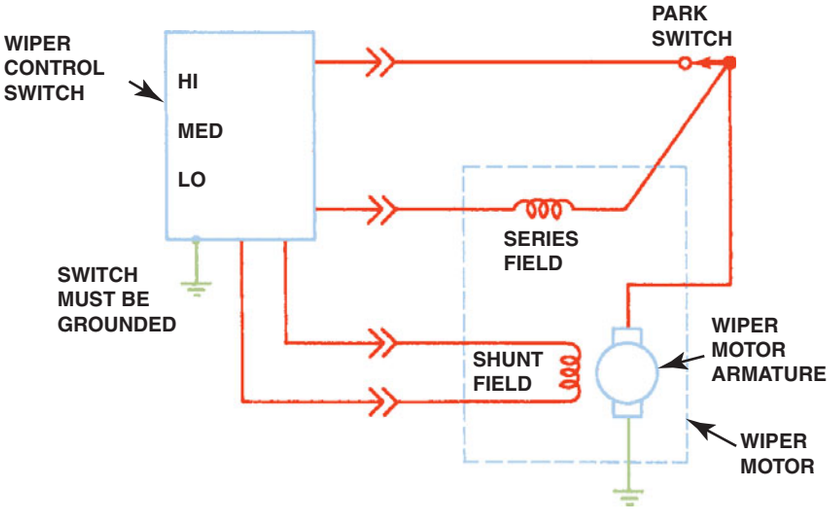

FIGURE 58–8 A wiring diagram of a three-speed windshield wiper circuit using a two-brush motor, but both a series-wound and a shunt field coil.

If the motor does not shut off, check for the following:

- Defective park switch inside the motor
- Defective wiper switch
- Poor ground connection at the wiper switch

WINDSHIELD WIPER TESTING

When the wiper motor does not operate with the linkage disconnected, perform the following steps to determine the fault. ● **SEE FIGURE 58–10.**

To test the wiper system, perform the following steps.

STEP 1 Refer to the circuit diagram or a connector pin chart for the vehicle being serviced to determine the test points for voltage measurements.

STEP 2 Switch the ignition on and set the wiper switch to a speed at which the motor does not operate.

STEP 3 Check for battery voltage available at the appropriate wiper motor terminal for the selected speed. If voltage is available to the motor, an internal motor problem is indicated. No voltage available indicates a switch or circuit failure.

? FREQUENTLY ASKED QUESTION

How Do Wipers Park?

Some vehicles have wiper arms that park lower than the normal operating position so that they are hidden below the hood when not in operation. This is called a *depressed park position.* When the wiper motor is turned off, the park switch allows the motor to continue to turn until the wiper arms reach the bottom edge of the windshield. Then the park switch reverses the current flow through the wiper motor, which makes a partial revolution in the opposite direction. The wiper linkage pulls the wiper arms down below the level of the hood and the park switch is opened, stopping the wiper motor.

TERMINAL	OPERATION SPEED
C	LOW
A	HIGH

FIGURE 58–10 A wiper motor connector pin chart.

STEP 4 Check for proper ground connections.

STEP 5 Check that battery voltage is available at the motor side of the wiper switch. If battery voltage is available, the circuit is open between the switch and motor. No voltage available indicates either a faulty switch or a power supply problem.

STEP 6 Check for battery voltage available at the power input side of the wiper switch. If voltage is available, the switch is defective. Replace the switch. No voltage available to the switch indicates a circuit problem between the battery and switch.

WINDSHIELD WIPER SERVICE

Wiper motors are replaced if defective. The motor usually mounts on the bulkhead (firewall). Bulkhead-mounted units are accessible from under the hood, while the cowl panel needs to be removed to service a motor mounted in the cowl. ● **SEE FIGURE 58–11.**

After gaining access to the motor, removal is simply a matter of disconnecting the linkage, unplugging the electrical connectors, and unbolting the motor. Move the wiper linkage through its full travel by hand to check for any binding before installing the new motor.

Rear window wiper motors are generally located inside the rear door panel of station wagons, or the rear hatch panel on vehicles with a hatchback or liftgate. ● **SEE FIGURE 58–12.**

After removing the trim panel covering the motor, replacement is essentially the same as replacing the front wiper motor.

Wiper control switches are either installed on the steering column or on the instrument panel.

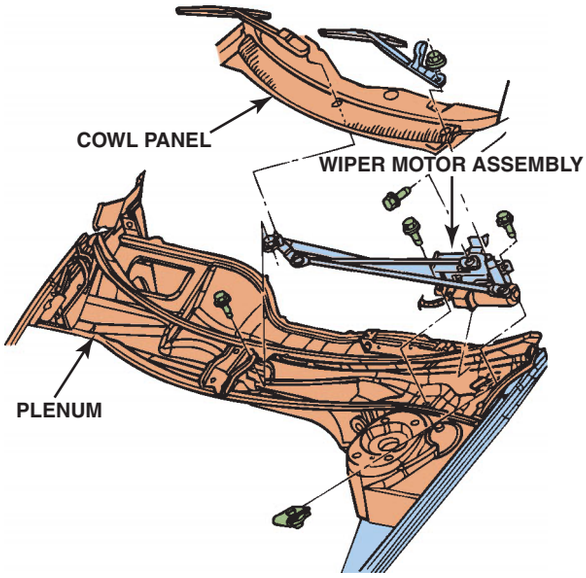

FIGURE 58–11 The wiper motor and linkage mount under the cowl panel on many vehicles.

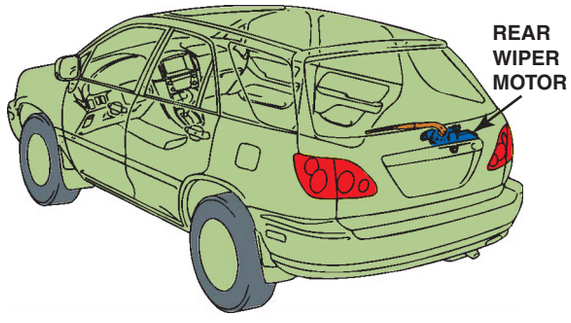

FIGURE 58–12 A single wiper arm mounts directly to the motor on most rear wiper applications.

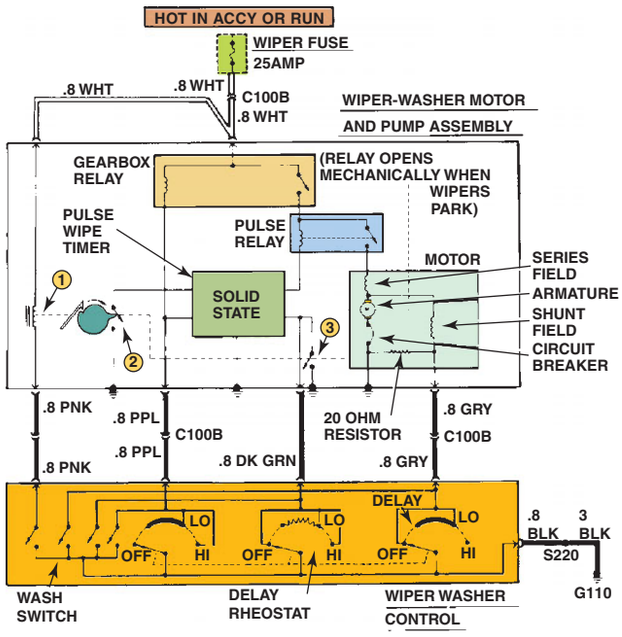
Steering column wiper switches, which are operated by controls on the end of a switch stalk (usually called a *multifunction switch*), require partial disassembly of the steering column for replacement.



PULSE WIPE SYSTEMS Windshield wipers may also incorporate a delay, or intermittent operation, feature commonly called pulse wipe. The length of the delay, or the frequency of the intermittent operation, is adjustable on some systems. Pulse wipe systems may rely on simple electrical controls, such as a variable-resistance switch, or be controlled electronically through a control module.

With any electronic control system, it is important to follow the diagnosis and test procedures recommended by the manufacturer for that specific vehicle.

A typical pulse, or interval, wiper system uses either a governor or a solid-state module that contains either a variable resistor or rheostat and capacitor. The module connects into the electrical circuitry between the wiper switch and wiper motor. The variable resistor or rheostat controls the length of the interval between wiper pulses. A solid-state pulse wipe timer regulates the control circuit of the pulse relay to direct current to the motor at the prescribed interval. ● **SEE FIGURE 58–13.**

The following troubleshooting procedure applies to most models.

STEP 1 If the wipers do not run at all, check the wiper fuse, fusible link, or circuit breaker and verify that voltage is available to the switch.

① RATCHET RELEASE SOLENOID
(OPERATED WHEN WASH SWITCH DEPRESSED)
② WASHER OVERRIDE SWITCH
(CLOSED DURING WASH CYCLE)
③ HOLDING SWITCH
(OPEN AT THE END OF EACH SWEEP)

FIGURE 58–13 Circuit diagram of a rheostat-controlled, electronically timed interval wiper.

STEP 2 Refer to a wiring diagram of the switch to determine how current is routed through it to the motor in the different positions.

STEP 3 Disconnect the switch and use fused jumper wires to apply power directly to the motor on the different speed circuits.

- If the motor now runs, the problem is in the switch or module.
- Check for continuity in the circuit for each speed through the control-to-ground if the wiper motor runs at some, but not all, speeds.

WINDSHIELD WASHER OPERATION Most vehicles use a positive-displacement or centrifugal-type washer pump located in the washer reservoir. A momentary contact switch, which is often part of a steering column–mounted combination switch assembly, energizes the washer pump. Washer pump switches are installed either on the steering column or on the instrument panel. The nozzles can be located on the bulkhead or in the hood depending on the vehicle.

WINDSHIELD WASHER DIAGNOSIS Inoperative windshield washers may be caused by the following:

- Blown fuse or open circuit
- Empty reservoir
- Clogged nozzle
- Broken, pinched, or clogged hose
- Loose or broken wire
- Blocked reservoir screen
- Leaking reservoir
- Defective pump

To diagnose the washer system, follow service information procedures that usually include the following steps.

TECH TIP

Use a Scan Tool to Check Accessories

Most vehicles built since 2000 can have the lighting and accessory circuits checked using a scan tool. A technician can use the following:

- Factory scan tool, such as:
  - Tech 2 or Multiple Diagnostic Interface (MDI) (General Motors vehicle)
  - DRB III or Star Scan or Star Mobile or WiTech (Chrysler-Jeep vehicles)
  - New Generation Star or IDS (Ford)
  - Honda Diagnostic System (HDS)
  - TIS Tech Stream (Toyota/Lexus)
- Enhanced aftermarket scan tool that has body bidirectional control capability, including:
  - Snap-on Modis, Solus, or Verus
  - OTC Genisys
  - Autoengenuity

Using a bidirectional scan tool allows the technician to command the operation of electrical accessories such as windows, lights, and wipers. If the circuit operates correctly when commanded by the scan tool and does not function using the switche(s), follow service information instructions to diagnose the switch circuits.

STEP 1 To quick check any washer system, make sure the reservoir has fluid and is not frozen, and then disconnect the pump hose and operate the washer switch.

NOTE: Always use good-quality windshield washer fluid from a closed container to prevent contaminated fluid from damaging the washer pump. Radiator antifreeze (ethylene glycol) should never be used in any windshield wiper system.

● **SEE FIGURE 58–14.**

STEP 2 If fluid squirts from the pump, the delivery system is at fault, not the motor, switch, or circuitry.

STEP 3 If no fluid squirts from the pump, the problem is most likely a circuit failure, defective pump, or faulty switch.

STEP 4 A clogged reservoir screen also may be preventing fluid from entering the pump.

WINDSHIELD WASHER SERVICE When a fluid delivery problem is indicated, check for:

- Blocked, pinched, broken, or disconnected hose
- Clogged nozzles
- Blocked washer pump outlet

If the pump motor does not operate, check for battery voltage available at the pump while operating the washer switch. If voltage is available and the pump does not run, check for continuity on the pump ground circuit. If there is no voltage drop on the ground circuit, replace the pump motor.

If battery voltage is not available at the motor, check for power through the washer switch. If voltage is available at and through the switch, there is a problem in the wiring between the switch and pump. Perform voltage drop tests to locate the fault. Repair the wiring as needed and retest.

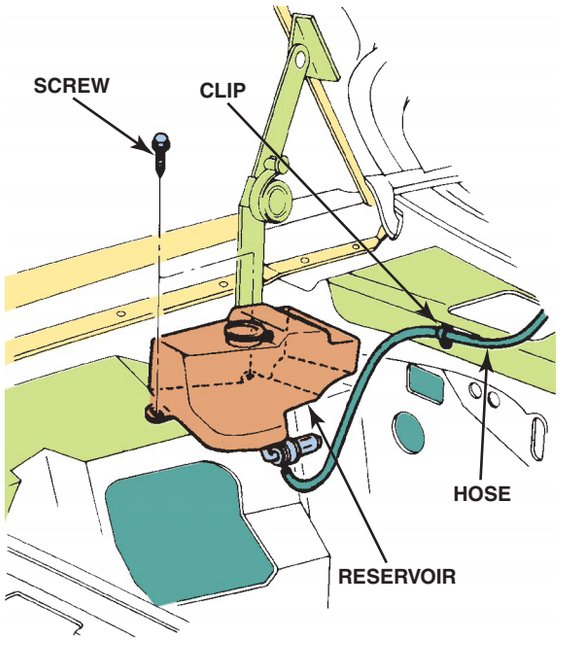


FIGURE 58–14 Disconnect the hose at the pump and operate the switch to check a washer pump.

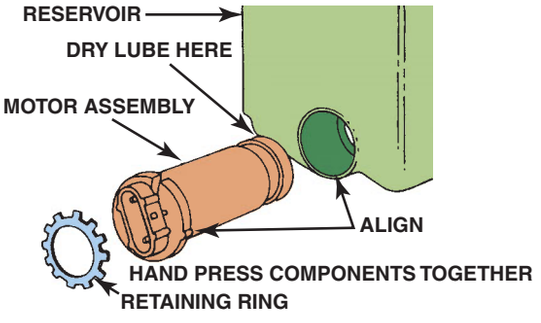

FIGURE 58–15 Washer pumps usually install into the reservoir and are held in place with a retaining ring.

Washer motors are not repairable and are simply replaced if defective. Centrifugal or positive-displacement pumps are located on or inside the washer reservoir tank or cover and secured with a retaining ring or nut. ● **SEE FIGURE 58–15.**

RAIN SENSE WIPER SYSTEM

PARTS AND OPERATION **Rain sense wiper** systems use a sensor located at the top of the windshield on the inside to detect rain droplets. This sensor is called the *rain sense module (RSM)* by General Motors. It determines and adjusts the time delay of the wiper based on how much moisture it detects on the windshield. The wiper switch can be left on the sense position all of the time and if no rain is sensed, the wipers will not swipe. ● **SEE FIGURES 58–16 AND 58–17.**

The control knob is rotated to the desired wiper sensibility level.

The microprocessor in the RSM sends a command to the body control module (BCM). RSM is a triangular-shaped black plastic housing. Fine openings on the windshield side of the housing are

FIGURE 58–16 A typical rain sensing module located on the inside of the windshield near the inside rearview mirror.

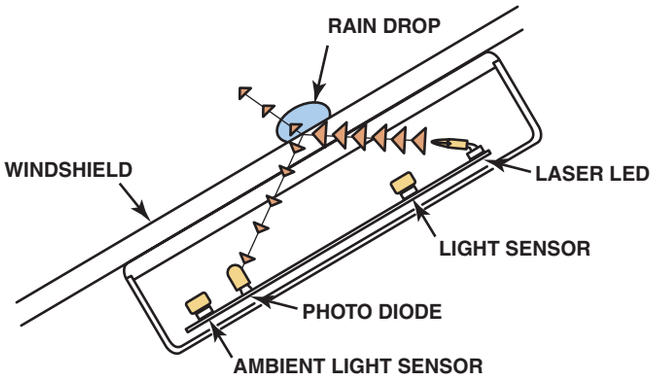

FIGURE 58–17 The electronics in the rain sense wiper module can detect the presence of rain drops under various lighting conditions.

fitted with eight convex clear plastic lenses. The unit contains four infrared (IR) diodes, two photocells, and a microprocessor.

The IR diodes generate IR beams that are aimed by four of the convex optical lenses near the base of the module through the windshield glass. Four additional convex lenses near the top of the RSM are focused on the IR light beam on the outside of the windshield glass and allow the two photocells to sense changes in the intensity of the IR light beam. When sufficient moisture accumulates, the RSM detects a change in the monitored IR light beam intensity. The RSM processes the signal BCM over the data BUS to command a swipe of the wiper.

DIAGNOSIS AND SERVICE

If there is a complaint about the rain sense wipers not functioning correctly, check the owner manual to be sure that they are properly set and adjusted. Also, verify that the windshield wipers are functioning correctly on all speeds before diagnosing the rain sensor circuits. Always follow the vehicle manufacturer's recommended diagnosis and testing procedures.

BLOWER MOTOR

PURPOSE AND FUNCTION

The same blower motor moves air inside the vehicle for:

1. Air conditioning
2. Heat
3. Defrosting

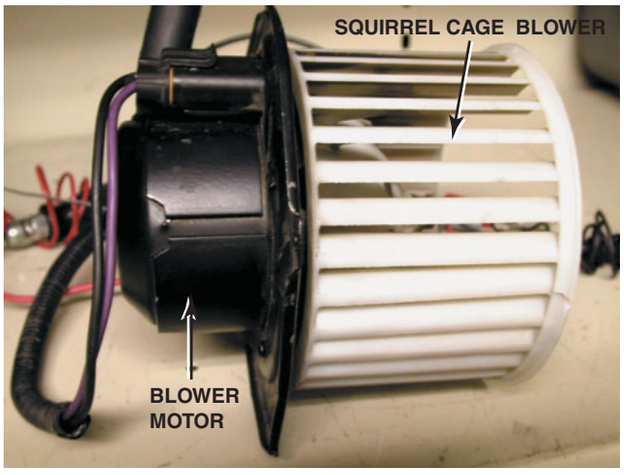

FIGURE 58–18 A squirrel cage blower motor. A replacement blower motor usually does not come equipped with the squirrel cage blower, so it has to be switched from the old motor.

4. Defogging
5. Venting of the passenger compartment

The motor turns a squirrel cage-type fan. A squirrel cage-type fan is able to move air without creating a lot of noise. The fan switch controls the path that the current follows to the blower motor. ● **SEE FIGURE 58–18.**

PARTS AND OPERATION

The motor is usually a permanent magnet, one-speed motor that operates at its maximum speed with full battery voltage. The switch gets current from the fuse panel with the ignition switch on, and then directs full battery voltage to the blower motor for high speed and to the blower motor through resistors for lower speeds.

VARIABLE SPEED CONTROL

The fan switch controls the path of current through a resistor pack to obtain different fan speeds of the blower motor. The electrical path can be:

- Full battery voltage for high-speed operation
- Through one or more resistors to reduce the voltage and the current to the blower motor which then rotates at a slower speed

The resistors are located near the blower motor and mounted in the duct where the airflow from the blower can cool the resistors. The current flow through the resistor is controlled by the switch and often uses a relay to carry the heavy current (10 to 12 amperes) needed to power the fan. Normal operation includes:

- **Low speed.** Current flows through three resistors in series to drop the voltage to about 4 volts and 4 amperes.
- **Medium speed.** Current is directed through two resistors in series to lower the voltage to about 6 volts and 6 amperes.
- **Medium-high speed.** Current is directed through one resistor resulting in a voltage of about 9 volts and 9 amperes.
- **High speed.** Full battery voltage, usually through a relay, is applied to the blower motor resulting in a current of about 12 amperes.

● **SEE FIGURES 58–19 AND 58–20.**

NOTE: Most Ford and some other vehicles place the blower motor resistors on the ground side of the motor circuit. The location of the resistors does not affect the operation because they are connected in series.

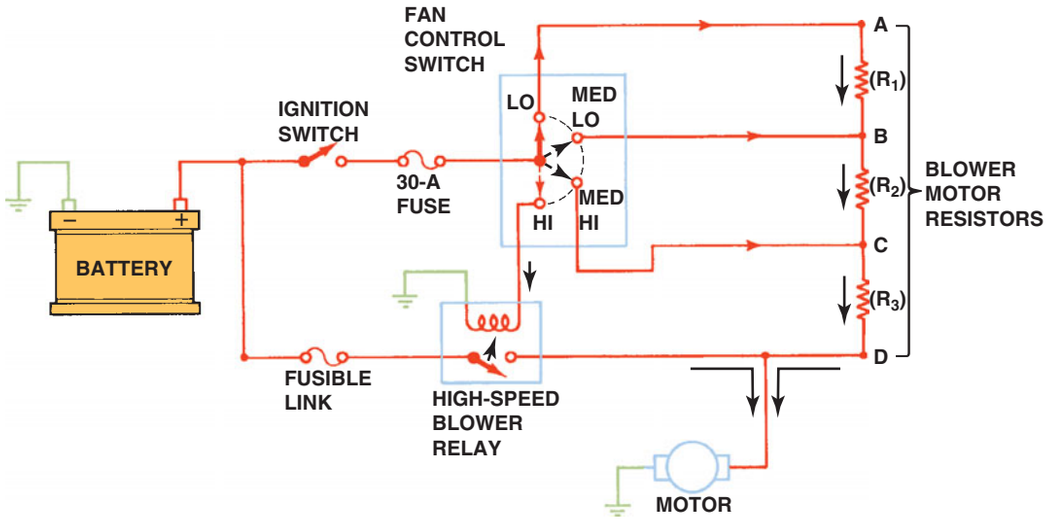

FIGURE 58–19 A typical blower motor circuit with four speeds. The three lowest fan speeds (low, medium-low, and medium-high) use the blower motor resistors to drop the voltage to the motor and reduce current to the motor. On high, the resistors are bypassed. The "high" position on the fan switch energizes a relay, which supplies the current for the blower on high through a fusible link.

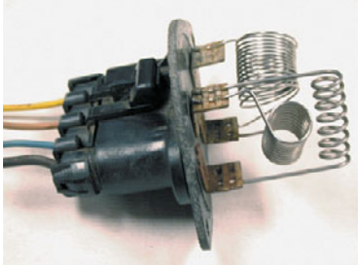

FIGURE 58–20 A typical blower motor resistor pack used to control blower motor speed. Some blower motor resistors are flat and look like a credit card and are called "credit card resistors".

FIGURE 58–21 A brushless DC motor that uses the body computer to control the speed. (*Courtesy of Sammy's Auto Service, Inc.*)

Some blower motors are electronically controlled by the body control module (BCM) and include electronic circuits to achieve a variable speed. ● **SEE FIGURE 58–21.**

BLOWER MOTOR DIAGNOSIS If the blower motor does not operate at any speed, the problem could be any of the following:

1. Defective ground wire or ground wire connection
2. Defective blower motor (not repairable; must be replaced)
3. Open circuit in the power-side circuit, including fuse, wiring, or fan switch

TECH TIP

The 20 Ampere Fuse Test

Most blower motors operate at about 12 A on high speed. If the bushings (bearings) on the armature of the motor become worn or dry, the motor turns more slowly. Because a motor also produces counterelectromotive force (CEMF) as it spins, a slower-turning motor will actually draw more amperes than a fast-spinning motor.

If a blower motor draws too many amperes, the resistors or the electronic circuit controlling the blower motor can fail. Testing the actual current draw of the motor is sometimes difficult because the amperage often exceeds the permissible amount for most digital meters.

One test recommended by General Motors Co. is to unplug the power lead to the motor (retain the ground on the motor) and use a fused jumper lead with one end connected to the battery's positive terminal and the other end to the motor terminal. Use a 20 A fuse in the test lead, and operate the motor for several minutes. If the blower motor is drawing more than 20 A, the fuse will blow. Some experts recommend using a 15 A fuse. If the 15 A fuse blows and the 20 A fuse does not, then you know the approximate blower motor current draw.

If the blower works on lower speeds but not on high speed, the problem is usually an inline fuse or high-speed relay that controls the heavy current flow for high-speed operation. The high-speed fuse or relay usually fails as a result of internal blower motor bushing wear, which causes excessive resistance to motor rotation. At slow blower speeds, the resistance is not as noticeable and the blower operates normally. The blower motor is a sealed unit, and if defective, must be replaced as a unit. The squirrel cage fan usually needs to be removed from the old motor and attached to the replacement motor. If the blower motor operates normally at high speed but not at any of the lower speeds, the problem could be melted wire resistors or a defective switch.

The blower motor can be tested using a clamp-on DC ammeter. **SEE FIGURE 58–22.**

Most blower motors do not draw more than 15 A on high speed. A worn or defective motor usually draws more current than normal and could damage the blower motor resistors or blow a fuse if not replaced.

FIGURE 58–22 Using a mini AC/DC clamp-on multimeter to measure the current draw of a blower motor.

PARTS INVOLVED

Cruise control (also called *speed control*) is a combination of electrical and mechanical components designed to maintain a constant, set vehicle speed without driver pressure on the accelerator pedal. Major components of a typical cruise control system include the following:

1. **Servo unit.** The servo unit attaches to the throttle linkage through a cable or chain.

   The servo unit controls the movement of the throttle by receiving a controlled amount of vacuum from a control module. ● **SEE FIGURE 59–1**.

   Some systems use a stepper motor and do not use engine vacuum.

2. **Computer or cruise control module.** This unit receives inputs from the brake switch, throttle position (TP) sensor, and vehicle speed sensor. It operates the solenoids or stepper motor to maintain the set speed.

3. **Speed set control.** A speed set control is a switch or control located on the steering column, steering wheel, dash, or console. Many cruise control units feature coast, accelerate, and resume functions. ● **SEE FIGURE 59–2**.

4. **Safety release switches.** When the brake pedal is depressed, the cruise control system is disengaged through use of an electrical or vacuum switch, usually located on the brake pedal bracket. Both electrical and vacuum releases are used to be certain that the cruise control system is released, even in the event of failure of one of the release switches.

CRUISE CONTROL OPERATION

A typical cruise control system can be set only if the vehicle speed is 30 mph or more. In a noncomputer-operated system, the transducer contains a low-speed electrical switch that closes when the speed-sensing section of the transducer senses a speed exceeding the minimum engagement speed.

NOTE: Toyota-built vehicles do not retain the set speed in memory if the vehicle speed drops below 25 mph (40 km/h). The driver is required to set the desired speed again. This is normal operation and not a fault with the cruise control system.

When the set button is depressed on the cruise control, solenoid values on the servo unit allow engine vacuum to be applied to one side of the diaphragm, which is attached to the throttle plate of the engine through a cable or linkage. The servo unit usually contains two solenoids to control the opening and closing of the throttle.

- One solenoid opens and closes to control the passage, which allows engine vacuum to be applied to the diaphragm of the servo unit, increasing the throttle opening.
- One solenoid bleeds air back into the sensor chamber to reduce the throttle opening.

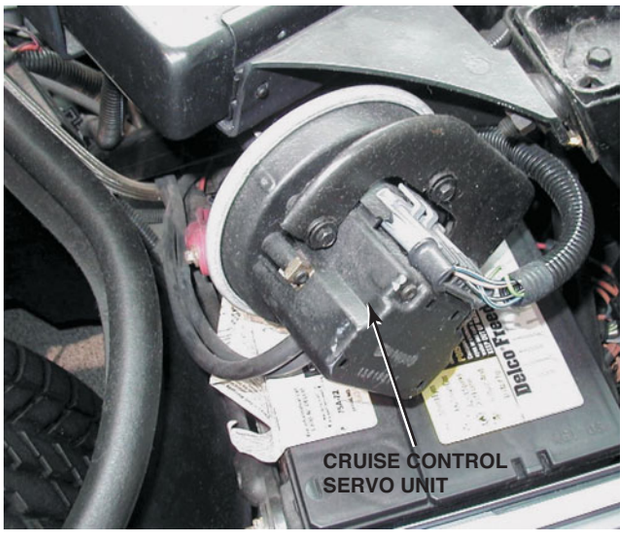

FIGURE 59–1 This cruise control servo unit has an electrical connection with wires that go to the cruise control module or the vehicle computer, depending on the vehicle. The vacuum hoses supply engine manifold vacuum to the rubber diaphragm that moves the throttle linkage to maintain the preset speed.

FIGURE 59–2 A cruise control used on a Toyota/Lexus.

WARNING

Most vehicle manufacturers warn in the owner manual that cruise control should not be used when it is raining or if the roads are slippery. Cruise control systems operate the throttle and, if the drive wheels start to hydroplane, the vehicle slows, causing the cruise control unit to accelerate the engine. When the engine is accelerated and the drive wheels are on a slippery road surface, vehicle stability will be lost and might possibly cause a crash.

TECH TIP

Bump Problems

Cruise control problem diagnosis can involve a complex series of checks and tests. The troubleshooting procedures vary among manufacturers (and year), so a technician should always consult a service manual for the exact vehicle being serviced. However, every cruise control system uses a brake safety switch and, if the vehicle has manual transmission, a clutch safety switch. The purpose of these safety switches is to ensure that the cruise control system is disabled if the brakes or the clutch is applied. Some systems use redundant brake pedal safety switches, one electrical to cut off power to the system and the other a vacuum switch used to bleed vacuum from the actuating unit.

If the cruise control "cuts out" or disengages itself while traveling over bumpy roads, the most common cause is a misadjusted brake (and/or clutch) safety switch(es). Often, a simple readjustment of these safety switches will cure the intermittent cruise control disengagement problems.

CAUTION: Always follow the manufacturer's recommended safety switch adjustment procedures. If the brake safety switch(es) is misadjusted, it could keep pressure applied to the master brake cylinder, resulting in severe damage to the braking system.

The throttle position (TP) sensor or a position sensor, inside the servo unit, sends the throttle position information to the cruise control module.

Most computer-controlled cruise control systems use the vehicle's speed sensor input to the engine control computer for speed reference. Computer-controlled cruise control units also use servo units for throttle control, control switches for driver control of cruise control functions, and both electrical and vacuum brake pedal release switches. ● **SEE FIGURE 59–3.**

TROUBLESHOOTING CRUISE CONTROL

Cruise control system troubleshooting is usually performed using the step-by-step procedure as specified by the vehicle manufacturer.

The usual steps in the diagnosis of an inoperative or incorrectly operating mechanical-type cruise control include the following:

STEP 1 Use a factory or enhanced scan tool to retrieve any cruise control diagnostic trouble codes (DTCs). Perform bidirectional testing if possible using the scan tool.

STEP 2 Check that the cruise control fuse is not blown and that the cruise control dash light is on when the cruise control is turned on.

STEP 3 Check for proper operation of the brake and/or clutch switch.

TECH TIP

Check the Third Brake Light

On many General Motors vehicles, the cruise control will not work if the third brake light is out. This third brake light is called the **center high-mounted stop light (CHMSL).** Always check the brake lights first if the cruise control does not work on a General Motors vehicle.

STEP 4 Inspect the throttle cable and linkage between the sensor unit and the throttle plate for proper operation without binding or sticking.

STEP 5 Check the vacuum hoses for cracks or other faults.

STEP 6 Check that the vacuum servo unit (if equipped), using a hand-operated vacuum pump, can hold vacuum without leaking.

STEP 7 Check the servo solenoids for proper operation, including a resistance measurement check.

ELECTRONIC THROTTLE CRUISE CONTROL

PARTS AND OPERATION Many vehicles are equipped with an **electronic throttle control (ETC)** system. Vehicles equipped with such a system do not use throttle actuators for the cruise control. The ETC system operates the throttle under all engine operating conditions. An ETC system uses a DC electric motor to move the throttle plate that is spring loaded to a partially open position. The motor actually closes the throttle at idle against spring pressure. The spring-loaded position is the default position and results in a high idle speed. The powertrain control module (PCM) uses the input signals from the *accelerator pedal position (APP)* sensor to determine the desired throttle position. The PCM then commands the throttle to the necessary position of the throttle plate. ● **SEE FIGURE 59–4.**

The cruise control on a vehicle equipped with an electronic throttle control system consists of a switch to set the desired speed. The PCM receives the vehicle speed information from the vehicle speed (VS) sensor and uses the ETC system to maintain the set speed.

DIAGNOSIS AND SERVICE Any fault in the APP sensor or ETC system will disable the cruise control function. Always follow the specified troubleshooting procedures, which will usually include the use of a scan tool to properly diagnose the ETC system.

RADAR CRUISE CONTROL

PURPOSE AND FUNCTION The purpose of a radar cruise control system is to give the driver more control over the vehicle by keeping an assured clear distance behind the vehicle in front. If the vehicle in front slows, the radar cruise control detects the slowing vehicle and automatically reduces the speed of the vehicle to keep a safe distance. Then if the vehicle speeds up, the radar cruise control also allows the vehicle to increase to the preset speed. This makes driving in congested areas easier and less tiring.

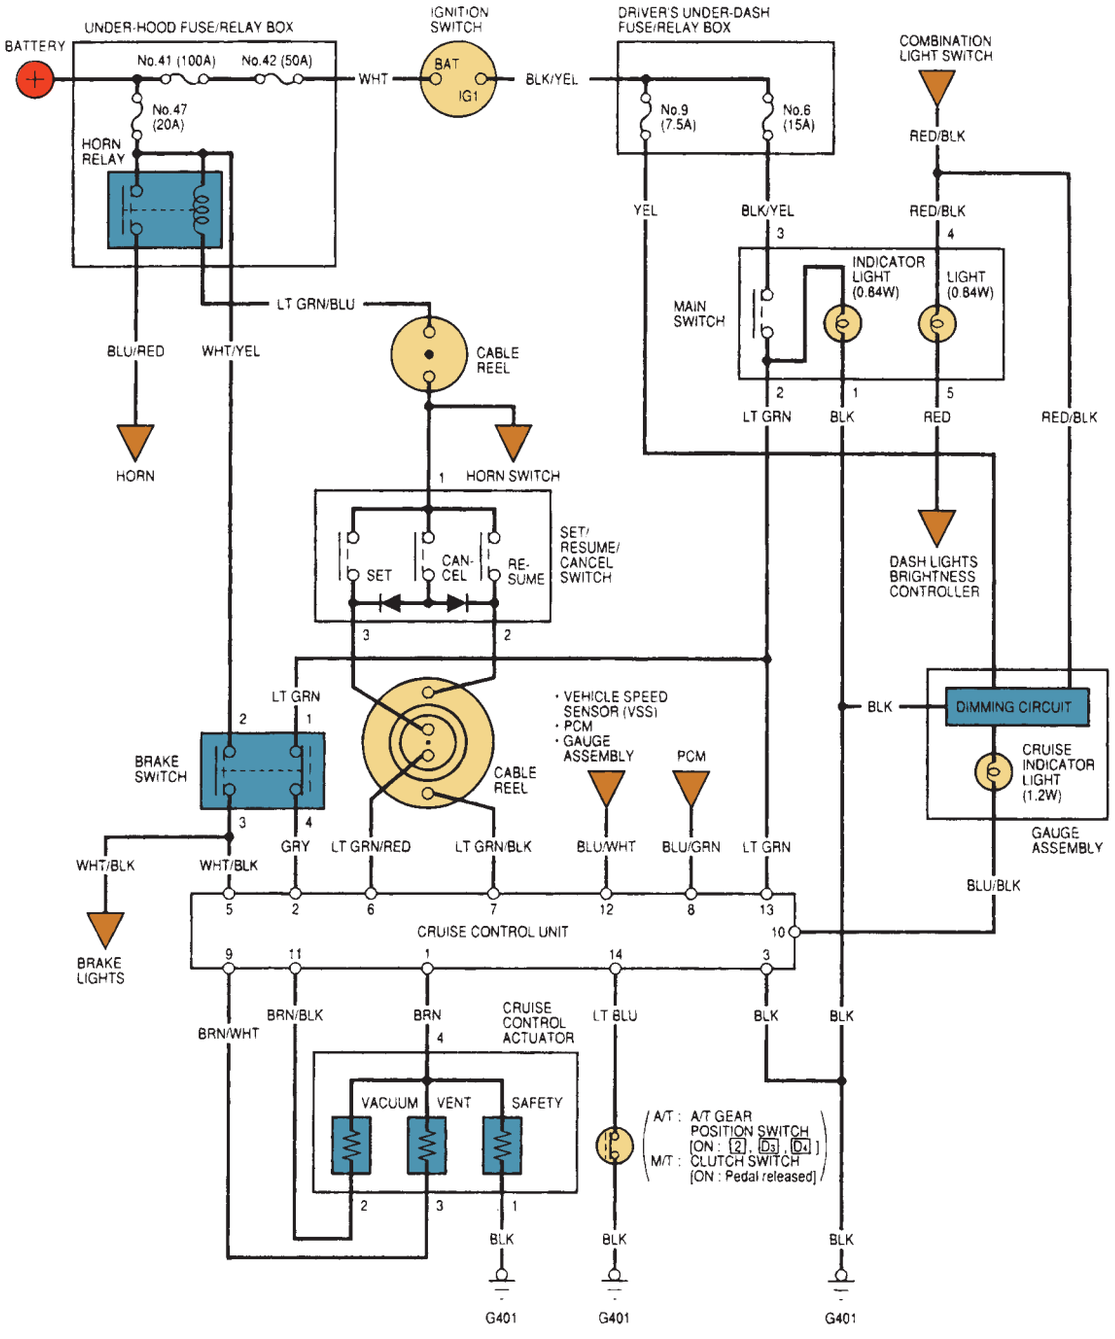

FIGURE 59–3 Circuit diagram of a typical electronic cruise control system.

FIGURE 59–4 A typical electronic throttle with the protective covers removed.

TECH TIP

Use Trailer Tow Mode

Some customers complain that when using cruise control while driving in hilly or mountainous areas that the speed of the vehicle will sometimes go 5 to 8 mph below the set speed. The automatic transmission then downshifts, the engine speed increases, and the vehicle returns to the set speed. To help avoid the slowdown and rapid acceleration, ask the customer to select the trailer towing position. When this mode is selected, the automatic transmission downshifts almost as soon as the vehicle speed starts to decrease. This results in a smoother operation and is less noticeable to both the driver and passengers. ● **SEE FIGURE 59–5.**

TERMINOLOGY Depending on the manufacturer, radar cruise control is also referred to as the following:

- **Adaptive cruise control** (Audi, Ford, General Motors, and Hyundai)
- **Dynamic cruise control** (BMW, Toyota/Lexus)
- **Active cruise control** (Mini Cooper, BMW)
- **Autonomous cruise control** (Mercedes)

It uses forward-looking radar to sense the distance to the vehicle in front and maintains an assured clear distance. This type of cruise control system works within the following conditions.

1. Speeds from 20 to 100 mph (30 to 161 km/h)
2. Designed to detect objects as far away as 500 ft (150 m)

The cruise control system is able to sense both distance and relative speed. ● **SEE FIGURE 59–6.**

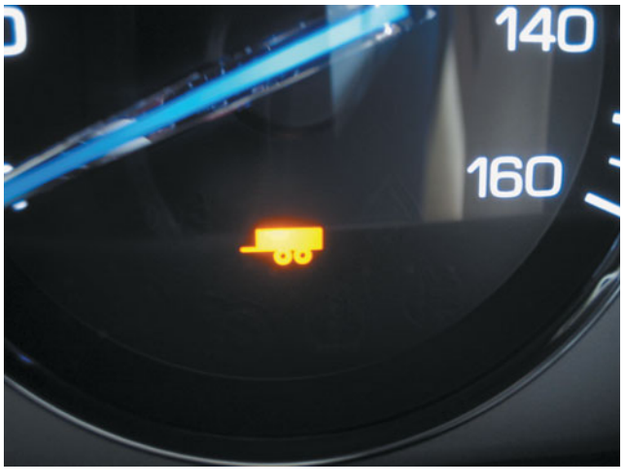

FIGURE 59–5 A trailer icon lights on the dash of this Cadillac when the transmission trailer towing mode is selected.

PARTS AND OPERATION Radar cruise control systems use long-range radar (LRR) to detect faraway objects in front of the moving vehicle. Some systems use a short-range radar (SRR) and/or infrared (IR) or optical cameras to detect distances for when the distance between the moving vehicle and another vehicle in front is reduced. ● **SEE FIGURE 59–7.**

The radar frequencies include:

- 76 to 77 GHz (long-range radar)
- 24 GHz (short-range radar)

? FREQUENTLY ASKED QUESTION

Will Radar Cruise Control Set Off My Radar Detector?

It is doubtful. The radar used for radar cruise control systems operates on frequencies that are not detectable by police radar detector units. Cruise control radar works on the following frequencies.

- 76 to 77 GHz (long range)
- 24 GHz (short range)

The frequencies used for the various types of police radar include:

- X-band: 8 to 12 GHz
- K-band: 24 GHz
- Ka-band: 33 to 36 GHz

The only time there may be interference is when the radar cruise control, as part of a precollision system, starts to use short-range radar (SRR) in the 24 GHz frequency. This would trigger the radar detector but would be an unlikely event and just before a possible collision with a vehicle coming toward you.

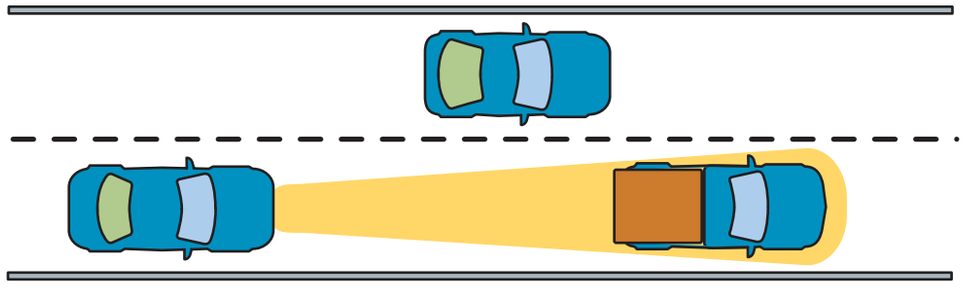

FIGURE 59–6 Radar cruise control uses sensors to keep the distance the same even when traffic slows ahead.

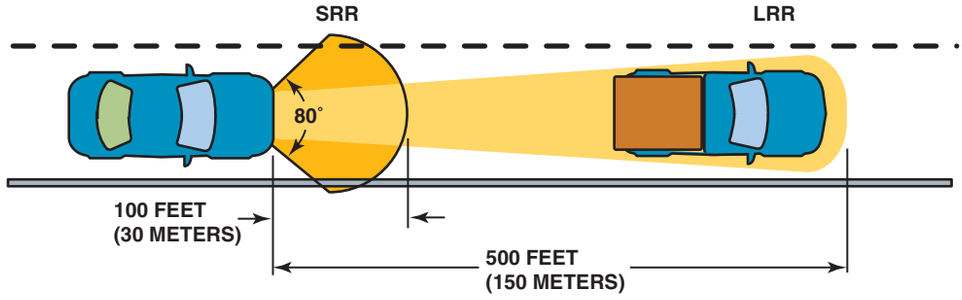

FIGURE 59–7 Most radar cruise control systems use radar, both long and short range. Some systems use optical or infrared cameras to detect objects.

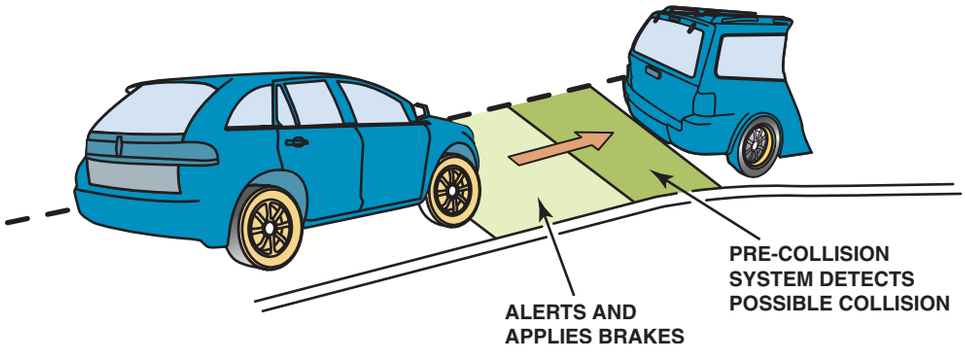

FIGURE 59–8 A precollision system is designed to prevent a collision first, and then interacts to prepare for a collision if needed.

PRECOLLISION SYSTEM

PURPOSE AND FUNCTION The purpose and function of a precollision system is to monitor the road ahead and prepare to avoid a collision, and to protect the driver and passengers. A precollision system uses components of the following systems.

1. The long-range and short-range radar or detection systems used by a radar cruise control system to detect objects in front of the vehicle
2. Antilock brake system (ABS)
3. Adaptive (radar) cruise control
4. Brake assist system

TERMINOLOGY Precollision systems can be called various names depending on the make of the vehicle. Some commonly used names for a precollision or precrash system include:

- **Ford/Lincoln:** Collision Warning with Brake Support
- **Honda/Acura:** Collision Mitigation Brake System (CMBS)
- **Mercedes-Benz:** Pre-Safe or Attention Assist
- **Toyota/Lexus:** Pre-Collision System (PCS) or Advanced Pre-Collision System (APCS)
- **General Motors:** Pre-Collision System (PCS)
- **Volvo:** Collision Warning with Brake Support or Collision Warning with Brake Assist

OPERATION The system functions by monitoring objects in front of the vehicle and can act to avoid a collision by the following actions.

- Sounds an alarm
- Flashes a warning lamp
- Applies the brakes and brings the vehicle to a full stop (if needed), if the driver does not react

SEE FIGURE 59–8.

If the system is unable to prevent a collision, the system will perform the following actions.

1. Apply the brakes full force to reduce vehicle speed as much as possible
2. Close all windows and the sunroof to prevent the occupants from being ejected from the vehicle
3. Move the seats to an upright position

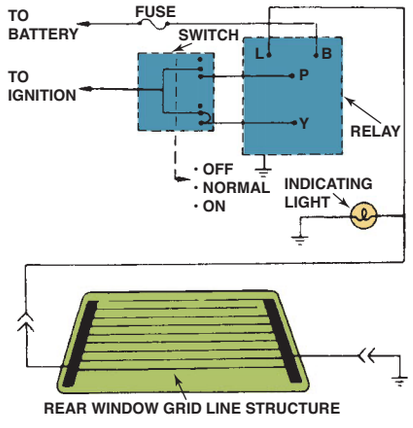

FIGURE 59–9 A switch and relay control current through the heating grid of a rear window defogger.

HEATED REAR WINDOW DEFOGGERS

PARTS AND OPERATION An electrically heated rear window defogger system uses an electrical grid baked on the glass that warms the glass to about 85°F (29°C) and clears it of fog or frost. The rear window is also called a **backlight.** The rear window defogger system is controlled by a driver-operated switch and a timer relay.

SEE FIGURE 59–9.

The timer relay is necessary because the window grid can draw up to 30 A, and continued operation would put a strain on the battery and the charging system. Generally, the timer relay permits current to flow through the rear window grid for only 10 minutes. If the window is still not clear of fog after 10 minutes, the driver can turn the defogger on again, but after the first 10 minutes any additional defogger operation is limited to 5 minutes.

PRECAUTION Electric grid-type rear window defoggers can be damaged easily by careless cleaning or scraping of the inside of the rear window glass. Short, broken sections of the rear window grid can be repaired using a special epoxy-based electrically conductive

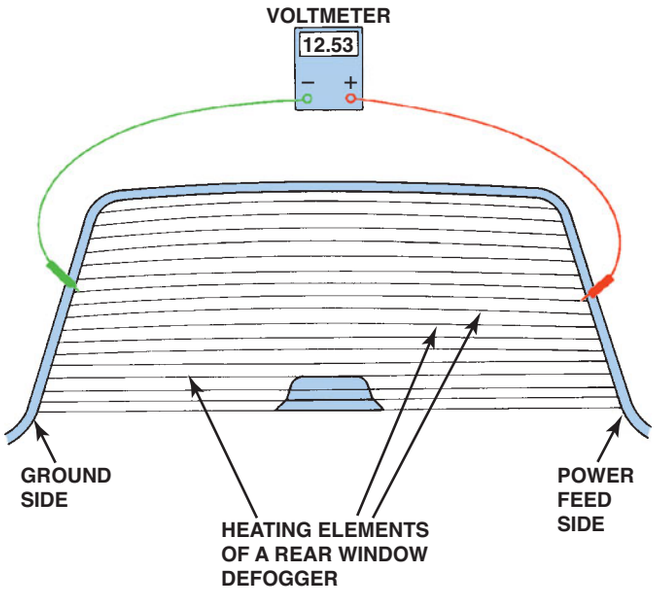

FIGURE 59–10 A rear window defogger electrical grid can be tested using a voltmeter to check for a decreasing voltage as the meter lead is moved from the power side toward the ground side. As the voltmeter positive lead is moved along the grid (on the inside of the vehicle), the voltmeter reading should steadily decrease as the meter approaches the ground side of the grid.

material. If more than one section is damaged or if the damaged grid length is greater than approximately 1.5 in. (3.8 cm), a replacement rear window glass may be required to restore proper defogger operation.

The electrical current through the grids depends, in part, on the temperature of the conductor grids. As the temperature decreases, the resistance of the grids decreases and the current flow increases, helping to warm the rear glass. As the temperature of the glass increases, the resistance of the conductor grids increases and the current flow decreases. Therefore, the defogger system tends to self-regulate the electrical current requirements to match the need for defogging.

NOTE: Some vehicles use the wire grid of the rear window defogger as the radio antenna. Therefore, if the grid is damaged, radio reception can also be affected.

HEATED REAR WINDOW DEFOGGER DIAGNOSIS

Troubleshooting a nonfunctioning rear window defogger unit involves using a test light or a voltmeter to check for voltage to the grid. If no voltage is present at the rear window, check for voltage at the switch and relay timer assembly. A poor ground connection on the opposite side of the grid from the power side can also cause the rear defogger not to operate. Because most defogger circuits use an indicator light switch and a relay timer, it is possible to have the indicator light on, even if the wires are disconnected at the rear window grid. A voltmeter can be used to test the operation of the rear window defogger grid. ● **SEE FIGURE 59–10.**

With the negative test terminal attached to a good body ground, carefully probe the grid conductors. There should be a decreasing voltage reading as the probe is moved from the power ("hot") side of the grid toward the ground side of the grid.

REPAIR OR REPLACEMENT

If there is a broken grid wire, it can be repaired using an electrically conductive substance available in a repair kit.

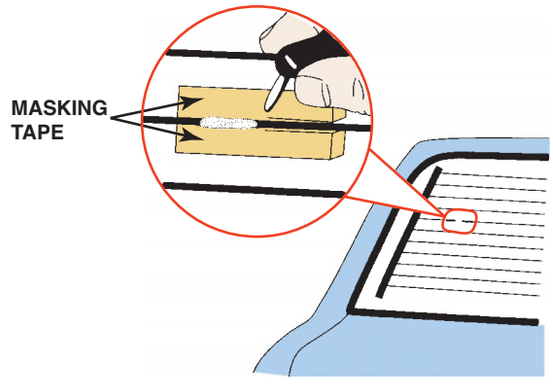

FIGURE 59–11 The typical repair material contains conductive silver-filled polymer, which dries in 10 minutes and is usable in 30 minutes.

TECH TIP

The Breath Test

It is difficult to test for the proper operation of all grids of a rear window defogger unless the rear window happens to be covered with fog. A common trick that works is to turn on the rear defogger and exhale onto the outside of the rear window glass. In a manner similar to that of people cleaning eyeglasses with their breath, this procedure produces a temporary fog on the glass so that all sections of the rear grids can quickly be checked for proper operation.

Most vehicle manufacturers recommend that grid wire less than 2 in. (5 cm) long be repaired. If a bad section is longer than 2 in., the entire rear window will need to be replaced. ● **SEE FIGURE 59–11.**

HEATED MIRRORS

PURPOSE AND FUNCTION

The purpose and function of heated outside mirrors is to heat the surface of the mirror, which evaporates moisture on the surface. The heat helps keep ice and fog off the mirrors, to allow for better driver visibility.

PARTS AND OPERATION

Heated outside mirrors are often tied into the same electrical circuit as the rear window defogger. Therefore, when the rear defogger is turned on, the heating grid on the backside of the mirror is also turned on. Some vehicles use a switch for each mirror.

DIAGNOSIS

The first step in any diagnosis procedure is to verify the customer concern. Check the owner's manual or service information for the proper method to use to turn on the heated mirrors.

NOTE: Heated mirrors are not designed to melt snow or a thick layer of ice.

If a fault has been detected, follow service information instructions for the exact procedure to follow. If the mirror itself is found to be defective, it is usually replaced as an assembly instead of being repaired.

FIGURE 59–12 Typical HomeLink garage door opener buttons. Notice that three different units can be controlled from the vehicle using the HomeLink system.

HOMELINK GARAGE DOOR OPENER

OPERATION

HomeLink is a device installed in many new vehicles that duplicates the radio-frequency code of the original garage door opener. The frequency range which HomeLink is able to operate is 288 to 418 MHz. The typical vehicle garage door opening system has three buttons that can be used to operate one or more of the following devices.

1. Garage doors equipped with a radio transmitter electric opener
2. Gates
3. Entry door locks
4. Lighting or small appliances

The devices include both fixed-frequency devices, usually older units, and rolling (encrypted) code devices. ● **SEE FIGURE 59–12.**

PROGRAMMING A VEHICLE GARAGE DOOR OPENER

When a vehicle is purchased, it must be programmed using the transmitter for the garage door opener or other device.

NOTE: The HomeLink garage door opening controller can only be programmed by using a transmitter. If an automatic garage door system does not have a remote transmitter, HomeLink cannot be programmed.

Normally, the customer is responsible for programming the HomeLink to the garage door opener. However, some customers may find that help is needed from the service department. The steps that are usually involved in programming HomeLink in the vehicle to the garage door opener are as follows:

STEP 1 Unplug the garage door opener during programming to prevent it from being cycled on and off, which could damage the motor.

STEP 2 Check that the frequency of the handheld transmitter is between 288 and 418 MHz.

STEP 3 Install new batteries in the transmitter to be assured of a strong signal being transmitted to the HomeLink module in the vehicle.

STEP 4 Turn the ignition on, engine off (KOEO).

STEP 5 While holding the transmitter 4 to 6 in. away from the HomeLink button, press and hold the HomeLink button while pressing and releasing the handheld transmitter every two seconds. Continue pressing and releasing the transmitter until the indicator light near the HomeLink button changes from slow blink to a rapid flash.

STEP 6 Verify that the vehicle garage door system (HomeLink) button has been programmed. Press and hold the garage door button. If the indicator light blinks rapidly for two seconds and then comes on steady, the system has been successfully programmed using a rolling code design. If the indicator light is on steady, then it has been successfully programmed to a fixed-frequency device.

DIAGNOSIS AND SERVICE

If a fault occurs with the HomeLink system, first verify that the garage door opener is functioning correctly. Also, check if the garage door opener remote control is capable of operating the door. Repair the garage door opener system as needed.

If the problem still exists, attempt reprogramming the HomeLink vehicle system, being sure that the remote has a newly purchased battery.

POWER WINDOWS

SWITCHES AND CONTROLS

Power windows use electric motors to raise and lower door glass. They can be operated by both a **master control switch** located beside the driver and additional **independent switches** for each electric window. Some power window systems use a **lockout switch** located on the driver's controls to prevent operation of the power windows from the independent switches. Power windows are designed to operate only with the ignition switch in the on (run) position, although some manufacturers use a time delay for accessory power after the ignition switch is turned off. This feature permits the driver and passengers an opportunity to close all windows or operate other accessories for about 10 minutes or until a vehicle door is opened after the ignition has been turned off. This feature is often called *retained accessory power.*

POWER WINDOW MOTORS

Most power window systems use **permanent magnet (PM) electric motors.** It is possible to run a PM motor in the reverse direction simply by reversing the polarity of the two wires going to the motor. Most power window motors do not require that the motor be grounded to the body (door) of the vehicle. The ground for all the power windows is most often centralized near the driver's master control switch. The up-and-down motion of the individual window motors is controlled by double-pole, double-throw (DPDT) switches. These DPDT switches have five contacts and permit battery voltage to be applied to the power window motor, as well as reverse the polarity and direction of the motor. Each motor is protected by an electronic circuit breaker. These circuit breakers are built into the motor assembly and are not a separate replaceable part. ● **SEE FIGURE 59–13.**

The power window motors rotate a mechanism called a **window regulator.** The window regulator is attached to the door glass and controls opening and closing of the glass. Door glass adjustments such as glass tilt and upper and lower stops are usually the same for both power and manual windows. ● **SEE FIGURE 59–14.**

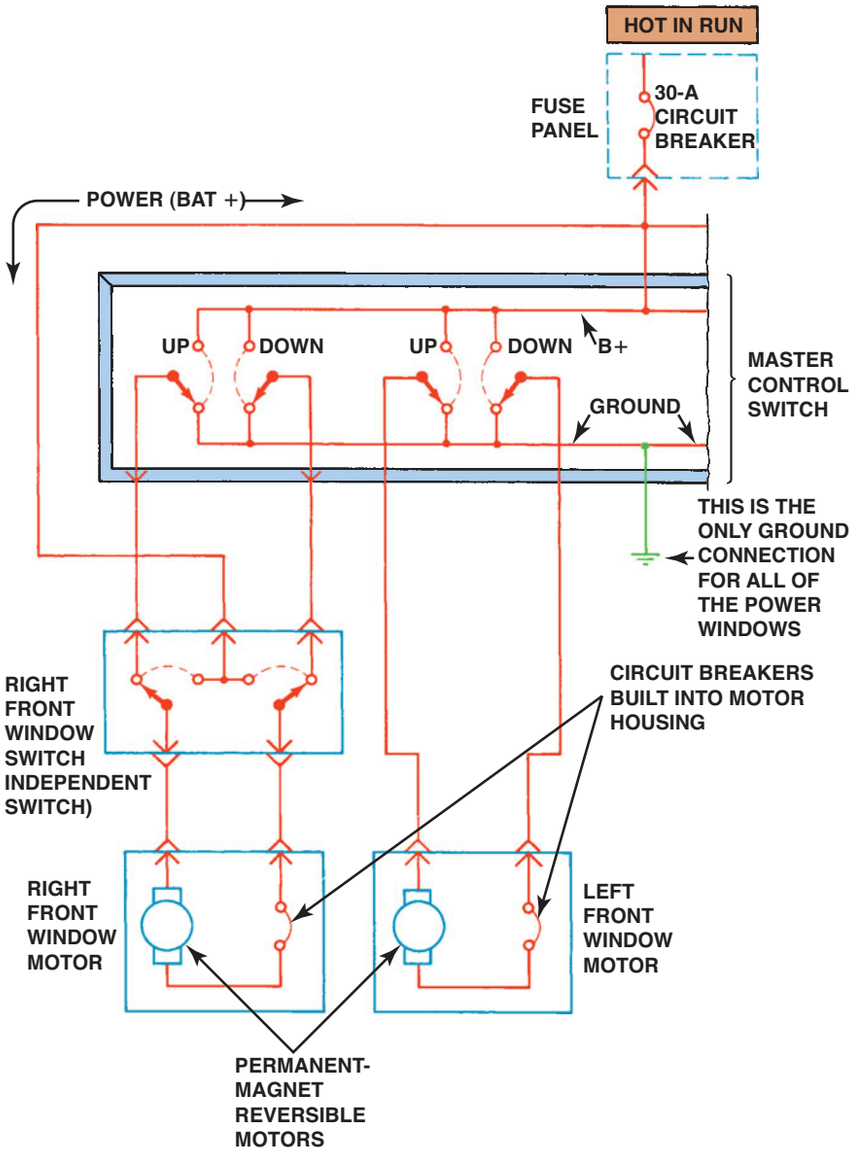

FIGURE 59–13 A typical power window circuit using PM motors. Control of the direction of window operation is achieved by directing the polarity of the current through the nongrounded motors. The only ground for the entire system is located at the master control (driver's side) switch assembly.

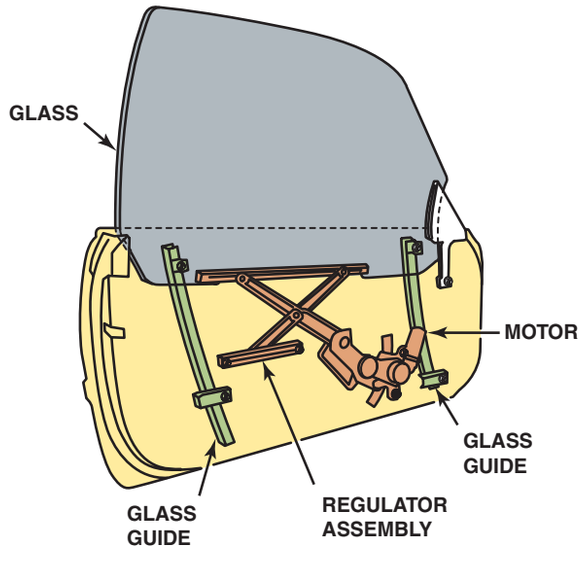

FIGURE 59–14 An electric motor and a regulator assembly raise and lower the glass on a power window.

AUTO DOWN/UP FEATURES Many power windows are equipped with an auto down feature that allows windows to be lowered all of the way if the control switch is moved to a detent or held down for longer than 0.3 second. The window will then move down all the way to the bottom, and then the motor stops.

Many vehicles are equipped with the auto up feature that allows the driver to raise the driver's side or all windows in some cases, with just one push of the button. A sensor in the window motor circuit measures the current through the motor. The circuit is opened if the window touches an object, such as a hand or finger. When the window reaches the top or hits an object, the current through the window motor increases. When the upper limit amperage draw is reached, the motor circuit is opened and the window either stops or reverses. Most newer power windows use network communications modules to operate the power windows, and the switches are simply voltage signals to the module which supplies current to the individual window motors. ● **SEE FIGURE 59–15.**

TROUBLESHOOTING POWER WINDOWS Before troubleshooting a power window problem, check for proper operation of all power windows. Check service information for the exact procedure

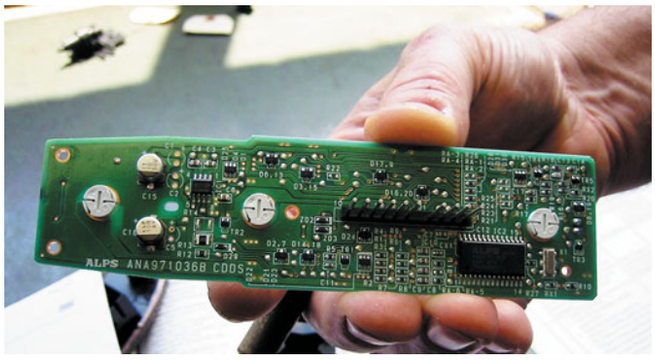

FIGURE 59–15 A master power window control panel with the buttons and the cover removed.

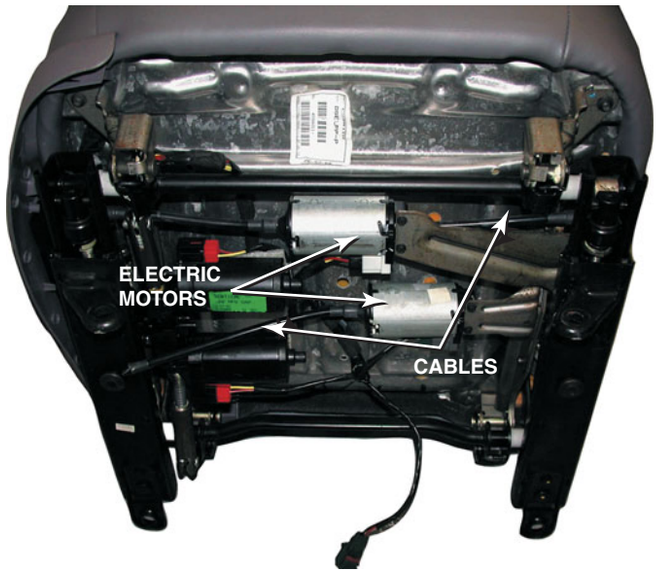

FIGURE 59–16 A power seat uses electric motors under the seat, which drive cables that extend to operate screw jacks (up and down) or gears to move the seat forward and back.

TECH TIP

Programming Auto Down Power Windows

Many vehicles are equipped with automatic operation that can cause the window to go all the way down (or up) if the switch is depressed beyond a certain point or held for a fraction of a second. Sometimes this feature is lost if the battery in the vehicle has been disconnected. Although this programming procedure can vary depending on the make and model, many times the window(s) can be reprogrammed without using a scan tool by simply depressing and holding the down button for 10 seconds. If the vehicle is equipped with an auto up feature, repeat the procedure by holding the button up for 10 seconds. Always check service information for the vehicle being serviced.

to follow. In a newer system, a scan tool can be used to perform the following:

- Check for B (body) or U (network) diagnostic trouble codes (DTCs)
- Operate the power windows using the bidirectional control feature
- Relearn or program the operation of the power windows after a battery disconnect

For older systems, if one of the **control wires** that run from the independent switch to the master switch is cut (open), the power window may operate in only one direction. The window may go down but not up, or vice versa. However, if one of the **direction wires** that run from the independent switch to the motor is cut (open), the window will not operate in either direction. The direction wires and the motor must be electrically connected to permit operation and change of direction of the electric lift motor in the door.

1. If *both* rear door windows fail to operate from the independent switches, check the operation of the window lockout (if the vehicle is so equipped) and the master control switch.
2. If one window can move in one direction only, check for continuity in the control wires (wires between the independent control switch and the master control switch).
3. If *all* windows fail to work or fail to work occasionally, check, clean, and tighten the ground wire(s) located either behind the driver's interior door panel or under the dash on the driver's side. A defective fuse or circuit breaker could also cause all the windows to fail to operate.
4. If one window fails to operate in both directions, the problem could be a defective window lift motor. The window could be stuck in the track of the door, which could cause the circuit breaker built into the motor to open the circuit to protect the wiring, switches, and motor from damage. To check for a stuck door glass, attempt to move (even slightly) the door glass up and down, forward and back, and side to side. If the window glass can move slightly in all directions, the power window motor should be able to at least move the glass.
5. Always refer to and follow service information when diagnosing power window circuits.

POWER SEATS

PARTS AND OPERATION A typical power-operated seat includes a reversible electric motor and a transmission assembly that may have three solenoids and six *drive cables* that turn the six seat adjusters. A six-way power seat offers seat movement forward and backward, plus seat cushion movement up and down at the front and the rear. The drive cables are similar to speedometer cables because they rotate inside a cable housing and connect the power output of the seat transmission to a gear or screw jack assembly that moves the seat. ● **SEE FIGURE 59–16.**

A **screw jack assembly** is often called a *gear nut.* It is used to move the front or back of the seat cushion up and down.

A **rubber coupling,** usually located between the electric motor and the transmission, and prevents electric motor damage in the event of a jammed seat. This coupling is designed to prevent motor damage.

Most power seats use a permanent magnet motor that can be reversed by simply reversing the polarity of the current sent to the motor by the seat switch. ● **SEE FIGURE 59–17.**

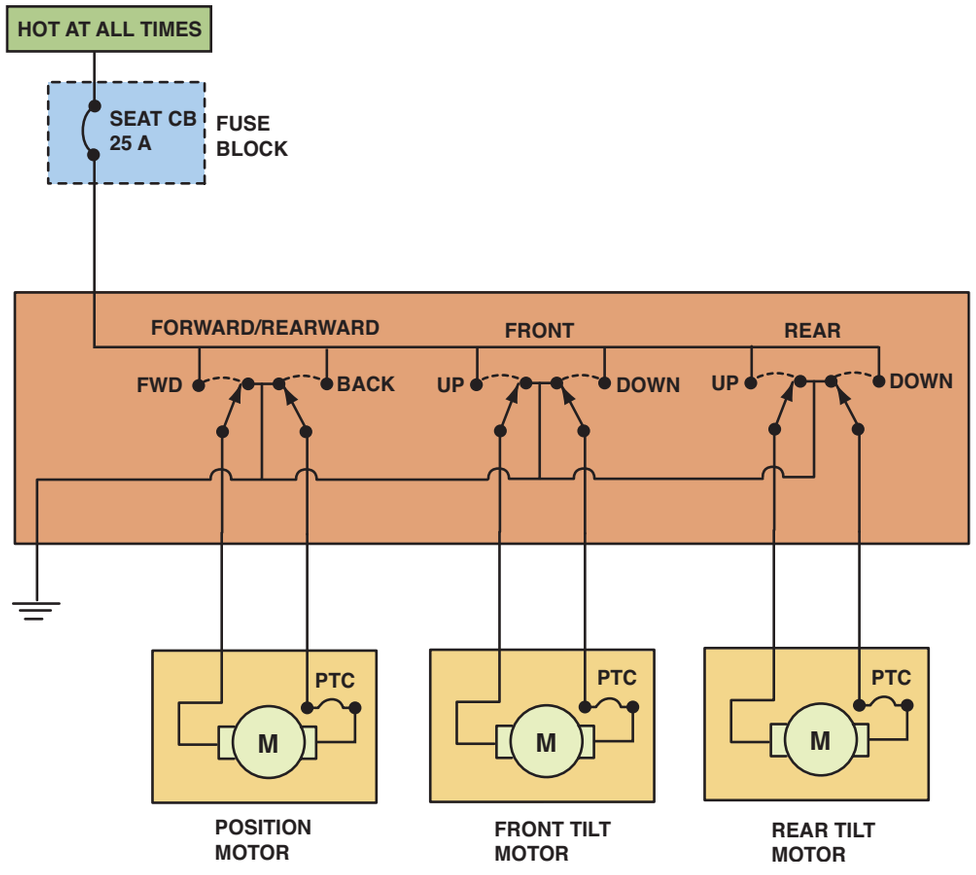

FIGURE 59–17 A typical power seat circuit diagram. Notice that each motor has a built-in electronic (solid-state) PTC circuit protector. The seat control switch can change the direction in which the motor(s) runs by reversing the direction in which the current flows through the motor.

POWER SEAT MOTOR(S) Most PM motors have a built-in circuit breaker or PTC circuit protector to protect the motor from overheating. Many Ford power seat motors use three separate armatures inside one large permanent magnet field housing. Some power seats use a series-wound electric motor with two separate field coils, one field coil for each direction of rotation. This type of power seat motor typically uses a relay to control the direction of current from the seat switch to the corresponding field coil of the seat motor. This type of power seat can be identified by the "click" heard when the seat switch is changed from up to down or front to back, or vice versa. The click is the sound of the relay switching the field coil current. Some power seats use as many as eight separate PM motors that operate all functions of the seat, including headrest height, seat length, and side bolsters, in addition to the usual six-way power seat functions.

NOTE: Some power seats use a small air pump to inflate a bag (or bags) in the lower part of the back of the seat, called the lumbar, because it supports the lumbar section of the spine. The lumbar section of the seat can also be changed, using a lever or knob that the driver can move to change the seat section for the lower back.

MEMORY SEAT Memory seats use a potentiometer to sense the position of the seat. The seat position can be programmed into the body control module (BCM) or memory seat module and stored by position number 1, 2, or 3. The driver pushes the desired button and the seat moves to the stored position. ● **SEE FIGURE 59–18** on page 668.

TECH TIP

Easy Exit Seat Programming

Some vehicles are equipped with memory seats that allow the seat to move rearward when the ignition is turned off to allow easy exit from the vehicle. Vehicles equipped with this feature include an *exit/entry* button that is used to program the desired exit/entry position of the seat for each of two drivers.

If the vehicle is not equipped with this feature and only one driver primarily uses the vehicle, the second memory position can be programmed for easy exit and entry. Simply set position 1 to the desired seat position and position 2 to the entry/exit position. Then, when exiting the vehicle, press memory 2 to allow easy exit and easy entry the next time. Press memory 1 when in the vehicle to return the seat memory to the desired driving position.

On some vehicles, the memory seat position is also programmed into the remote keyless entry key fob.

TROUBLESHOOTING POWER SEATS Power seats are usually wired from the fuse panel so they can be operated without having to turn the ignition switch to on (run). If a power seat does not

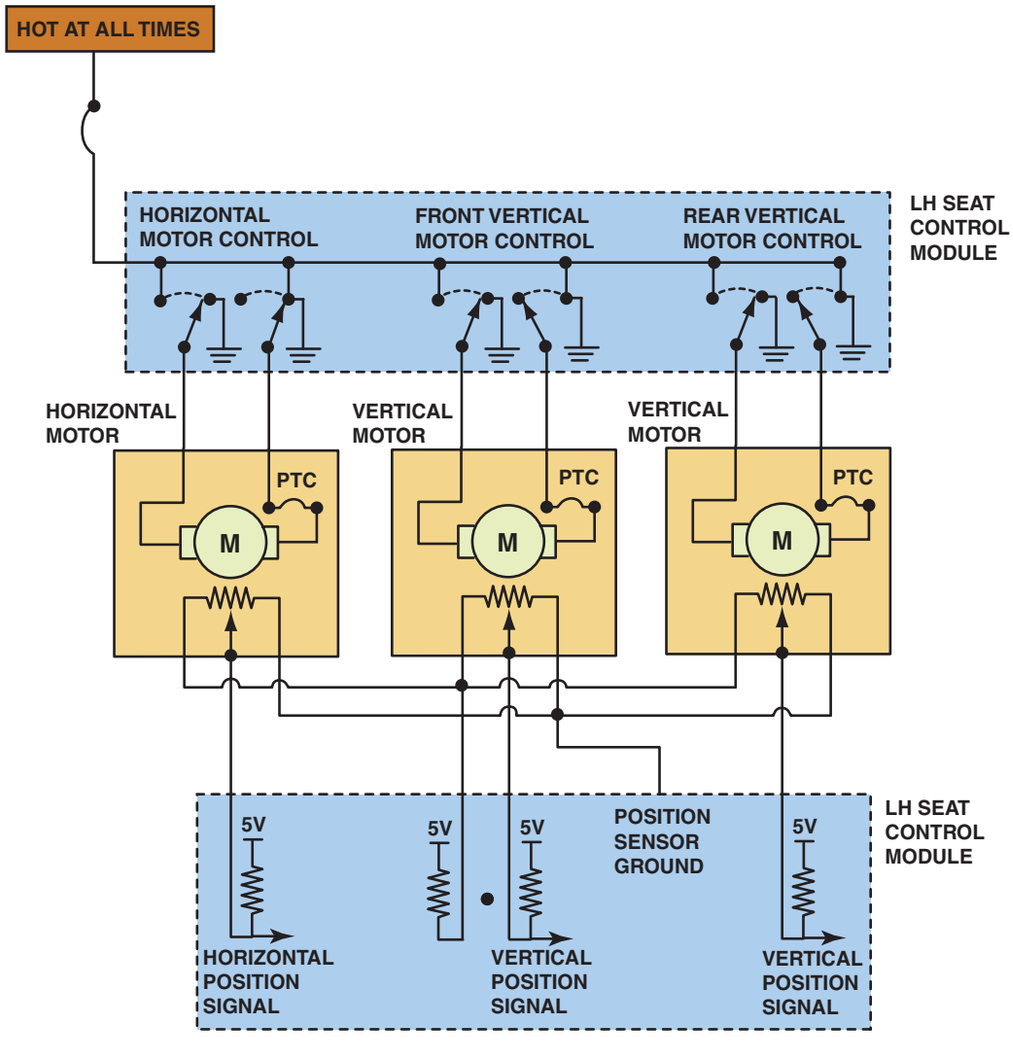

FIGURE 59–18 A typical memory seat module showing the three-wire potentiometer used to determine seat position.

TECH TIP

What Every Driver Should Know About Power Seats

Power seats use an electric motor or motors to move the position of the seat. These electric motors turn small cables that operate mechanisms that move the seat. *Never* place rags, newspapers, or any other object under a power seat. Even ice scrapers can get caught between moving parts of the seat and can often cause serious damage or jamming of the power seat.

operate or make any noise, the circuit breaker (or fuse, if the vehicle is so equipped) should be checked first. The steps usually include:

STEP 1 Check service information for the exact procedure to follow when diagnosing power seats. If the seat relay clicks, the circuit breaker is functioning, but the relay or electric motor may be defective.

STEP 2 Remove the screws or clips that retain the controls to the inner door panel or seat and check for voltage at the seat control.

STEP 3 Check the ground connection(s) at the transmission and clutch control solenoids (if equipped). The solenoids must be properly grounded to the vehicle body for the power seat circuit to operate.

If the power seat motor runs but does not move the seat, the most likely fault is a worn or defective rubber clutch sleeve between the electric seat motor and the transmission.

If the seat relay clicks but the seat motor does not operate, the problem is usually a defective seat motor or defective wiring between the motor and the relay. If the power seat uses a motor relay, the motor has a double reverse-wound field for reversing the motor direction. This type of electric motor must be properly grounded. Permanent magnet motors do not require grounding for operation.

NOTE: Power seats are often difficult to service because of restricted working room. If the entire seat cannot be removed from the vehicle because the track bolts are covered, attempt to remove the seat from the top of the power seat assembly. These bolts are almost always accessible regardless of seat position.

ELECTRICALLY HEATED SEATS

PARTS AND OPERATION Heated seats use electric heating elements in the seat bottom, as well as in the seat back in many vehicles. The heating element is designed to warm the seat and/or back of the seat to about 100°F (37°C) or close to normal

FIGURE 59–19 The heating element of a heated seat is a replaceable part, but service requires that the upholstery be removed. The yellow part is the seat foam material and the entire white cover is the replaceable heating element. This is then covered by the seat material.

body temperature (98.6°F). Many heated seats also include a high-position or a variable temperature setting, so the temperature of the seats can therefore be as high as 110°F (44°C).

A temperature sensor in the seat cushion is used to regulate the temperature. The sensor is a variable resistor which changes with temperature and is used as an input signal to a heated seat control module. The heated seat module uses the seat temperature input, as well as the input from the high-low (or variable) temperature control, to turn the current on or off to the heating element in the seat. Some vehicles are equipped with heated seats in both the rear and the front seats.

DIAGNOSIS AND SERVICE When diagnosing a heated seat concern, start by verifying that the switch is in the on position and that the temperature of the seat is below normal body temperature. Using service information, check for power and ground at the control module and to the heating element in the seat. Most vehicle manufacturers recommend replacing the entire heating element if it is defective. ● **SEE FIGURE 59–19.**

HEATED AND COOLED SEATS

PARTS AND OPERATION Most electrically heated and cooled seats use a **thermoelectric device (TED)** located under the seat cushion and seat back. The thermoelectric device consists of positive and negative connections between two ceramic plates. Each ceramic plate has copper fins to allow the transfer of heat to air passing over the device and directed into the seat cushion. The thermoelectric device uses the **Peltier effect,** named after the inventor, Jean C. A. Peltier, a French clockmaker. When electrical current flows through the module, one side is heated and the other side is cooled. Reversing the polarity of the current changes which side is heated. ● **SEE FIGURE 59–20.**

Most vehicles equipped with heated and cooled seats use two modules per seat, one for the seat cushion and one for the seat back. When the heated and cooled seats are turned on, air is forced through a filter and then through the thermoelectric modules. The air is then directed through passages in the foam of the seat cushion and seat back. Each thermoelectric device has a temperature sensor, called a thermistor. The control module uses sensors to determine the temperature of the fins in the thermoelectric device so the controller can maintain the set temperature.

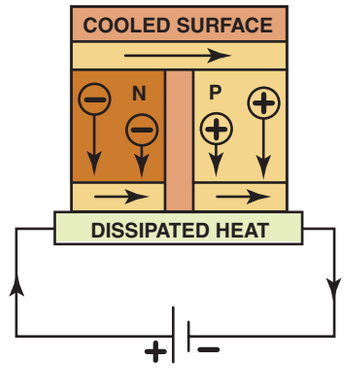

FIGURE 59–20 A Peltier effect device is capable of heating or cooling, depending on the polarity of the applied current.

TECH TIP

Check the Seat Filter

Heated and cooled seats often use a filter to trap dirt and debris to help keep the air passages clean. If a customer complains of a slow heating or cooling of the seat, check the air filter and replace or clean as necessary. Check service information for the exact location of the seat filter and for instructions on how to remove and/or replace it.

DIAGNOSIS AND SERVICE The first step in any diagnosis is to verify that the heated-cooled seat system is not functioning. Check the owner's manual or service information for the specified procedures. If the system works partially, check the air filter, usually located under the seat for each thermoelectric device. A partially clogged filter can restrict airflow and reduce the heating or cooling effect. If the system control indicator light is not on or the system does not work at all, check for power and ground at the thermoelectric devices. Always follow the vehicle manufacturer's recommended diagnosis and service procedures.

HEATED STEERING WHEEL

PARTS INVOLVED A heated steering wheel usually consists of the following components.

- Steering wheel with a built-in heater in the rim
- Heated steering wheel control switch
- Heated steering wheel control module

OPERATION When the steering wheel heater control switch is turned on, a signal is sent to the control module and electrical current flows through the heating element in the rim of the steering wheel. ● **SEE FIGURE 59–21.**

FIGURE 59–21 The heated steering wheel is controlled by a switch on the steering wheel in this vehicle.

The system remains on until the ignition switch is turned off or the driver turns off the control switch. The temperature of the steering wheel is usually calibrated to stay at about 90°F (32°C), and it requires three to four minutes to reach that temperature depending on the outside temperature.

DIAGNOSIS AND SERVICE Diagnosis of a heated steering wheel starts with verifying that the heated steering wheel is not working as designed.

NOTE: Most heated steering wheels do not work if the temperature inside the vehicle is about 90°F (32°C) or higher.

If the heated steering wheel is not working, follow the service information testing procedures which would include a check of the following:

1. Check the heated steering wheel control switch for proper operation. This is usually done by checking for voltage at both terminals of the switch. If voltage is available at only one of the two terminals of the switch and the switch has been turned on and off, an open (defective) switch is indicated.
2. Check for voltage and ground at the terminals leading to the heating element. If voltage is available at the heating element and the ground has less than 0.2 volt drop to a good chassis ground, the heating element is defective. The entire steering wheel has to be replaced if the element is defective.

Always follow the vehicle manufacturer's recommended diagnosis and testing procedures.

ADJUSTABLE PEDALS

PURPOSE AND FUNCTION **Adjustable pedals,** also called **electric adjustable pedals (EAP),** place the brake pedal and the accelerator pedal on movable brackets that are motor operated. A typical adjustable pedal system includes the following components.

- **Adjustable pedal position switch.** Allows the driver to position the pedals
- **Adjustable pedal assembly.** Includes the motor, threaded adjustment rods, and a pedal position sensor

SEE FIGURE 59–22.

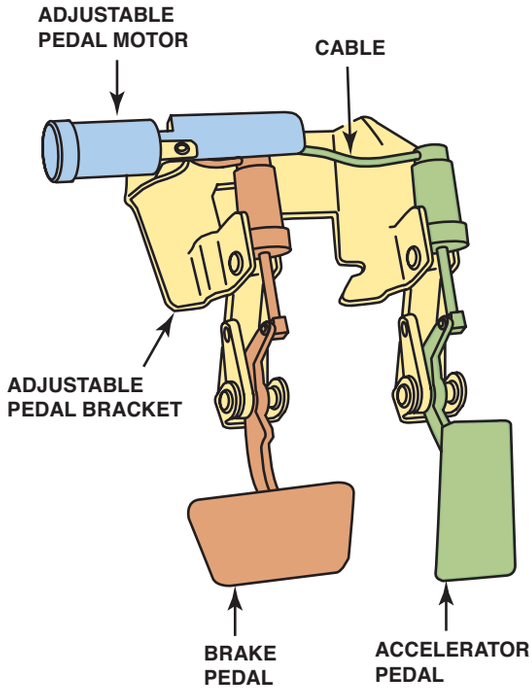

FIGURE 59–22 A typical adjustable pedal assembly. Both the accelerator and the brake pedal can be moved forward and rearward by using the adjustable pedal position switch.

TECH TIP

Check the Remote

The memory function may be programmed to a particular key fob remote, which would command the adjustable pedals to move to the position set in memory. Always check both remote settings before attempting to repair a problem that may not be a problem.

The position of the pedals, as well as the position of the seat system, is usually included as part of the memory seat function and can be set for two or more drivers.

DIAGNOSIS AND SERVICE The first step when there is a customer concern about the functioning of the adjustable pedals is to verify that the unit is not working as designed. Check the owner manual or service information for the proper operation. Follow the vehicle manufacturer's recommended troubleshooting procedure. Many diagnostic procedures include the use of a factory scan tool with bidirectional control capabilities to test this system.

OUTSIDE FOLDING MIRRORS

Mirrors that can be electrically folded inward are a popular feature, especially on larger sport utility vehicles. A control inside is used to fold both mirrors inward when needed, such as when entering a garage or close parking spot. For diagnosis and servicing of outside folding mirrors, check service information for details.

FIGURE 59–23 Electrically folded mirror in the folded position.

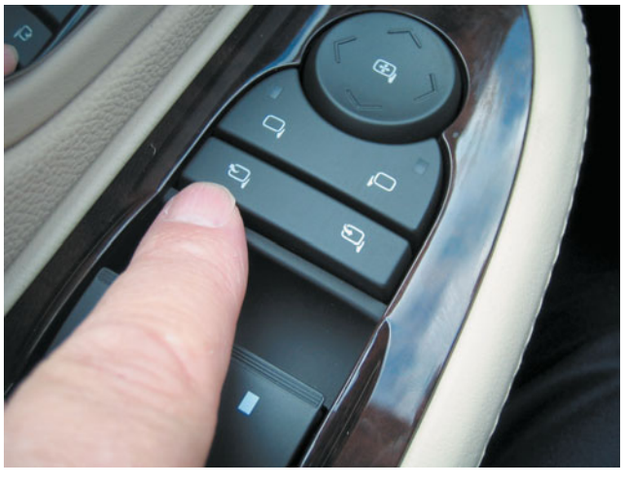

FIGURE 59–24 The electric mirror control is located on the driver's side door panel on this Cadillac Escalade.

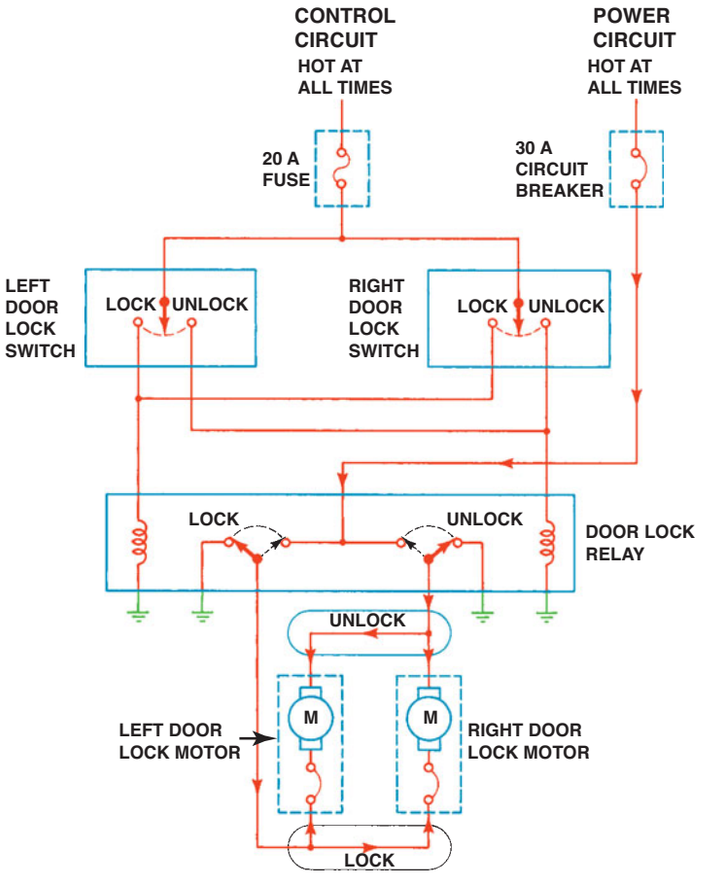

FIGURE 59–25 A typical electric power door lock circuit diagram. Note that the control circuit is protected by a fuse, whereas the power circuit is protected by a circuit breaker. As with the operation of power windows, power door locks typically use reversible permanent magnet (PM) nongrounded electric motors. These motors are geared mechanically to the lock-unlock mechanism.

REAL WORLD FIX

The Case of the Haunted Mirrors

The owner complained that while driving, either one or the other outside mirror would fold in without any button being depressed. Unable to verify the customer concern, the service technician looked at the owner's manual to find out exactly how the mirrors were supposed to work. In the manual, a caution statement said that if the mirror is electrically folded inward and then manually pushed out, the mirror will not lock into position. The power folding mirrors must be electrically cycled outward, using the mirror switches to lock them in position. After cycling both mirrors inward and outward electrically, the problem was solved. ● **SEE FIGURES 59–23 AND 59–24.**

ELECTRIC POWER DOOR LOCKS

Electric power door locks use a permanent magnet (PM) reversible motor to lock or unlock all vehicle door locks from a control switch or switches.

The electric motor uses a built-in circuit breaker and operates the lock-activating rod. PM reversible motors do not require grounding because, as with power windows, the motor control is determined by the polarity of the current through the two motor wires. ● **SEE FIGURE 59–25.**

Some two-door vehicles do *not* use a power door lock relay because the current flow for only two PM motors can be handled through the door lock switches. However, most four-door vehicles and vans with power locks on rear and side doors use a relay to control the current flow necessary to operate four or more power door lock motors. The door lock relay is controlled by the door lock switch and is commonly the location of the one and only *ground* connection for the entire door lock circuit.

KEYLESS ENTRY

Even though some Ford vehicles use a keypad located on the outside of the door, most keyless entry systems use a wireless transmitter built into the key or key fob. A **key fob** is a decorative tab or item on a key chain. ● **SEE FIGURE 59–26.**

The transmitter broadcasts a signal that is received by the electronic control module, which is generally mounted in the trunk or under the instrument panel. ● **SEE FIGURE 59–27.**

The electronic control unit sends a voltage signal to the door lock actuator(s) located in the doors. Generally, if the transmitter unlock button is depressed once, only the driver's door is unlocked. If the unlock button is depressed twice, then all doors unlock.

ROLLING CODE RESET PROCEDURE Many keyless remote systems use a rolling code type of transmitter and receiver. In a conventional system, the transmitter emits a certain fixed frequency, which is received by the vehicle control module. This single frequency can be intercepted and rebroadcast to open the vehicle.

A rolling code type of transmitter emits a different frequency every time the transmitter button is depressed and then rolls over to another frequency so that it cannot be intercepted. Both the transmitter and the receiver must be kept in synchronized order so that the remote will function correctly.

If the transmitter is depressed when it is out of range from the vehicle, the proper frequency may not be recognized by the receiver, which did not roll over to the new frequency when the transmitter was depressed. If the transmitter does not work, try to resynchronize the transmitter to the receiver by depressing and holding both the lock and the unlock button for 10 seconds when within range of the receiver.

KEYLESS ENTRY DIAGNOSIS A small battery powers the transmitter, and a weak battery is a common cause of remote power locks failing to operate. If the keyless entry system fails to operate after the transmitter battery has been replaced, check the following items.

- Mechanical binding in the door lock
- Low vehicle battery voltage
- Blown fuse
- Open circuit to the control module
- Defective control module
- Defective transmitter

PROGRAMMING A NEW REMOTE If a new or additional remote transmitter is to be used, it must be programmed to the vehicle. The programming procedure varies and may require the use of a scan tool. Check service information for the exact procedure to follow. ● **SEE CHART 59–1.**

ANTITHEFT SYSTEMS

PARTS AND OPERATION Antitheft devices flash lights or sound an alarm if the vehicle is broken into or vandalized. In addition to the alarm, some systems prevent the engine from starting by disabling the starter, ignition, or fuel system once the antitheft device is activated. Others permit the engine to start, but then disable it after several seconds. Switches in the doorjambs, trunk, and hood provide an input signal to the control module should an undesirable entry occur on a typical system. Some antitheft systems are more complex and also have electronic sensors that trigger the alarm if there is a change in battery current draw, a violent vehicle motion, or if glass is broken. These sensors also provide an input signal to the control module, which may be a separate antitheft

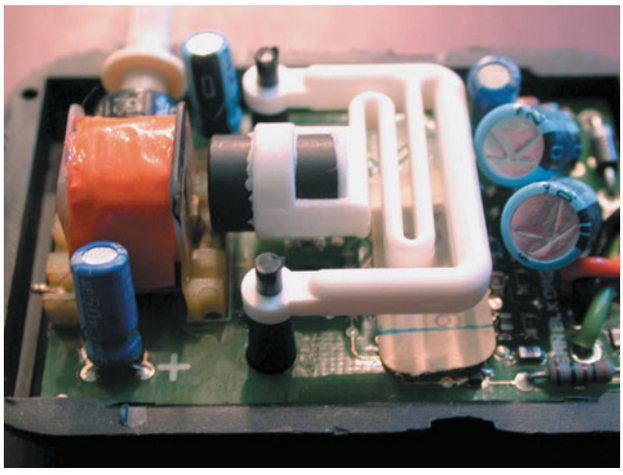

FIGURE 59–28 A shock sensor used in alarm and antitheft systems. If the vehicle is moved, the magnet will move relative to the coil, inducing a small voltage that will trigger the alarm.

unit or incorporated into the PCM or BCM. ● **SEE FIGURE 59–28** on page 360 for an example of a shock sensor used in an antitheft alarm system.

ANTITHEFT SYSTEM DIAGNOSIS

Most factory-installed antitheft systems are integrated with several other circuits to form a complex, multiple-circuit system. The major steps are as follows:

1. It is essential to have accurate diagrams, specifications, and test procedures for the specific model being serviced.
2. The easiest way to reduce circuit complexity is to use the wiring diagram to break the entire system into its subcircuits, then check only those related to the problem.
3. If any step indicates that a subcircuit is not complete, check the power source, ground, components, and wiring in that subcircuit.

Many systems use a computer chip in the plastic part of the key. Most systems are electronically regulated and have a self-diagnostic program. This self-diagnostic program is generally accessed and activated using a scan tool. Diagnostic and test procedures are similar as for any of the other electronic control systems used on the vehicle.

ANTITHEFT SYSTEM TESTING AND SERVICE

Before performing any diagnostic checks, make sure that all of the following electrical devices function correctly.

- Parking and low-beam headlights
- Dome and courtesy lights
- Horn
- Electric door locks

Circuit information from these devices often provides basic inputs to the control module. If a problem is detected in any of these circuits, such as a missing signal or a signal that is out of range, the control module disables the antitheft system and may record a diagnostic trouble code (DTC).

If all of the previously mentioned devices are operational, check all the circuits leading to the antitheft control module. Make

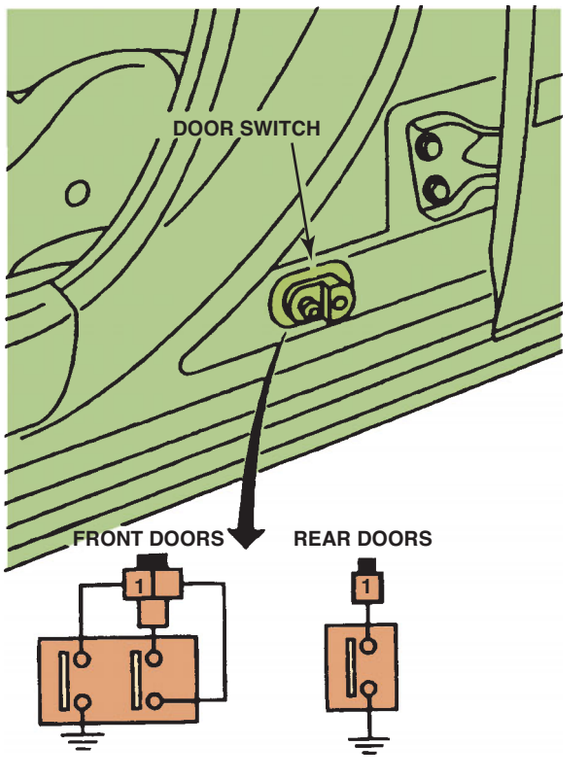

FIGURE 59–29 Door switches, which complete the ground circuit with the door open, are a common source of high resistance.

sure all switches are in their normal or off positions. Doorjamb switches complete the ground circuit when a door is opened. ● **SEE FIGURE 59–29.**

Frequently, corrosion that builds up on the switch contacts prevents the switch from operating properly. Conduct voltage drop tests to isolate faulty components and circuit problems. Repair as needed and retest to confirm that the system is operational. Follow procedures from the manufacturer to clear DTC records, and then run the self-diagnostic program to verify repairs. Some system diagnostic procedures specify the use of special testers. ● **SEE FIGURE 59–30.**

● **SEE CHART 59–2** for programming procedures for selected vehicles.

MAKE/MODEL	NOTES	PROCEDURES
Chrysler Pacifica Town and Country PT Cruiser Sebring 300 Some other models **Dodge** Caravan Durango Magnum Neon Pickup Stratus **Jeep** Liberty Grand Cherokee Some other models	Programming is by scan tool or by "customer learn" mode. Customer learn mode requires at least two functioning Sentry keys. If no functioning Sentry keys are available, the scan tool and the vehicle PIN number are required for programming. Both the immobilizer and RKE are programmed with this procedure. Only a blank key transponder can be programmed. Once programmed, the key cannot be used in another vehicle. The customer learn mode will exit after each key is programmed. The complete procedure must be completed for each key to be programmed. A total of eight keys can be programmed by the Sentry Key Remote Entry Module (four on some models).	CUSTOMER LEARN MODE 1. Using a blank Sentry key, cut the key to match the lock cylinder code. 2. Insert one of the two valid keys into the ignition and turn the ignition on. 3. After 3 seconds, but before 15 seconds expire, turn off the ignition and remove the key. 4. Within 15 seconds insert the second valid key and turn the ignition on. 5. Within 10 seconds a chime will sound and/or the indicator lamp will flash, indicating customer learn mode is active. 6. Within 60 seconds turn the ignition off, insert the blank Sentry key, and turn the ignition on. 7. After about 10 seconds a single chime will sound and the indicator lamp will stay on solid for about 3 seconds; this indicates the key has been programmed.
Ford Taurus Some other models **Lincoln** Some models **Mercury** Grand Marquis Milan Montego	This procedure requires two or more programmed keys. If two programmed keys are not available a scan tool must be used. Maximum of eight keys can be programmed. Repeat the complete procedure for each key to be learned. If the programming is not successful the antitheft indicator will flash and the vehicle will not start. Leave the key on for 30 seconds and then retry the procedure.	1. Using the first programmed key, turn the ignition from off to run. Leave the switch in run for at least 3 seconds but not more than 10 seconds. 2. Turn the switch to off. Within 10 seconds repeat step 1 with the second programmed key. 3. Turn the ignition switch off. 4. Within 20 seconds, insert the un-programmed key and turn the ignition switch from off to run. 5. After 3 seconds, attempt to start the vehicle. If the programming is successful the vehicle will start and the antitheft indicator will light for 3 seconds and go out.
Ford Crown Victoria Some other models	This procedure requires two or more programmed keys. If two programmed keys are not available a scan tool must be used. Maximum of eight keys can be programmed. Repeat the complete procedure for each key to be learned. If the programming is not successful the antitheft indicator will flash and the vehicle will not start. Leave the key on for 30 seconds and then retry the procedure.	1. Using the first programmed key, turn the ignition from off to run. Leave the switch in run for 1 second. 2. Turn the switch to off. Within 5 seconds repeat step 1 with the second programmed key. 3. Turn the ignition switch off. 4. Within 10 seconds, insert the un-programmed key and turn the ignition switch from off to run. 5. After 1 second, attempt to start the vehicle. If the programming is successful the vehicle will start and the antitheft indicator will light for 3 seconds and go out.
General Motors Passkey Passkey II (except vehicles with BCM)	The Passkey decoder will learn the first pellet read when the decoder module is first installed. This learned value cannot be changed. A Passkey Interrogator special tool is needed to read key pellet resistance when replacing keys. The tool will read out a code number related to the pellet resistance.	NEW DECODER MODULE 1. Install the new decoder module. 2. Insert the key and start the vehicle to program the pellet code into the new module. DUPLICATE KEY 1. Use the Interrogator tool to read the existing key code. 2. Obtain a key with the matching pellet code and cut the key to match the original key.

The BCM can learn the pellet code of a replacement key using a scan tool or this procedure. Make sure that the battery is fully charged. If the learning procedure is not successful check the system for codes and repair.	1. Insert the key to be learned and turn the ignition on. Leave the switch on for 11 minutes. The security lamp will be on or flashing during this time. 2. When the security lamp goes off turn the ignition off for 30 seconds. 3. Repeat step 1 two more times. 4. Turn the ignition off for 30 seconds. 5. Attempt to start the vehicle. The vehicle should start and run if the learn is successful.
General Motors Passkey III Passkey III+	Quick-Learn requires at least one programmed master (black) key. Keys can be learned with a scan tool. If no programmed master key is available the 30 minute Auto Learn procedure must be used. Auto Learn procedure will erase all learned keys. Make sure that the battery is fully charged. On vehicles with a driver information center (DIC) a "STARTING DISABLED DUE TO THEFT" message will display during the 10 minute timer.	QUICK LEARN 1. Insert a programmed master key and turn on the ignition. 2. Turn the ignition off and remove the key. 3. Within 10 seconds insert the key to be learned and turn the ignition on. 4. Turn the ignition off for 5 seconds. 3. Repeat steps 1 and 2 two more times (30 minutes total). 4. From the off position turn on and start the vehicle. 5. The vehicle should start and run, indicating the key has been learned.
General Motors Passlock (early systems)	Passlock systems do not have coded keys. Replacement or new keys do not have to be learned. Early Passlock systems pass an "R" code to the instrument cluster and then the IPC sends a password on to the PCM. Perform this procedure if replacing the instrument cluster, lock cylinder, or PCM.	1. After parts are installed, attempt to start the vehicle. 2. The vehicle should start and stall. 3. Leave the key on and wait until the flashing theft lamp stays on steady. 4. Attempt to start the vehicle again. It should start and continue to run. 5. The theft lamp should flash for 10 seconds and then go out to indicate the password has been learned.
General Motors Passlock (later models)	Replacement or additional keys do not have to be learned. Programming is necessary if the Passlock sensor, BCM, or PCM has been replaced.	1. Turn the ignition on and attempt to start the vehicle. 2. The vehicle will not start. Release the key to on. Wait about 10 minutes for the security lamp to go off. 3. Turn off the ignition for 5 seconds.

SAFETY BELTS AND RETRACTORS

SAFETY BELTS

Safety belts are used to keep the driver and passengers secured to the vehicle in the event of a collision. Most safety belts include three-point support and are constructed of nylon webbing about 2 in. (5 cm) wide. The three support points include two points on either side of the seat for the belt over the lap and one crossing over the upper torso, which is attached to the "B" pillar or seat back. Every crash consists of three types of collisions.

Collision 1: The vehicle strikes another vehicle or object.

Collision 2: The driver and/or passengers hit objects inside the vehicle if unbelted.

Collision 3: The internal organs of the body hit other organs or bones, which causes internal injuries.

If a safety belt is being worn, the belt stretches, absorbing a lot of the impact, thereby preventing collision with other objects in the vehicle and reducing internal injuries. ● **SEE FIGURE 60–1**.

BELT RETRACTORS

Safety belts are also equipped with one of the following types of retractors.

- Nonlocking retractors, which are used primarily on recoiling
- Emergency locking retractors, which lock the position of the safety belt in the event of a collision or rollover
- Emergency and web speed-sensitive retractors, which allow freedom of movement for the driver and passenger but lock if the vehicle is accelerating too fast or if the vehicle is decelerating too fast.

● **SEE FIGURE 60–2** for an example of an inertia-type seat belt locking mechanism.

SAFETY BELT LIGHTS AND CHIMES

All late-model vehicles are equipped with a safety belt warning light on the dash and a chime that sounds if the belt is not fastened. ● **SEE FIGURE 60–3**.

Some vehicles will intermittently flash the reminder light and sound a chime until the driver and sometimes the front passenger fasten their safety belts.

PRETENSIONERS

A **pretensioner** is an explosive (pyrotechnic) device that is part of the seat belt retractor assembly and tightens the seat belt as the airbag is being deployed. The purpose of the pretensioning device is to force the occupant back into position against the seat back and to remove any slack in the seat belt. ● **SEE FIGURE 60–4**.

CAUTION: The seat belt pretensioner assemblies must be replaced in the event of an airbag deployment. Always follow the vehicle manufacturer's recommended service procedure. Pretensioners are explosive devices that could be ignited if voltage is applied to the terminals. Do not use a jumper wire or powered test light around the wiring near the seat belt latch wiring. Always follow the vehicle manufacturer's recommended test procedures.

FRONT AIRBAGS

PURPOSE AND FUNCTION

Airbag passive restraints are designed to cushion the driver (or passenger, if the passenger side is so equipped) during a frontal collision. The system consists of one

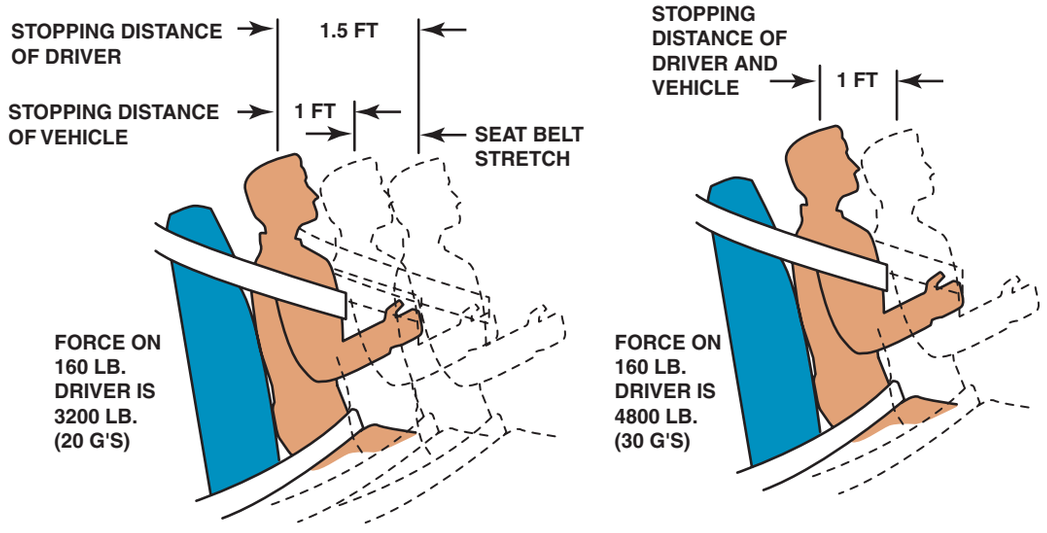

FIGURE 60–1 (a) Safety belts are the primary restraint system. (b) During a collision the stretching of the safety belt slows the impact to help reduce bodily injury.

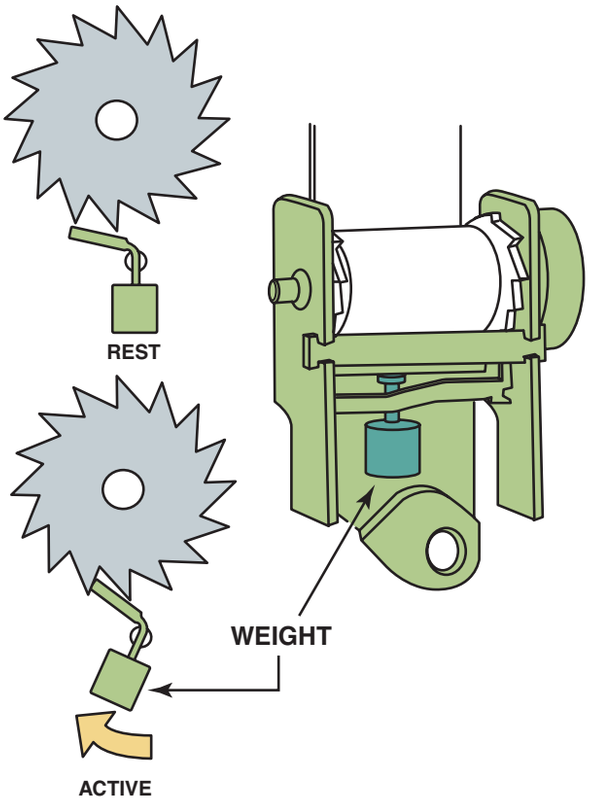

FIGURE 60–2 Most safety belts have an inertia-type mechanism that locks the belt in the event of rapid movement.

FIGURE 60–3 A typical safety belt warning light.

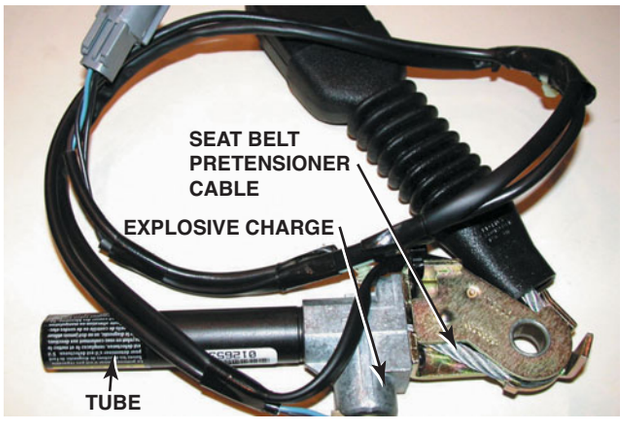

FIGURE 60–4 A small explosive charge in the pretensioner forces the end of the seat belt down the tube, which removes any slack in the seat belt.

or more nylon bags folded up in compartments located in the steering wheel, dashboard, interior panels, or side pillars of the vehicle. During a crash of sufficient force, pressurized gas instantly fills the airbag and then deploys out of the storage compartment to protect the occupant from serious injury. These airbag systems may be known by many different names, including the following:

1. **Supplemental restraint system (SRS)**
2. **Supplemental inflatable restraints (SIR)**
3. **Supplemental air restraints (SAR)**

Most airbags are designed to supplement the safety belts in the event of a collision, and front airbags are meant to be deployed only in the event of a frontal impact within 30 degrees of center. Front (driver and passenger side) airbag systems are *not* designed to inflate during side or rear impact. The force required to deploy a typical airbag is approximately equal to the force of a vehicle hitting a wall at over 10 mph (16 km/hr).

The force required to trigger the sensors within the system prevents accidental deployment if curbs are hit or the brakes are rapidly applied. The system requires a substantial force to deploy the airbag to help prevent accidental inflation.

PARTS INVOLVED

● **SEE FIGURE 60–5** for an overall view of the parts included in a typical airbag system.

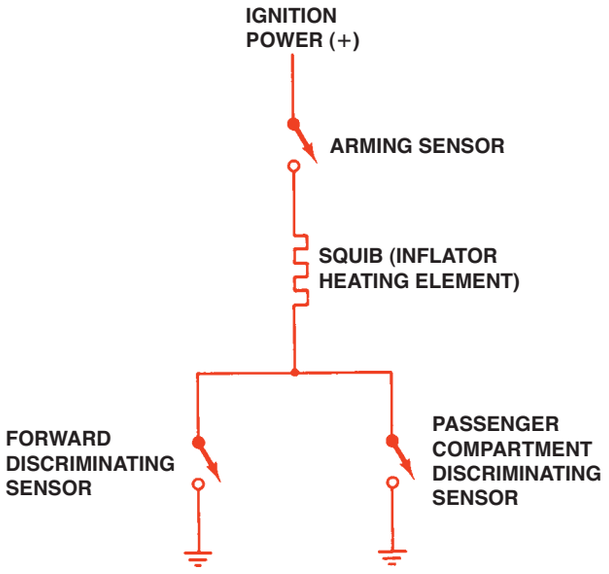

FIGURE 60–6 A simplified airbag deployment circuit. Note that both the arming sensor and at least one of the discriminating sensors must be activated at the same time. The arming sensor provides the power, and either one of the discriminating sensors can provide the ground for the circuit.

The parts include:

1. Sensors
2. Airbag (inflator) module
3. Clockspring wire coil in the steering column
4. Control module
5. Wiring and connectors

OPERATION

To cause inflation, the following events must occur.

- To cause a deployment of the airbag, two sensors must be triggered at the same time. The **arming sensor** is used to provide electrical power, and a *forward* or *discriminating sensor* is used to provide the ground connection.
- The arming sensor provides the electrical power to the airbag heating unit, called a **squib,** inside the inflator module.
- The squib uses electrical power and converts it into heat for ignition of the propellant used to inflate the airbag.
- Before the airbag can inflate, however, the squib circuit also must have a ground provided by the forward or the discriminating sensor. In other words, two sensors (arming and forward sensors) *must* be triggered *at the same time* before the airbag will be deployed. ● **SEE FIGURE 60–6**.

TYPES OF AIRBAG INFLATORS

There are two different types of inflators used in airbags.

1. **Solid fuel.** This type uses sodium azide pellets and, when ignited, generates a large quantity of nitrogen gas that quickly inflates the airbag. This was the first type used and is still commonly used in driver and passenger side airbag inflator modules. ● **SEE FIGURE 60–7**. The squib is the electrical heating element used to ignite the gas-generating material, usually sodium azide. It requires about 2 A of current to heat the heating element and ignite the inflator.
2. **Compressed gas.** Commonly used in passenger side airbags and roof-mounted systems, the compressed gas system uses a canister filled with argon gas, plus a small percentage of helium at 3,000 psi (435 kPa). A small igniter ruptures a burst disc to release the gas when energized. The compressed gas inflators are long cylinders that can be installed inside the instrument panel, seat back, door panel, or along any side rail or pillar of the vehicle. ● **SEE FIGURE 60–8**.

FIGURE 60–7 The inflator module is being removed from the airbag housing. The squib, inside the inflator module, is the heating element that ignites the pyrotechnic gas generator that rapidly produces nitrogen gas to fill the airbag.

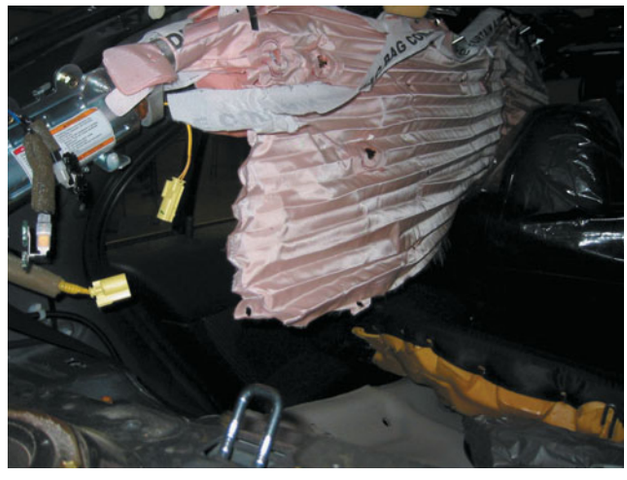

FIGURE 60–8 This shows a deployed side curtain airbag on a training vehicle.

Once the inflator is ignited, the nylon bag quickly inflates (in about 30 ms or 0.030 second) with nitrogen gas generated by the inflator. During an actual frontal collision accident, the driver is being thrown forward by the driver's own momentum toward the steering wheel. The strong nylon bag inflates at the same time. Personal injury is reduced by the spreading of the stopping force over the entire upper-body region. The normal collapsible steering column remains in operation and collapses in a collision when equipped with an airbag system. The bag is equipped with two large side vents that allow the bag to deflate immediately after inflation, once the bag has cushioned the occupant in a collision.

TIMELINE FOR AIRBAG DEPLOYMENT

Following are the times necessary for an airbag deployment in milliseconds (each millisecond is equal to 0.001 second or 1/1,000 of a second).

1. Collision occurs: 0.0 ms
2. Sensors detect collision: 16 ms (0.016 second)
3. Airbag is deployed and seam cover rips: 40 ms (0.040 second)

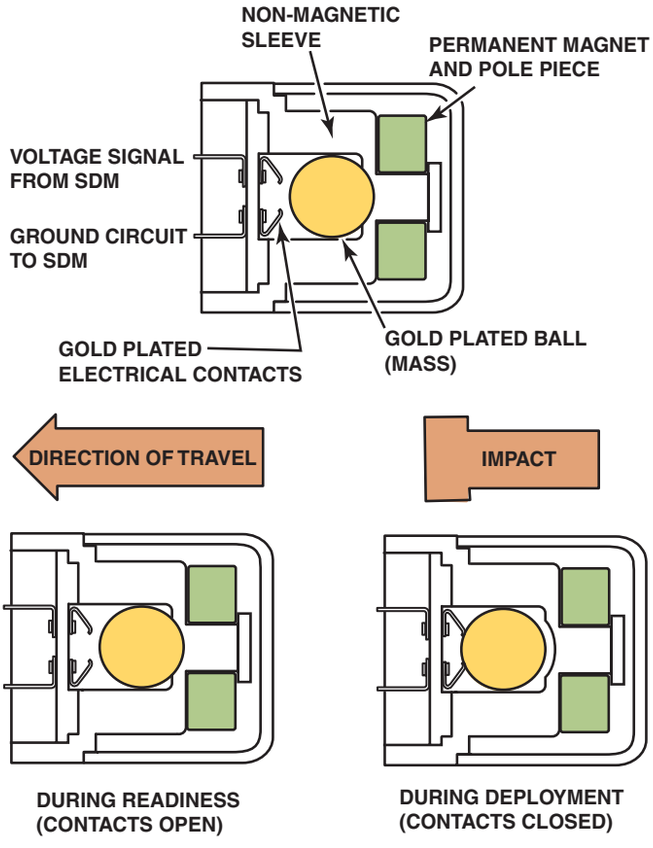

FIGURE 60–9 An airbag magnetic sensor.

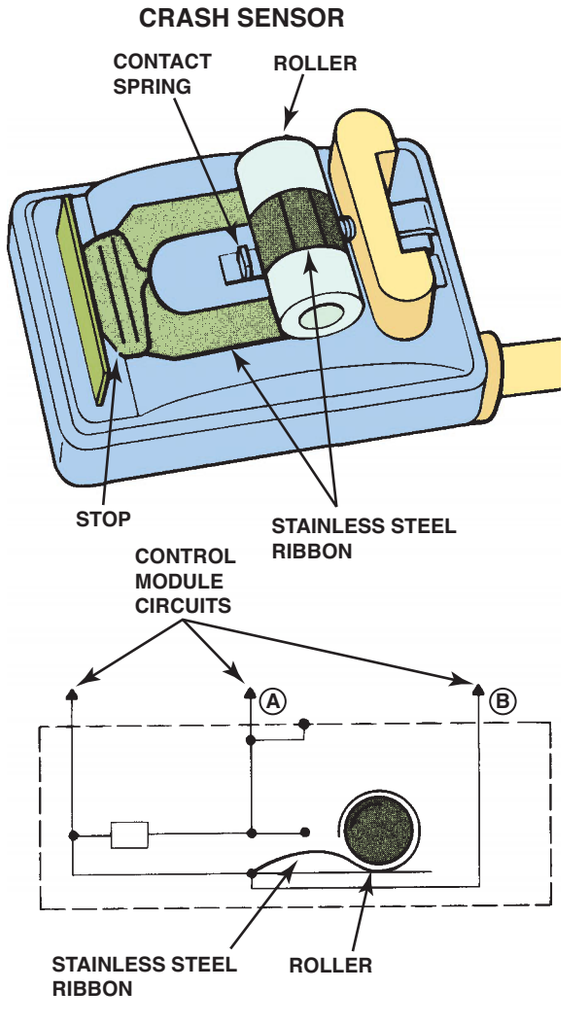

FIGURE 60–10 Some vehicles use a ribbon-type crash sensor.

4. Airbag is fully inflated: 100 ms (0.100 second)
5. Airbag deflated: 250 ms (0.250 second)

In other words, an airbag deployment occurs and is over in about a quarter of a second.

SENSOR OPERATION All three sensors are basically switches that complete an electrical circuit when activated. The sensors are similar in construction and operation, and the *location* of the sensor determines its name. All airbag sensors are rigidly mounted to the vehicle and *must* be mounted with the arrow pointing toward the front of the vehicle to ensure that the sensor can detect rapid forward deceleration.

There are three basic styles (designs) of airbag sensors.

1. **Magnetically retained gold-plated ball sensor.** This sensor uses a permanent magnet to hold a gold-plated steel ball away from two gold-plated electrical contacts. ● **SEE FIGURE 60–9**.

   If the vehicle (and the sensor) stops rapidly enough, the steel ball is released from the magnet because the inertia force of the crash was sufficient to overcome the magnetic pull on the ball and then makes contact with the two gold-plated electrodes. The steel ball only remains in contact with the electrodes for a relatively short time because the steel ball is drawn back into contact with the magnet.

2. **Rolled up stainless-steel ribbon-type sensor.** This sensor is housed in an airtight package with nitrogen gas inside to prevent harmful corrosion of the sensor parts. If the vehicle (and the sensor) stops rapidly, the stainless-steel roll "unrolls" and contacts the two gold-plated contacts. Once the force is stopped, the stainless-steel roll will roll back into its original shape. ● **SEE FIGURE 60–10**.

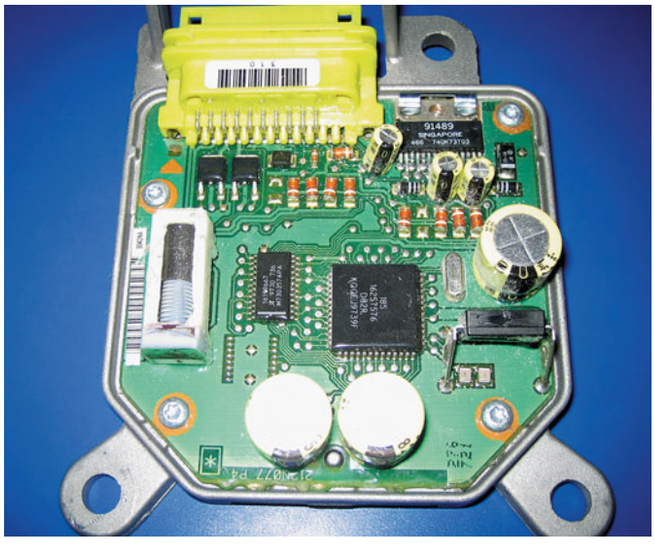

FIGURE 60–11 A sensing and diagnostic module that includes an accelerometer.

3. **Integral sensor.** Some vehicles use electronic **deceleration sensors** built into the inflator module, called **integral sensors.** For example, General Motors uses the term *sensing and diagnostic module* (*SDM*) to describe their integrated sensor/module assembly. These units contain an accelerometer-type sensor which measures the rate of deceleration and, through computer logic, determines if the airbags should be deployed. ● **SEE FIGURE 60–11**.

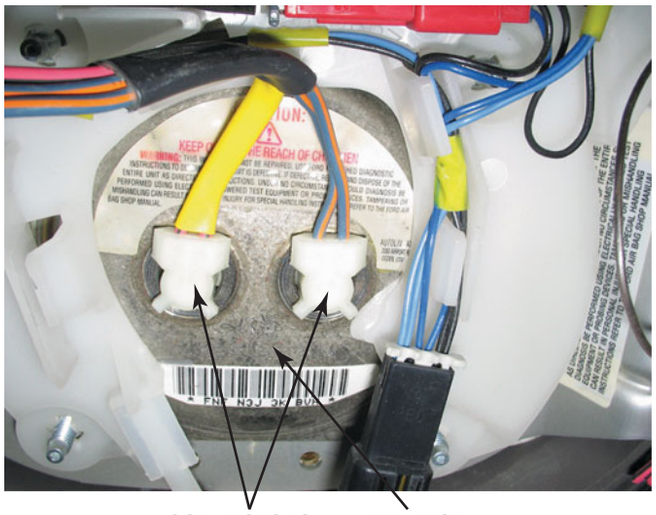

FIGURE 60–12 A driver's side airbag showing two inflator connectors. One is for the lower force inflator and the other is for the higher force inflator. Either can be ignited or both at the same time if the deceleration sensor detects a severe impact.

TWO-STAGE AIRBAGS Two-stage airbags, often called advanced airbags or smart airbags, use an accelerometer-type of sensor to detect force of the impact. This type of sensor measures the actual amount of deceleration rate of the vehicle and is used to determine whether one or both elements of a two-stage airbag should be deployed.

- **Low-stage deployment.** This lower force deployment is used if the accelerometer detects a low-speed crash.
- **High-stage deployment.** This stage is used if the accelerometer detects a higher speed crash or a more rapid deceleration rate.
- **Both low- and high-stage deployment.** Under severe high-speed crashes, both stages can be deployed.

● **SEE FIGURE 60–12.**

WIRING Wiring and connectors are very important for proper identification and long life. Airbag-related circuits have the following features.

- All electrical wiring and conduit for airbags are colored yellow.
- To ensure proper electrical connection to the inflator module in the steering wheel, a coil assembly is used in the steering column. This coil is a ribbon of copper wires that operates much like a window shade when the steering wheel is rotated. As the steering wheel is rotated, this coil, usually called a **clockspring,** prevents the lack of continuity between the sensors and the inflator assembly that might result from a horn-ring type of sliding conductor.
- Inside the yellow plastic airbag connectors are gold-plated terminals which are used to prevent corrosion.

● **SEE FIGURE 60–13.**

Most airbag systems also contain a diagnostic unit that often includes an auxiliary power supply, which is used to provide the current to inflate the airbag if the battery is disconnected from the vehicle during a collision. This auxiliary power supply normally uses capacitors that are discharged through the squib of the inflation module. When the ignition is turned off these capacitors are discharged. Therefore, after a few minutes an airbag system will not deploy if the vehicle is hit while parked.

SAFETY TIP

Dual-Stage Airbag Caution

Many vehicles are equipped with **dual-stage airbags** (two-stage airbags) that actually contain two separate inflators, one for less severe crashes and one for higher speed collisions. These systems are sometimes called *smart airbag systems* because the accelerometer-type sensor used can detect how severe the impact is and deploy one or both stages. If one stage is deployed, the other stage is still active and could be accidentally deployed. A service technician cannot tell by looking at the airbag whether both stages have deployed. Always handle a deployed airbag as if it has not been deployed and take all precautions necessary to keep any voltage source from getting close to the inflator module terminals.

TECH TIP

Pocket the Ignition Key to Be Safe

When replacing any steering gear such as a rack-and-pinion steering unit, be sure that no one accidentally turns the steering wheel. If the steering wheel is turned without being connected to the steering gear, the airbag wire coil (clockspring) can become off center. This can cause the wiring to break when the steering wheel is rotated after the steering gear has been replaced. To help prevent this from occurring, simply remove the ignition key from the ignition and keep it in your pocket while servicing the steering gear.

AIRBAG DIAGNOSIS TOOLS AND EQUIPMENT

SELF-TEST PROCEDURE The electrical portion of airbag systems is constantly checked by the circuits within the airbag-energizing power unit or through the airbag controller. The electrical airbag components are monitored by applying a small-signal voltage from the airbag controller through the various sensors and components. Each component and sensor uses a resistor in parallel with the load or open sensor switch for use by the diagnostic signals. If continuity exists, the testing circuits will measure a small voltage drop. If an open or short circuit occurs, a dash warning light is lighted and a possible diagnostic trouble code (DTC) is stored. Follow exact manufacturer's recommended procedures for accessing and erasing airbag diagnostic trouble codes.

Diagnosis and service of airbag systems usually require some or all of the following items.

- Digital multimeter (DMM)
- Airbag simulator, often called a load tool
- Scan tool
- Shorting bar or shorting connector(s)
- Airbag system tester

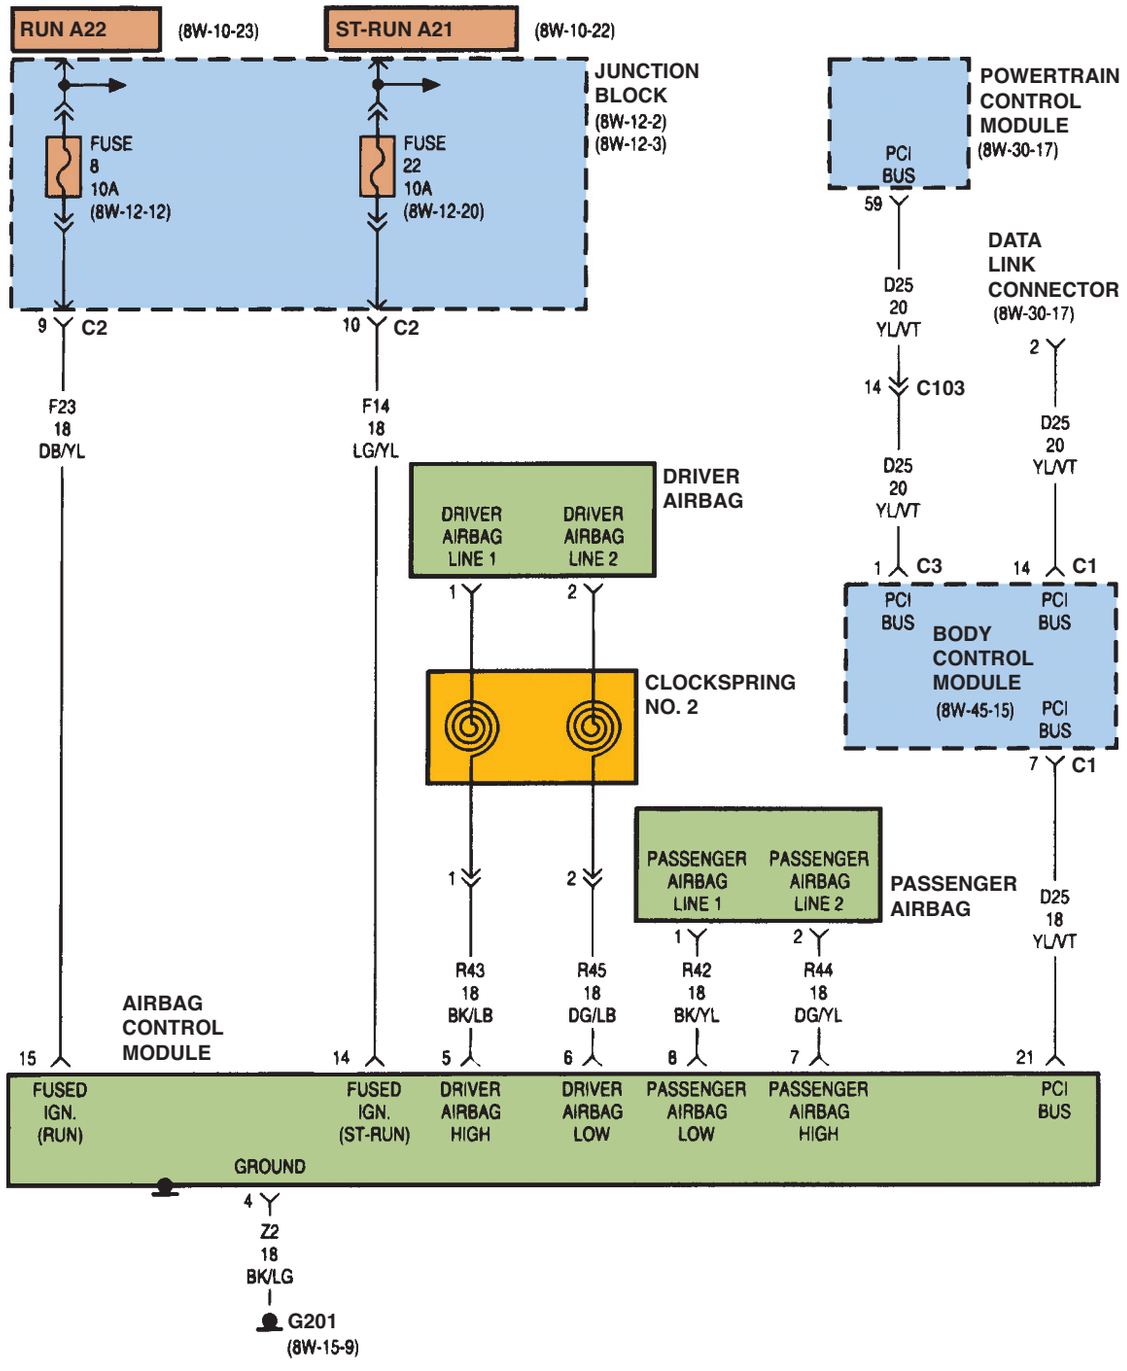

FIGURE 60–13 The airbag control module is linked to the powertrain control module (PCM) and the body control module (BCM) on this Chrysler system. Notice the airbag wire connecting the module to the airbag through the clockspring. Both power, labeled "driver airbag high" and ground, labeled "driver airbag low" are conducted through the clockspring.

- Vehicle-specific test harness
- Special wire repair tools or connectors, such as crimp-and-seal weatherproof connectors

● **SEE FIGURE 60–14.**

CAUTION: Most vehicle manufacturers specify that the negative battery terminal be removed when testing or working around airbags. Be aware that a memory saver device used to keep the computer and radio memory alive can supply enough electrical power to deploy an airbag.

PRECAUTIONS Take the following precautions when working with or around airbags.

1. Always follow all precautions and warning stickers on vehicles equipped with airbags.
2. Maintain a safe working distance from all airbags to help prevent the possibility of personal injury in the unlikely event of an unintentional airbag deployment.
   - Side impact airbag: 5 in. (13 cm) distance
   - Driver front airbag: 10 in. (25 cm) distance
   - Passenger front airbag: 20 in. (50 cm) distance
3. In the event of a collision in which the bag(s) is deployed, the inflator module *and* all sensors usually must be replaced to ensure proper future operation of the system.
4. Avoid using a self-powered test light around the yellow airbag wiring. Even though it is highly unlikely, a self-powered test light

FIGURE 60–14 An airbag diagnostic tester. Included in the plastic box are electrical connectors and a load tool that substitutes for the inflator module during troubleshooting.

could provide the necessary current to accidentally set off the inflator module and cause an airbag deployment.

5. Use care when handling the inflator module section when it is removed from the steering wheel. Always hold the inflator away from your body.
6. If handling a deployed inflator module, always wear gloves and safety glasses to avoid the possibility of skin irritation from the sodium hydroxide dust, which is used as a lubricant on the bag(s), that remains after deployment.
7. Never jar or strike a sensor. The contacts inside the sensor may be damaged, preventing the proper operation of the airbag system in the event of a collision.
8. When mounting a sensor in a vehicle, make certain that the arrow on the sensor is pointing toward the front of the vehicle. Also be certain that the sensor is securely mounted.

AIRBAG SYSTEM SERVICE

DIS-ARMING The airbags should be dis-armed, (temporarily disconnected), whenever performing service work on any of the follow locations.

- Steering wheel
- Dash or instrument panel
- Glove box (instrument panel storage compartment)

Check service information for the exact procedure, which usually includes the following steps.

STEP 1 Disconnect the negative battery cable.

STEP 2 Remove the airbag fuse (has a yellow cover).

STEP 3 Disconnect the yellow electrical connector located at the base of the steering column to disable the driver's side airbag.

STEP 4 Disconnect the yellow electrical connector for the passenger side airbag.

This procedure is called "disabling air bags" in most service information. Always follow the vehicle manufacturer's specified procedures.

? FREQUENTLY ASKED QUESTION

What Are Smart Airbags?

Smart airbags use the information from sensors to determine the level of deployment. Sensors used include:

- **Vehicle speed (VS) sensors.** This type of sensor has a major effect on the intensity of a collision. The higher the speed is, the greater the amount of impact force.
- **Seat belt fastened switch.** If the seat belt is fastened, as determined by the seat belt buckle switch, the airbag system will deploy accordingly. If the driver or passenger is not wearing a seat belt, the airbag system will deploy with greater force compared to when the seat belt is being worn.
- **Passenger seat sensor.** The sensor in the seat on the passenger's side determines the force of deployment. If there is not a passenger detected, the passenger side airbag will not deploy on the vehicle equipped with a passenger seat sensor system.

? FREQUENTLY ASKED QUESTION

Why Change Knee Bolsters If Switching to Larger Wheels?

Larger wheels and tires can be installed on vehicles, but the powertrain control module (PCM) needs to be reprogrammed so the speedometer and other systems that are affected by a change in wheel/tire size can work effectively. When 20 in. wheels are installed on General Motors trucks or sport utility vehicles (SUVs), GM specifies that replacement knee bolsters be installed. Knee bolsters are the padded area located on the lower part of the dash where a driver or passenger's knees would hit in the event of a front collision. The reason for the need to replace the knee bolsters is to maintain the crash testing results. The larger 20 in. wheels would tend to be forced farther into the passenger compartment in the event of a front-end collision. Therefore to maintain the frontal crash rating standard, the larger knee bolsters are required.

WARNING: Failure to perform the specified changes when changing wheels and tires could result in the vehicle not being able to provide occupant protection as designed by the crash test star rating that the vehicle originally achieved.

DIAGNOSTIC AND SERVICE PROCEDURE Airbag system components and their location in the vehicle vary according to system design, but the basic principles of testing are the same as for other electrical circuits. Use service information to determine how the circuit is designed and the correct sequence of tests to be followed.

- Some airbag systems require the use of special testers. The built-in safety circuits of such testers prevent accidental deployment of the airbag.
- If such a tester is not available, follow the recommended alternative test procedures specified by the manufacturer.

- Access the self-diagnostic system and check for diagnostic trouble code (DTC) records.
- The scan tool is needed to access the data stream on most systems.

SELF-DIAGNOSIS All airbag systems can detect system electrical faults, and if found will disable the system and notify the driver through an airbag warning lamp in the instrument cluster. Depending on circuit design, a system fault may cause the warning lamp to fail to illuminate, remain lit continuously, or flash. Some systems use a tone generator that produces an audible warning when a system fault occurs or if the warning lamp is inoperative.

The warning lamp should illuminate with the ignition key on and engine off as a bulb check. If not, the diagnostic module is likely disabling the system. If the airbag warning light remains on, the airbags may or may not be disabled, depending on the specific vehicle and the fault detected. Some warning lamp circuits have a timer that extinguishes the lamp after a few seconds. The airbag system generally does not require service unless there is a failed component. However, a steering wheel–mounted airbag module is routinely removed and replaced in order to service switches and other column-mounted devices.

KNEE AIRBAGS Some vehicles are equipped with **knee airbags** usually on the driver's side. Use caution if working under the dash and always follow the vehicle manufacturer's specified service procedures.

DRIVER SIDE AIRBAG MODULE REPLACEMENT

For the specific model being serviced, carefully follow the procedures provided by the vehicle manufacturer to disable and remove the airbag module. Failure to do so may result in serious injury and extensive damage to the vehicle. Replacing a discharged airbag is costly. The following procedure reviews the basic steps for removing an airbag module. Do not substitute these general instructions for the specific procedure recommended by the manufacturer.

1. Turn the steering wheel until the front wheels are positioned straight ahead. Some components on the steering column are removed only when the front wheels are straight.
2. Switch the ignition off and disconnect the negative battery cable, which cuts power to the airbag module.
3. Once the battery is disconnected, wait as long as recommended by the manufacturer before continuing. When in doubt, wait at least 10 minutes to make sure the capacitor is completely discharged.
4. Loosen and remove the nuts or screws that hold the airbag module in place. On some vehicles, these fasteners are located on the back of the steering wheel. On other vehicles, they are located on each side of the steering wheel. The fasteners may be concealed with plastic finishing covers that must be pried off with a small screwdriver to access them.
5. Carefully lift the airbag module from the steering wheel and disconnect the electrical connector. Connector location varies: Some are below the steering wheel behind a plastic trim cover; others are at the top of the column under the module. ● **SEE FIGURES 60–15 AND 60–16.**

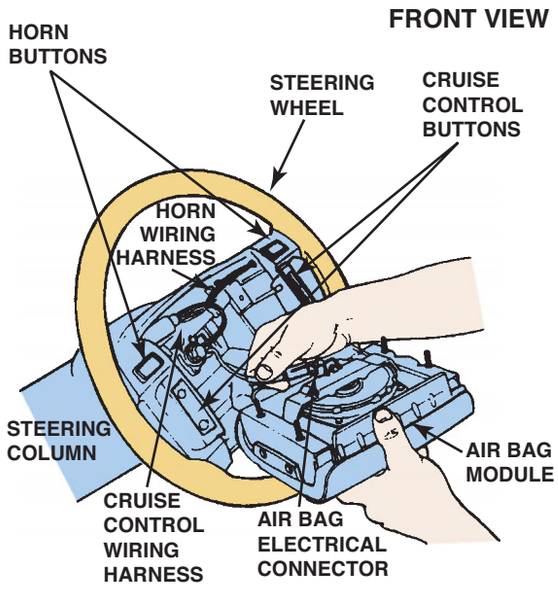

FIGURE 60–15 After disconnecting the battery and the yellow connector at the base of the steering column, the airbag inflator module can be removed from the steering wheel and the yellow airbag electrical connector at the inflator module disconnected.

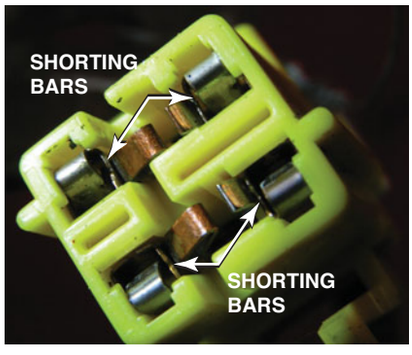

FIGURE 60–16 Shorting bars are used in most airbag connectors. These spring-loaded clips short across both terminals of an airbag connector when it is disconnected to help prevent accidental deployment of the airbag. If electrical power was applied to the terminals, the shorting bars would simply provide a low-resistance path to the other terminal and not allow current to flow past the connector. The mating part of the connector has a tapered piece that spreads apart the shorting bars when the connector is reconnected.

6. Store the module pad side up in a safe place where it will not be disturbed or damaged while the vehicle is being serviced. Do not attempt to disassemble the airbag module. If the airbag is defective, replace the entire assembly.

When installing the airbag module, make sure the clockspring is correctly positioned to ensure module-to-steering-column continuity. ● **SEE FIGURE 60–17.**

Always route the wiring exactly as it was before removal. Also, make sure the module seats completely into the steering wheel. Secure the assembly using new fasteners, if specified.

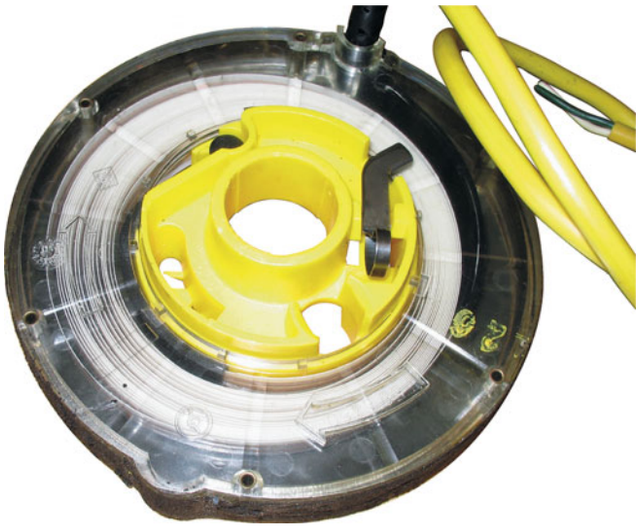

FIGURE 60–17 An airbag clockspring showing the flat conductor wire. It must be properly positioned to ensure proper operation.

SAFETY WHEN MANUALLY DEPLOYING AIRBAGS

Airbag modules cannot be disposed of unless they are deployed. Do the following to prevent injury when manually deploying an airbag.

- When possible, deploy the airbag outside of the vehicle. Follow the vehicle manufacturer's recommendations.
- Follow the vehicle manufacturer's procedures and equipment recommendations.
- Wear the proper hearing and eye protection.
- Deploy the airbag with the trim cover facing up.
- Stay at least 20 ft (6 m) from the airbag. (Use long jumper wires attached to the wiring and routed outside the vehicle to a battery.)
- Allow the airbag module to cool.

● **SEE FIGURE 60–18**.

OCCUPANT DETECTION SYSTEMS

PURPOSE AND FUNCTION The U.S. Federal Motor Vehicle Safety Standard 208 (FMVSS) specifies that the passenger side airbag be disabled or deployed with reduced force under the following conditions. This system is referred to as an **occupant detection system (ODS)** or the **passenger presence system (PPS).**

- When there is no weight on the seat and no seat belt is fastened, the passenger side airbag will not deploy and the passenger airbag light should be off. ● **SEE FIGURE 60–19**.
- The passenger side airbag will be disabled and the disabled airbag light will be on if only 10 to 37 lb (4.5 to 17 kg) is on the passenger seat, which would generally represent a seated child.

FIGURE 60–19 A dash warning lamp will light if the passenger side airbag is off because no passenger was detected by the seat sensor.

- If 38 to 99 lb (17 to 45 kg) is detected on the passenger seat, which represents a child or small adult, the airbag will deploy at a decreased force.
- If 99 lb (45 kg) or more is detected on the passenger seat, the airbag will deploy at full force, depending on the severity of the crash, speed of the vehicle, and other factors which may result in the airbag deploying at a reduced force.

● **SEE FIGURE 60–20**.

FIGURE 60–20 The passenger side airbag "on" lamp will light if a passenger is detected on the passenger seat.

FIGURE 60–21 A gel-filled (bladder-type) occupant detection sensor showing the pressure sensor and wiring.

TYPE OF SEAT SENSOR

The passenger presence system (PPS) uses one of three types of sensors.

- **Gel-filled bladder sensor.** This type of occupant sensor uses a silicone-filled bag that has a pressure sensor attached. The weight of the passenger is measured by the pressure sensor, which sends a voltage signal to the module controlling the airbag deployment. A safety belt tension sensor is also used with a gel-filled bladder system to monitor the tension on the belt. The module then uses the information from both the bladder and the seat belt sensor to determine if a tightened belt may be used to restrain a child seat. ● **SEE FIGURE 60–21**.
- **Capacitive strip sensors.** This type of occupant sensor uses several flexible conductive metal strips under the seat cushion. These sensor strips transmit and receive a low-level electric field, which changes due to the weight of the front passenger seat occupant. The module determines the weight of the occupant based on the sensor values.
- **Force-sensing resistor sensors.** This type of occupant sensor uses resistors, which change their resistance based on the stress that is applied. These resistors are part of the seat structure, and the module can determine the weight of the occupant based on the change in the resistance of the sensors. ● **SEE FIGURE 60–22**.

FIGURE 60–22 A resistor-type occupant detection sensor. The weight of the passenger strains these resistors, which are attached to the seat, thereby signaling to the module the weight of the occupant.

FIGURE 60–23 A test weight is used to calibrate the occupant detection system on a Chrysler vehicle.

CAUTION: Because the resistors are part of the seat structure, it is very important that all seat fasteners be torqued to factory specifications to ensure proper operation of the occupant detection system. A *seat track position (STP) sensor* is used by the airbag controller to determine the position of the seat. If the seat is too close to the airbag, the controller may disable the airbag.

DIAGNOSING OCCUPANT DETECTION SYSTEMS

A fault in the system may cause the passenger side airbag light to turn on when there is no weight on the seat. A scan tool is often used to check or calibrate the seat, which must be empty, by commanding the module to rezero the seat sensor. Some systems, such as those on Chrysler vehicles, use a unit that has various weights along with a scan tool to calibrate and diagnose the occupant detection system. ● **SEE FIGURE 60–23**.

SEAT AND SIDE CURTAIN AIRBAGS

SEAT AIRBAGS

Side and/or *curtain airbags* use a variety of sensors to determine if they need to be deployed. **Side airbags** are mounted in one of two general locations.

- In the side bolster of the seat (● **SEE FIGURE 60–24**.)
- In the door panel

Most side airbag sensors use an electronic accelerometer to detect when to deploy the airbags, which are usually mounted to the

FIGURE 60–24 A typical seat (side) airbag that deploys from the side of the seat.

TECH TIP

Aggressive Driving and OnStar

If a vehicle equipped with the OnStar system is being driven aggressively and the electronic stability control system has to intercede to keep the vehicle under control, OnStar may call the vehicle to see if there has been an accident. The need for a call from OnStar usually will be determined if the accelerometer registers slightly over 1 g-force, which could be achieved while driving on a race track.

bottom of the left and right "B" pillars (where the front doors latch) behind a trim panel on the inside of the vehicle.

CAUTION: Avoid using a lockout tool (e.g., a "slim jim") in vehicles equipped with side airbags to help prevent damage to the components and wiring in the system.

SIDE CURTAIN AIRBAGS Side curtain airbags are usually deployed by a module based on input from many different sensors, including a lateral acceleration sensor and wheel speed sensors. For example, in one system used by Ford, the ABS controller commands that the brakes on one side of the vehicle be applied, using down pressure while monitoring the wheel speed sensors. If the wheels slow down with little brake pressure, the controller assumes that the vehicle could roll over, thereby deploying the side curtain airbags.

EVENT DATA RECORDERS

PARTS AND OPERATION As part of the airbag controller on many vehicles, the **event data recorder (EDR)** is used to record parameters just before and slightly after an airbag deployment. The following parameters are recorded.

- Vehicle speed
- Brake on/off
- Seat belt fastened
- G-forces as measured by the accelerometer

Unlike an airplane event data recorder, a vehicle unit is not a separate unit and does not record voice conversations and does not include all crash parameters. This means that additional crash data, such as skid marks and physical evidence at the crash site, will be needed to fully reconstruct the incident.

The EDR is embedded into the airbag controller and receives data from many sources and at varying sample rates. The data is constantly being stored in a memory buffer and not recorded into the EPROM unless an airbag deployment has been commanded. The combined data is known as an *event file.* The airbag is commanded on, based on input mainly from the accelerometer sensor. This sensor, usually built into the airbag controller, is located inside the vehicle. The accelerometer calculates the rate of change of the speed of the vehicle. This determines the acceleration rate and is used to predict if that rate is high enough to deploy the frontal airbags. The airbags will be deployed if the threshold g-value is exceeded. The passenger side airbag will also be deployed unless it is suppressed by either of the following:

- No passenger is detected.
- The passenger side airbag switch is off.

DATA EXTRACTION Data extraction from the event data recorder in the airbag controller can only be achieved using a piece of equipment known as the Crash Data Retrieval System, manufactured by Vetronics Corporation. This is the only authorized method for retrieving event files and only certain organizations are allowed access to the data. These groups or organizations include:

- Original equipment manufacturer's representatives
- National Highway Traffic Safety Administration
- Law enforcement agencies
- Accident reconstruction companies

Crash data retrieval must only be done by a trained crash data retrieval (CDR) technician or analyst. A technician undergoes specialized training and must pass an examination. An analyst must attend additional training beyond that of a technician to achieve CDR analyst certification.

AUDIO FUNDAMENTALS

INTRODUCTION The audio system of today's vehicles is a complex combination of antenna system, receiver, amplifier, and speakers all designed to provide living room–type music reproduction while the vehicle is traveling in city traffic or at highway speed.

Audio systems produce audible sounds and include:

- Radio (AM, FM, and satellite)
- Antenna systems that are used to capture electronic energy broadcast to radios
- Speaker systems
- Aftermarket enhancement devices that increase the sound energy output of an audio system
- Diagnosis of audio-related problems

Many audio-related problems can be addressed and repaired by a service technician.

TYPES OF ENERGY There are two types of energy that affect audio systems.

- **Electromagnetic energy or radio waves.** Antennas capture the radio waves which are then sent to the radio or receiver to be amplified.
- **Acoustical energy, usually called sound.** Radios and receivers amplify the radio wave signals and drive speakers which reproduce the original sound as transmitted by radio waves.

  ● **SEE FIGURE 61–1**.

TERMINOLOGY Radio waves travel at approximately the speed of light (186,282,000 miles per second) and are electromagnetic. Radio waves are measured in two ways, wavelength and frequency. A radio wave has a series of high points and low points. A **wavelength** is the time and distance between two consecutive points, either high or low. A wavelength is measured in meters. **Frequency,** also known as **radio frequency (RF),** is the number of times a particular waveform repeats itself in a given amount of time, and is measured in **hertz (Hz).** A signal with a frequency of 1 Hz is one radio wavelength per second. Radio frequencies are measured in kilohertz (kHz), thousands of wavelengths per second, and megahertz (MHz), millions of wavelengths per second. ● **SEE FIGURE 61–2**.

- The higher the frequency, the shorter the wavelength.
- The lower the frequency, the longer the wavelength.

A longer wavelength can travel a farther distance than a shorter wavelength. Therefore, lower frequencies provide better reception at farther distances.

- AM radio frequencies range from 530 to 1,710 kHz.
- FM radio frequencies range from 87.9 to 107.9 MHz.

MODULATION **Modulation** is the term used to describe when information is added to a constant frequency. The base radio frequency used for RF is called the *carrier wave.* A carrier is a radio wave that is changed to carry information. The two types of modulation are:

- **Amplitude modulation (AM)**
- **Frequency modulation (FM)**

AM waves are radio waves that have amplitude that can be varied, transmitted, and detected by a receiver. Amplitude is the height of the wave as graphed on an oscilloscope. ● **SEE FIGURE 61–3**.

FM waves are also radio waves that have a frequency that can be varied, transmitted, and detected by a receiver. This type of modulation changes the number of cycles per second, or frequency, to carry the information. ● **SEE FIGURE 61–4**.

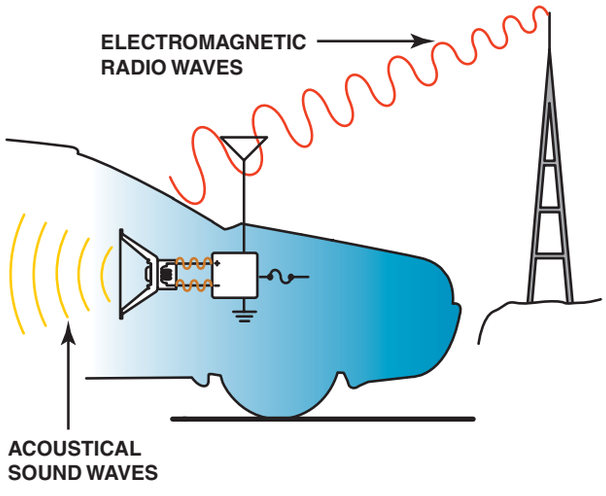

FIGURE 61–1 Audio systems use both electromagnetic radio waves and sound waves to reproduce sound inside the vehicle.

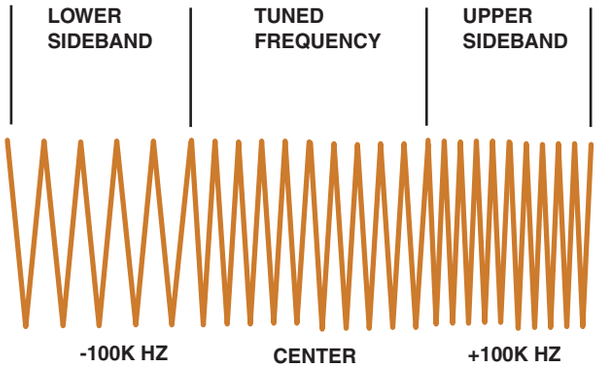

FIGURE 61–5 Using upper and lower sidebands allows stereo to be broadcast. The receiver separates the signals to provide left and right channels.

FREQUENTLY ASKED QUESTION

What Does a "Capture" Problem Mean?

A capture problem affects only FM reception and means that the receiver is playing more than one station if two stations are broadcasting at the same frequency. Most radios capture the stronger signal and block the weaker signal. However, if the stronger signal is weakened due to being blocked by buildings or mountains, the weaker signal will then be used. When this occurs, it will sound as if the radio is changing stations by itself. This is not a fault with the radio, but simply a rare occurrence with FM radio.

RADIO WAVE TRANSMISSION More than one signal can be carried by a radio wave. This process is called *sideband operation.* Sideband frequencies are measured in kilohertz. The amount of the signal above the assigned frequency is referred to as the upper sideband. The amount of the signal below the assigned frequency is called the lower sideband. This capability allows radio signals to carry stereo broadcasts. Stereo broadcasts use the upper sideband to carry one channel of the stereo signal, and the lower sideband to carry the other channel. When the signal is decoded by the radio, these two signals become the right and left channels. ● **SEE FIGURE 61–5**.

NOISE Because radio waves are a form of electromagnetic energy, other forms of energy can impact them. For example, a bolt of lightning generates broad radio-frequency bandwidths known as radio-frequency interference (RFI). RFI is one type of electromagnetic interference (EMI) and is the frequency that interferes with radio transmission.

AM CHARACTERISTICS AM radio reception can be achieved over long distances from the transmitter because the waves can bounce off the ionosphere, usually at night. Even during the day, the AM signals can be picked up some distance from the transmitter. AM radio reception depends on a good antenna. If there is a fault in the antenna circuit, AM reception is affected the most.

FM CHARACTERISTICS Because FM waves have a high RF and a short wavelength, they travel only a short distance. The waves cannot follow the shape of the earth but instead travel in a straight line from the transmitter to the receiver. FM waves will travel through the ionosphere and into space and do not reflect back to earth like AM waves.

MULTIPATH Multipath is caused by reflected, refracted, or line of sight signals reaching an antenna at different times. Multipath results from the radio receiving two signals to process on the same frequency. This causes an echo effect in the speakers. *Flutter,* or *picket fencing* as it is sometimes called, is caused by the blocking of part of the FM signal. This blocking causes a weakening of the signal resulting in only part of the signal getting to the antenna, causing an on-again off-again radio sound. Flutter also occurs when the transmitter and the receiving antenna are far apart.

The antenna receives the radio wave where it is converted into very weak fluctuating electrical current. This current travels along the antenna lead-in to the radio that amplifies the signal and sends the new signal to the speakers where it is converted into acoustical energy.

Most late-model radios and receivers use five input/output circuits.

1. **Power.** Usually a constant 12 volt feed to keep the internal clock alive
2. **Ground.** This is the lowest voltage in the circuit and connects indirectly to the negative terminal of the battery.
3. **Serial data.** Used to turn the unit on and off and provide other functions such as steering wheel control operation
4. **Antenna input.** From one or more antennas
5. **Speaker outputs.** These wires connect the receiver to the speakers or as an input to an amplifier.

ANTENNAS

TYPES OF ANTENNAS The typical radio electromagnetic energy from the broadcast antenna induces a signal in the antenna that is very small, only about 25 microvolts AC (0.000025 VAC) in strength. The radio contains amplifier circuits that increase the received signal strength into usable information.

For example, the five types of antennas used on vehicles include:

- **Slot antenna.** The slot antenna is concealed in the roof of some plastic body vehicles such as older General Motors plastic body vans. This antenna is surrounded by metal on a Mylar sheet.

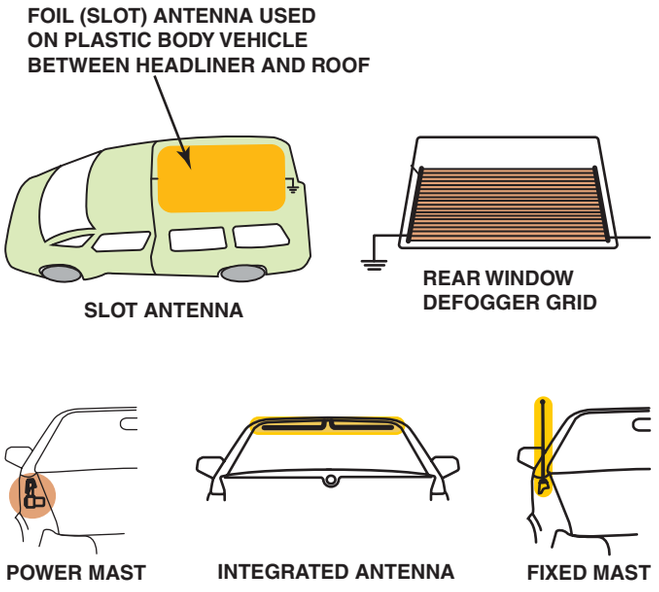

FIGURE 61–6 The five types of antennas used on General Motors vehicles include the slot antenna, fixed mast antenna, rear window defogger grid antenna, a powered mast antenna, and an integrated antenna.

- **Rear window defogger grid.** This type of system uses the heating wires to receive the signals and special circuitry to separate the RF from the DC heater circuit.
- **Powered mast.** These antennas are controlled by the radio. When the radio is turned on, the antenna is raised; when the radio is shut off, the antenna is retracted. The antenna system consists of an antenna mast and a drive motor controlled by the radio "on" signal through a relay.
- **Fixed mast antenna.** This antenna offers the best overall performance currently available. The mast is simply a vertical rod. Mast antennas are typically located on the fender or rear quarter panel of the vehicle.
- **Integrated antenna.** This type of antenna is sandwiched in the windshield and an appliqué on the rear window glass. The antenna in the rear window is the primary antenna and receives both AM and FM signals. The secondary antenna is located in the front windshield typically on the passenger side of the vehicle. This antenna receives only FM signals.

  ● **SEE FIGURE 61–6.**

ANTENNA DIAGNOSIS

ANTENNA HEIGHT The antenna collects all radio-frequency signals. An AM radio operates best with as long an antenna as possible, but FM reception is best when the antenna height is exactly 31 in. (79 cm). Most fixed-length antennas are, therefore, exactly this height. Even the horizontal section of a windshield antenna is 31 in. (79 cm) long.

A defective antenna will:

- Greatly affect AM radio reception
- May affect FM radio reception

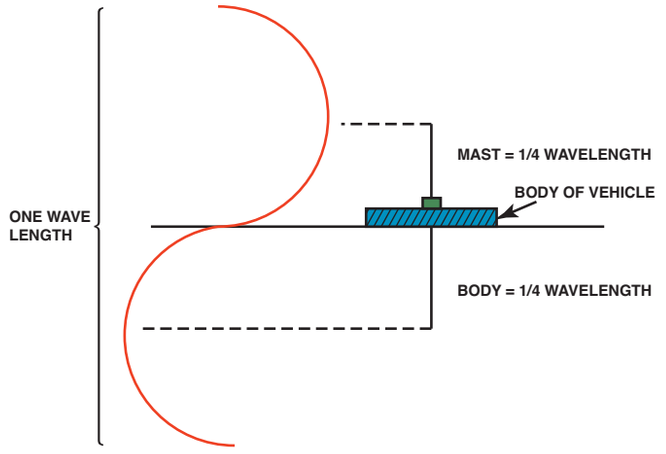

FIGURE 61–7 The ground plane is actually one-half of the antenna.

FREQUENTLY ASKED QUESTION

What Is a Ground Plane?

Antennas designed to pick up the electromagnetic energy that is broadcast through the air to the transmitting antenna are usually one-half wavelength high, and the other half of the wavelength is the **ground plane.** This one-half wavelength in the ground plane is literally underground.

For ideal reception, the receiving antenna should also be the same as the wavelength of the signal. Because this length is not practical, a design compromise uses the length of the antenna as one-fourth of the wavelength; in addition, the body of the vehicle itself is one-fourth of the wavelength. The body of the vehicle, therefore, becomes the ground plane. ● **SEE FIGURE 61–7.**

Any faulty condition in the ground plane circuit will cause the ground plane to lose effectiveness, such as:

- Loose or corroded battery cable terminals
- Acid buildup on battery cables
- Engine grounds with high resistance
- Loss of antenna or audio system grounds
- Defective alternator, causing an AC ripple exceeding 50 mV (0.050 V)

ANTENNA TESTING If the antenna or lead-in cable is broken (open), FM reception will be heard but may be weak, and there will be *no* AM reception. An ohmmeter should read infinity between the center antenna lead and the antenna case. For proper reception and lack of noise, the case of the antenna must be properly grounded to the vehicle body. ● **SEE FIGURE 61–8.**

POWER ANTENNA TESTING AND SERVICE Most power antennas use a circuit breaker and a relay to power a reversible, permanent magnet (PM) electric motor that moves a nylon cord attached to the antenna mast. Some vehicles have a dash-mounted control that can regulate antenna mast height and/or operation, whereas many operate automatically when the radio is turned on and off. The power antenna assembly is usually mounted between the outer and inner front fender or in the rear quarter panel. The unit contains the motor, a spool for the cord, and upper- and lower-limit

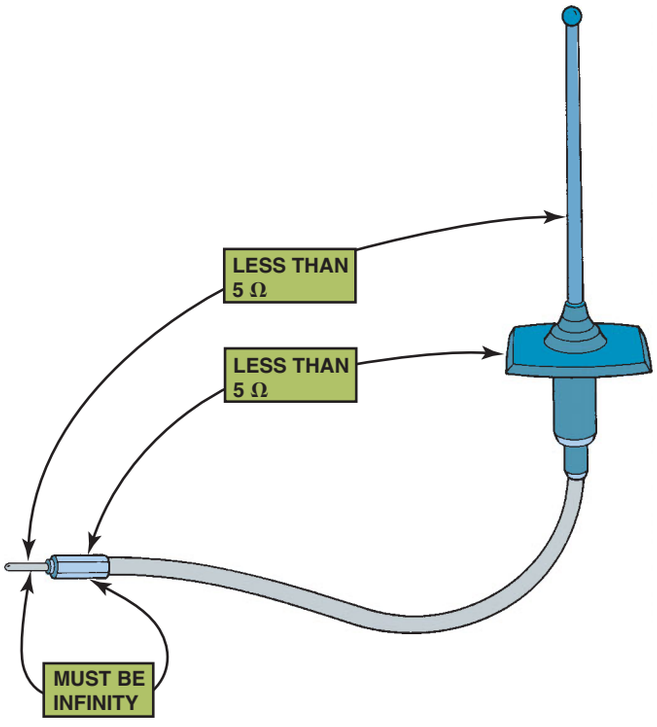

FIGURE 61–8 If all ohmmeter readings are satisfactory, the antenna is good.

FIGURE 61–9 Cutting a small hole in a fender cover helps to protect the vehicle when replacing or servicing an antenna.

TECH TIP

The Hole in the Fender Cover Trick

A common repair is to replace the mast of a power antenna. To help prevent the possibility of causing damage to the body or paint of the vehicle, cut a hole in a fender cover and place it over the antenna. ● **SEE FIGURE 61–9**.

If a wrench or tool slips during the removal or installation process, the body of the vehicle will be protected.

switches. The power antenna mast is tested in the same way as a fixed-mast antenna. (An infinity reading should be noted on an ohmmeter when the antenna is tested between the center antenna terminal and the housing or ground.) Except in the case of cleaning or mast replacement, most power antennas are either replaced as a unit or repaired by specialty shops. ● **SEE FIGURE 61–10**.

Making certain that the drain holes in the motor housing are not plugged with undercoating, leaves, or dirt can prevent many power antenna problems. All power antennas should be kept clean by wiping the mast with a soft cloth and lightly oiling with light oil such as WD-40 or similar.

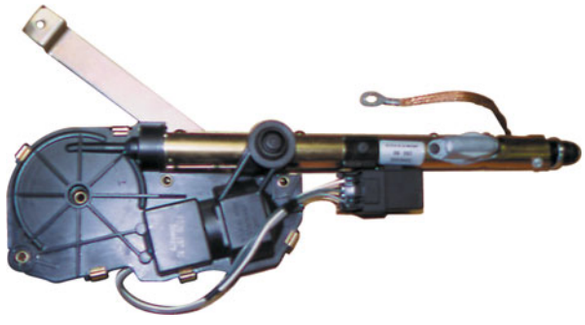

FIGURE 61–10 A typical power antenna assembly. Note the braided ground wire used to ensure that the antenna has a good ground plane.

SPEAKERS

PURPOSE AND FUNCTION The purpose of any **speaker** is to reproduce the original sound as accurately as possible. Speakers are also called *loudspeakers.* The human ear is capable of hearing sounds from a very low frequency of 20 Hz (cycles per seconds) to as high as 20,000 Hz. No one speaker is capable of reproducing sound over such a wide frequency range. ● **SEE FIGURE 61–11**.

Good-quality speakers are the key to a proper sounding radio or sound system. Replacement speakers should be securely mounted and wired according to the correct *polarity*. ● **SEE FIGURE 61–12**.

IMPEDANCE MATCHING All speakers used on the same radio or amplifier should have the same internal coil resistance, called **impedance.** If unequal-impedance speakers are used, sound quality may be reduced and serious damage to the radio may result. ● **SEE FIGURE 61–13**.

All speakers should have the same impedance. For example, if two 4 ohm speakers are being used for the rear and they are connected in parallel, the total impedance is 2 ohms.

$$R_T = \frac{4\Omega \text{ (impedance of each speaker)}}{2 \text{ (number of speakers in parallel)}} = 2 \text{ ohms}$$

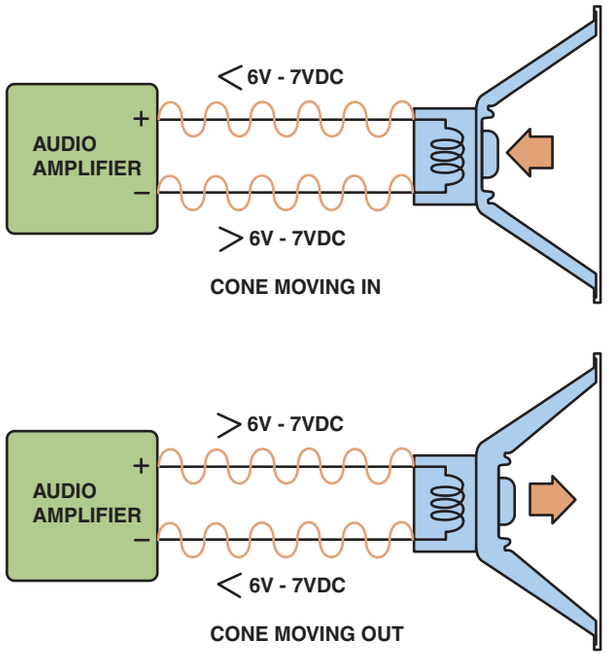

FIGURE 61–11 Between 6 and 7 volts is applied to each speaker terminal, and the audio amplifier then increases the voltage on one terminal and at the same time decreases the voltage on the other terminal causing the speaker cone to move. The moving cone then moves the air, causing sound.

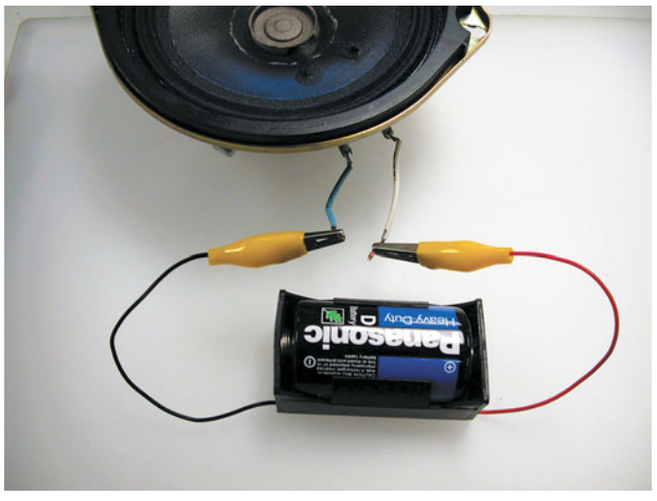

FIGURE 61–12 A typical automotive speaker with two terminals. The polarity of the speakers can be identified by looking at the wiring diagram in the service manual or by using a 1.5 volt battery to check. When the battery positive is applied to the positive terminal of the speaker, the cone will move outward. When the battery leads are reversed, the speaker cone will move inward.

The front speakers should also represent a 2 ohm load from the radio or amplifier. See the following example.

Two front speakers: each 2 ohms

Two rear speakers: each 8 ohms

Solution: Connect the front speakers in series (connect the positive [+] of one speaker to the negative [–] of the other) for a total impedance of 4 ohms (2 Ω + 2 Ω = 4 Ω). Connect the two rear speakers in parallel (connect the positive [+] of each speaker together and the negative [–] of each speaker together) for a total impedance of 4 ohms (8 Ω ÷ 2 = 4 Ω).

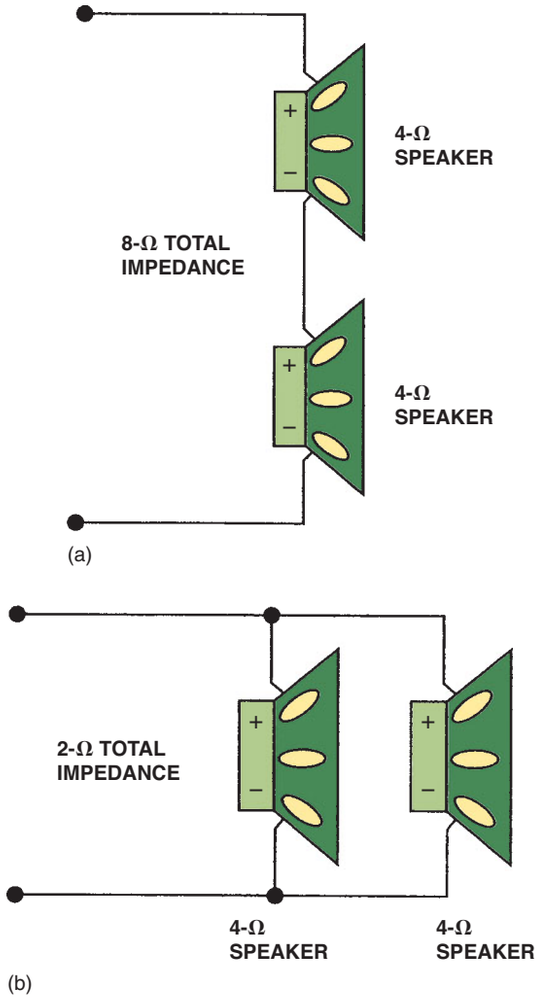

FIGURE 61–13 (a) Two 4 ohm speakers connected in series result in total impedance of 8 ohms. (b) Two 4 ohm speakers connected in parallel result in total impedance of 2 ohms.

TECH TIP

Skin Effect

When a high-frequency signal (AC voltage) is transmitted through a wire, the majority of it travels on the outside surface of the wire. This characteristic is called **skin effect.** The higher the frequency is, the closer to the outer surface the signal moves. To increase audio system output, most experts recommend the use of wire that has many strands of very fine wire to increase the surface area or the skin area of the conductor. Therefore, most aftermarket speaker wire is stranded with many small-diameter copper strands.

SPEAKER WIRING The wire used for speakers should be as large a wire (as low an AWG gauge number) as is practical in order to be assured that full power is reaching the speakers. Typical "speaker wire" is about 22 gauge (0.35 mm^2), yet tests conducted by audio engineers have concluded that increasing the wire gauge—up to 4 gauge (19 mm^2) or larger—greatly increases sound quality. All wiring connections should be soldered after making certain that all speaker connections have the correct polarity.

CAUTION: Be careful when installing additional audio equipment on a General Motors vehicle system that uses a two-wire speaker connection called a floating ground system. Other systems run only one power (hot) lead to each speaker and ground the other speaker lead to the body of the vehicle.

This arrangement helps prevent interference and static that could occur if these components were connected to a chassis (vehicle) ground. If the components are chassis grounded, there may be a difference in the voltage potential (voltage); this condition is called a *ground loop.*

CAUTION: Regardless of radio speaker connections used, *never* operate any radio without the speakers connected, or the speaker driver section of the radio may be damaged as a result of the open speaker circuit.

SPEAKER TYPES

INTRODUCTION No one speaker is capable of reproducing sound over such a wide frequency range. Therefore, speakers are available in three basic types.

1. Tweeters are for high-frequency ranges.
2. Midrange are for mid-frequency ranges.
3. Woofers and subwoofers are for low-frequency ranges.

WARNING

Hearing loss is possible if exposed to loud sounds. According to noise experts (audiologists), hearing protection should be used whenever the following occurs.

1. You must raise your voice to be heard by others next to you.
2. You cannot hear someone else speaking who is less than 3 ft (1 m) away.
3. You are operating power equipment, such as a lawnmower.

TWEETER A **tweeter** is a speaker designed to reproduce high-frequency sounds, usually between 4,000 and 20,000 Hz (4 and 20 kHz). Tweeters are very directional. This means that the human ear is most likely to be able to detect the location of the speaker while listening to music. This also means that a tweeter should be mounted in the vehicle where the sound can be directed in line of sight to the listener. Tweeters are usually mounted on the inside door near the top, windshield "A" pillar, or similar locations.

MIDRANGE A midrange speaker is designed and manufactured to be able to best reproduce sounds in the middle of the human hearing range, from 400 to 5,000 Hz. Most people are sensitive to the sound produced by these midrange speakers. These speakers are also directional in that the listener can usually locate the source of the sound.

SUBWOOFER A **subwoofer,** sometimes called a *woofer,* produces the lowest frequency of sounds, usually 125 Hz and lower. A *midbass* speaker may also be used to reproduce those frequencies between 100 and 500 Hz. Low-frequency sounds from these speakers are *not* directional. This means that the listener usually cannot detect the source of the sound from these speakers. The low-frequency sounds seem to be everywhere in the vehicle, so the location of the speakers is not as critical as with the higher frequency speakers.

The subwoofer can be placed almost anywhere in the vehicle. Most subwoofers are mounted in the rear of the vehicle where there is more room for the larger subwoofer speakers.

FREQUENTLY ASKED QUESTION

What Is a Bass Blocker?

A bass blocker is a capacitor and coil assembly that effectively blocks low frequencies. A bass blocker is normally used to block low frequencies being sent to the smaller front speakers. Using a bass blocker allows the smaller front speakers to more efficiently reproduce the midrange and high-range frequency sounds.

SPEAKER FREQUENCY RESPONSE Frequency response is how a speaker responds to a range of frequencies. A typical frequency response for a midrange speaker may be 500 to 4,000 Hz.

SOUND LEVELS

DECIBEL SCALE A **decibel (dB)** is a measure of sound power, and it is the faintest sound a human can hear in the midband frequencies. The dB scale is not linear (straight line) but logarithmic, meaning that a small change in the dB reading results in a large change in volume of noise. An increase of 10 dB in sound pressure is equal to doubling the perceived volume. Therefore, a small difference in dB rating means a big difference in the sound volume of the speaker.

EXAMPLES Some examples of decibel sound levels include:

- Quiet, faint — 30 dB: whisper, quiet library; 40 dB: quiet room
- Moderate — 50 dB: moderate range sound; 60 dB: normal conversation
- Loud — 70 dB: vacuum cleaner, city traffic; 80 dB: busy noisy traffic, vacuum cleaner
- Extremely loud — 90 dB: lawnmower, shop tools; 100 dB: chain saw, air drill
- Hearing loss possible — 110 dB: loud rock music

CROSSOVERS

DEFINITION A **crossover** is designed to separate the frequency of a sound and send a certain frequency range, such as low bass sounds, to a woofer designed to reproduce these low-frequency sounds. There are two types of crossovers: passive and active.

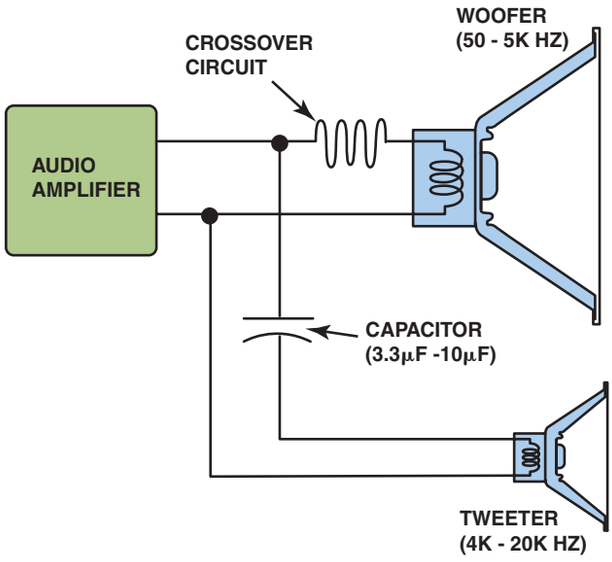

FIGURE 61–14 Crossovers are used in audio systems to send high-frequency sounds to the small (tweeter) speakers and low-frequency sounds to larger (woofer) speakers.

FIGURE 61–15 Two capacitors connected in parallel provide the necessary current flow to power large subwoofer speakers.

PASSIVE CROSSOVER A passive crossover does not use an external power source. Rather it uses a coil and a capacitor to block certain frequencies that a particular type of speaker cannot handle and allow just those frequencies that it can handle to be applied to the speaker. For example, a 6.6 millihenry coil and a 200 microfarad capacitor can effectively pass 100 Hz frequency sound to a large 10 in. subwoofer. This type of passive crossover is called a **low-pass filter,** because it passes (transfers) only the low-frequency sounds to the speaker and blocks all other frequencies. A **high-pass filter** is used to transfer higher frequency (over 100 Hz) to smaller speakers.

ACTIVE CROSSOVER **Active crossovers** use an external power source and produce superior performance. An active crossover is also called an *electronic crossover* or *crossover network.* These units include many powered filters and are considerably more expensive than passive crossovers. Two amplifiers are necessary to fully benefit from an active crossover. One amplifier is for the higher frequencies and midrange and the other amplifier is for the subwoofers. If you are on a budget and plan to use just one amplifier, then use passive crossover. If you can afford to use two or more amplifiers, then consider using the electronic (active) crossover. ● **SEE FIGURE 61–14** for an example of crossovers used in factory-installed systems.

AFTERMARKET SOUND SYSTEM UPGRADE

POWER AND GROUND UPGRADES If adding an amplifier and additional audio components, be sure to include the needed power and ground connections. These upgrades can include:

- A separate battery for the audio system
- An inline fuse near the battery to protect the wiring and the components
- Wiring that is properly sized to the amperage draw of the system and the length of wire (The higher the output wattage the greater the amperage required and the larger the wire gauge needed. The longer the distance between the battery and the components, the larger the wire gauge needed for best performance.)
- Ground wires at least the same gauge as the power side wiring (Some experts recommend using extra ground wires for best performance.)

Read, understand, and follow all instructions that come with audio system components.

POWERLINE CAPACITOR A **powerline capacitor,** also called a **stiffening capacitor,** refers to a large capacitor (often abbreviated CAP) of 0.25 farad or larger connected to an amplifier power wire. The purpose and function of this capacitor is to provide the electrical reserve energy needed by the amplifier to provide deep bass notes. ● **SEE FIGURE 61–15**.

Battery power is often slow to respond; and when the amplifier attempts to draw a large amount of current, the capacitor will try to stabilize the voltage level at the amplifier by discharging stored current as needed.

A rule of thumb is to connect a capacitor with a capacity of 1 farad for each 1,000 watts of amplifier power. ● **SEE CHART 61–1**.

POWERLINE CAPACITOR USAGE GUIDE

WATTS (AMPLIFIER)	RECOMMENDED CAPACITOR IN FARADS (MICROFARADS)
100 W	0.10 farad (100,000 µF)
200 W	0.20 farad (200,000 µF)
250 W	0.25 farad (250,000 µF)
500 W	0.50 farad (500,000 µF)
750 W	0.75 farad (750,000 µF)
1,000 W	1.00 farad (1,000,000 µF)

CHART 61–1

The rating of the capacitor needed to upgrade an audio system is directly related to the wattage of the system.

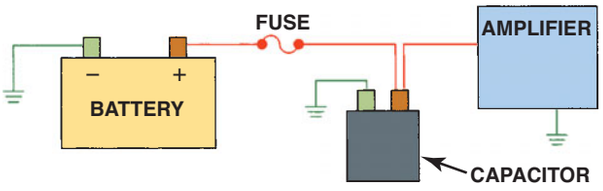

FIGURE 61–16 A powerline capacitor should be connected through the power wire to the amplifier as shown. When the amplifier requires more electrical power (watts) than the battery can supply, the capacitor will discharge into the amplifier and supply the necessary current for the fraction of a second it is needed by the amplifier. At other times when the capacitor is not needed, it draws current from the battery to keep it charged.

CAPACITOR INSTALLATION

A powerline capacitor connects to the power leads between the inline fuse and the amplifier. ● **SEE FIGURE 61–16**.

If the capacitor were connected to the circuit as shown without "precharging," the capacitor would draw so much current that it would blow the inline fuse. To safely connect a large capacitor, it must be *precharged.* To precharge the capacitor, follow these steps.

STEP 1 Connect the negative (−) terminal of the capacitor to a good chassis ground.

STEP 2 Insert an automotive 12 V light bulb, such as a headlight or parking light, between the positive (+) terminal of the capacitor and the positive terminal of the battery. The light will light as the capacitor is being charged and then go out when the capacitor is fully charged.

STEP 3 Disconnect the light from the capacitor, then connect the power lead to the capacitor. The capacitor is now fully charged and ready to provide the extra power necessary to supplement battery power to the amplifier.

VOICE RECOGNITION

PARTS AND OPERATION

Voice recognition is an expanding technology. It allows the driver of a vehicle to perform tasks, such as locate an address in a navigation system by using voice commands rather than buttons. In the past, users had to say the exact words to make it work such as the following examples listed from an owner manual for a vehicle equipped with a voice-actuated navigation system.

"Go home"

"Repeat guidance"

"Nearest ATM"

The problem with these simple voice commands was that the exact wording had to be spoken. The voice recognition software would compare the voice command to a specific list of words or phrases stored in the system in order for a match to occur. Newer systems recognize speech patterns and take action based on learned patterns. Voice recognition can be used for the following functions.

1. Navigation system operation (● **SEE FIGURE 61–17**.)
2. Sound system operation
3. Climate control system operation
4. Telephone dialing and other related functions (● **SEE FIGURE 61–18**.)

FIGURE 61–17 Voice commands can be used to control many functions, including navigation systems, climate control, telephone, and radio.

? FREQUENTLY ASKED QUESTION

What Do the Amplifier Specifications Mean?

RMS power	**RMS** means root-mean-square and is the rating that indicates how much power the amplifier is capable of producing continuously.
RMS power at 2 ohms	This specification in watts indicates how much power the amplifier delivers into a 2 ohm speaker load. This 2 ohm load is achieved by wiring two 4 ohm speakers in parallel or by using 2 ohm speakers.
Peak power	Peak power is the maximum wattage an amplifier can deliver in a short burst during a musical peak.
THD	**Total harmonic distortion (THD)** represents the amount of change of the signal as it is being amplified. The lower the number, the better the amplifier (e.g., a 0.01% rating is better than a 0.07% rating).
Signal-to-noise ratio	This specification is measured in decibels (dB) and compares the strength of the signal with the level of the background noise (hiss). A higher volume indicates less background noise (e.g., a 105 dB rating is better than a 100 dB rating).

A microphone is usually placed in the driver's side sun visor or in the overhead console in the center top portion of the windshield area.

DIAGNOSIS AND SERVICE

Voice recognition is usually incorporated into many functions of the vehicle. If a problem occurs with the system, perform the following steps.

1. Verify the customer complaint (concern). Check the owner manual or service information for the proper voice commands and verify that the system is not functioning correctly.

FIGURE 61–18 The voice command icon on the steering wheel of a Cadillac.

FIGURE 61–19 Bluetooth earpiece that contains a microphone and speaker unit that is paired to a cellular phone. The telephone has to be within 33 ft (10 m) of the earpiece.

2. Check for any aftermarket accessories that may interfere or were converted to components used by the voice recognition system, such as remote start units, MP3 players, or any other electrical component.
3. Check for stored diagnostic trouble codes (DTCs) using a scan tool.
4. Follow the recommended troubleshooting procedures as stated in service information.

BLUETOOTH

OPERATION

Bluetooth is a (radio frequency) standard for short-range communications. The range of a typical Bluetooth device is 33 ft (10 m) and it operates in the ISM (industrial, scientific, and medical) band between 2.4000 and 2.4835 MHz.

Bluetooth is a wireless standard that works on two levels.

- It provides physical communication using low power, requiring only about 1 milliwatt (1/1,000 of a watt) of electrical power, making it suitable for use with small handheld or portable devices, such as an ear-mounted speaker/microphone.
- It provides a standard protocol for how bits of data are sent and received.

The Bluetooth standard is an advantage because it is wireless, low cost, and automatic. The automotive use of Bluetooth technology is in the operation of a cellular telephone being tied into the vehicle. The vehicle allows the use of hands-free telephone usage. A vehicle that is Bluetooth telephone equipped has the following components.

- A Bluetooth receiver can be built into the navigation or existing sound system.
- A microphone allows the driver to use voice commands as well as telephone conversations from the vehicle to the cell via Bluetooth wireless connections.

Many cell phones are equipped with Bluetooth which may allow the caller to use an ear-mounted microphone and speaker. ● **SEE FIGURE 61–19**.

If the vehicle and the cell phone are equipped with Bluetooth, the speaker and microphone can be used as a hands-free telephone when the phone is in the vehicle. The cell phone can be activated in the vehicle by using voice commands.

? FREQUENTLY ASKED QUESTION

Where Did Bluetooth Get Its Name?

The early adopters of the standard used the term Bluetooth, and they named it for Harold Bluetooth, the king of Denmark in the late 900s. The king was able to unite Denmark and part of Norway into a single kingdom.

? FREQUENTLY ASKED QUESTION

Can Two Bluetooth Telephones Be Used in a Vehicle?

Usually. In order to use two telephones, the second phone needs to be given a name. When both telephones enter the vehicle, check which one is recognized. Say "phone status" and the system will tell you to which telephone the system is responding. If it is not the one you want, simply say, "next phone" and it will move to the other one.

SATELLITE RADIO

PARTS AND OPERATION

Satellite radio, also called **Satellite Digital Audio Radio Services** or **SDARS,** is a fee-based system that uses satellites to broadcast high-quality radio. SDARS broadcasts on the S-band of 2.1320 to 2.345 GHz.

SIRIUS/XM RADIO

Sirius/XM radio is standard equipment or optional in most vehicles. XM radio uses two satellites launched in 2001 called Rock (XM-2) and Roll (XM-1) in a geosynchronous orbit above North America. Two replacement satellites, Rhythm (XM-3) and Blues (XM-4) were launched in 2006. Sirius and XM radio combined in 2008 and now share some programming. The two types of satellite radios use different protocols and, therefore, require separate radios unless a combination unit is purchased.

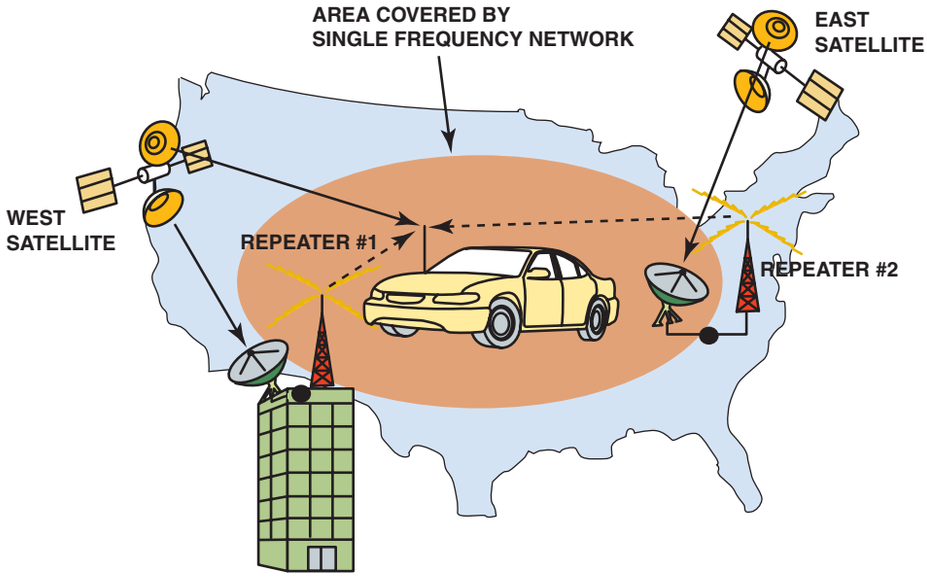

FIGURE 61–20 SDARS uses satellites and repeater stations to broadcast radio.

FIGURE 61–21 An aftermarket XM radio antenna mounted on the rear deck lid. The deck lid acts as the ground plane for the antenna.

FIGURE 61–22 A shark-fin-type factory antenna used for both XM and OnStar.

RECEPTION Reception from satellites can be affected by tall buildings and mountains. To help ensure consistent reception, both SDARS providers do the following:

- Include in the radio itself a buffer circuit that can store several seconds of broadcasts to provide service when traveling out of a service area
- Provide land-based repeater stations in most cities (● **SEE FIGURE 61–20**.)

ANTENNA To be able to receive satellite radio, the antenna needs to be able to receive signals from both the satellite and the repeater stations located in many large cities. There are various types and shapes of antennas, including those shown in ● **FIGURES 61–21 AND 61–22**.

DIAGNOSIS AND SERVICE The first step in any diagnosis is to verify the customer complaint (concern). If no satellite service is being received, first check with the customer to verify that the monthly service fee has been paid and the account is up to date. If poor reception is the cause, carefully check the antenna for damage or faults with the lead-in wire. The antennas must be installed on a metal surface to provide the proper ground plane.

For all other satellite radio fault problems, check service information for the exact tests and procedures. Always follow the factory recommended procedures. Check the following websites for additional information.

RADIO INTERFERENCE

DEFINITION Radio interference is caused by variations in voltage in the powerline or picked up by the antenna. A "whine" that increases in frequency with increasing engine speed is usually referred to as an **alternator whine** and is eliminated by installing a radio choke or a filter capacitor in the power feed wire to the radio. ● **SEE FIGURE 61–23**.

CAPACITOR USAGE Ignition noise is usually a raspy sound that varies with the speed of the engine. This noise is usually eliminated by the installation of a capacitor on the positive side of the ignition coil. The capacitor should be connected to the power feed wire to either the radio or the amplifier, or both. The capacitor *has* to be grounded. A capacitor allows AC interference to pass through to

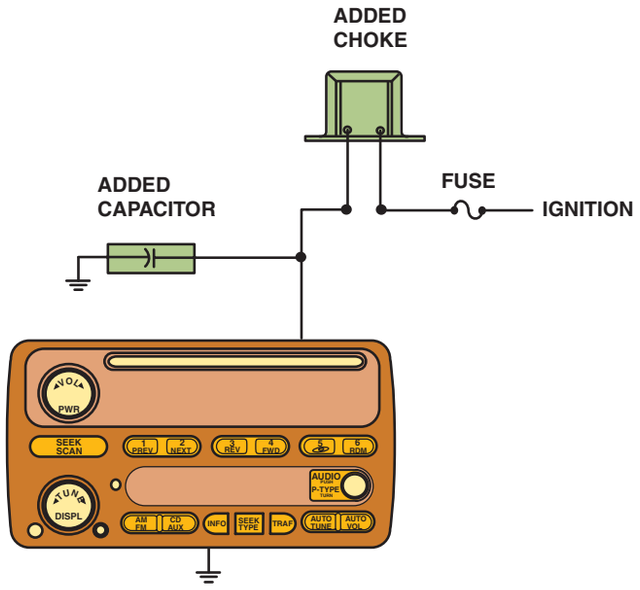

FIGURE 61–23 A radio choke and/or a capacitor can be installed in the power feed lead to any radio, amplifier, or equalizer.

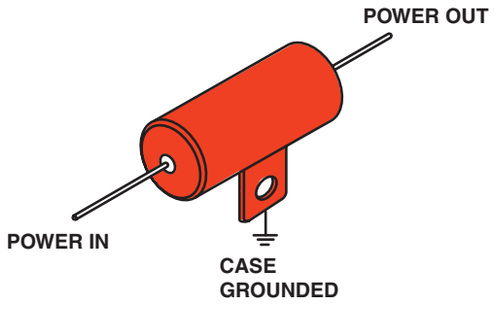

FIGURE 61–24 Many automobile manufacturers install a coaxial capacitor, like this one, in the power feed wire to the blower motor to eliminate interference caused by the blower motor.

ground while blocking the flow of DC current. Use a 470 µF, 50 volt electrolytic capacitor, which is readily available from most radio supply stores. A special coaxial capacitor can also be used in the powerline. ● **SEE FIGURE 61–24**.

RADIO CHOKE A **radio choke,** which is a coil of wire, can also be used to reduce or eliminate radio interference. Again, the radio choke is installed in the power feed wire to the radio equipment. Radio interference being picked up by the antenna can best be eliminated by stopping the source of the interference and making certain that all units containing a coil, such as electric motors, have a capacitor or diode attached to the power-side wire.

BRAIDED GROUND WIRE Using a braided ground wire is usually specified when electrical noise is a concern. The radio-frequency signals travel on the surface of a conductor rather than through the core of the wire. A braided ground strap is used because the overlapped wires short out any radio-frequency signals traveling on the surface.

AUDIO NOISE SUMMARY In summary:

- Radio noise can be broadcast or caused by noise (voltage variations) in the power circuit to the radio.
- Most radio interference complaints come when someone installs an amplifier, power booster, equalizer, or other radio accessory.
- *A major cause of this interference is the variation in voltage through the ground circuit wires. To prevent or reduce this interference, make sure all ground connections are clean and tight.*
- Placing a capacitor in the ground circuit also may be beneficial.

CAUTION: Amplifiers sold to boost the range or power of an antenna often increase the level of interference and radio noise to a level that disturbs the driver.

Capacitor and/or radio chokes are the most commonly used components. Two or more capacitors can be connected in parallel to increase the capacity of the original capacitor. A "sniffer" can be used to locate the source of the radio noise. A sniffer is a length of antenna wire with a few inches of insulation removed from the antenna end. The sniffer is attached to the antenna input terminal of the radio, and the radio is turned on and set to a weak station. The other end of the sniffer is then moved around areas of the dash to locate where the source of the interference originates. The radio noise will greatly increase if the end of the sniffer comes close to where electromagnetic leakage is occurring. ● **SEE FIGURE 61–25**.

● **SEE CHART 61–2**.

FIGURE 61–25 A "sniffer" can be made from an old antenna lead-in cable by removing about 3 in. of the outer shielding from the end. Plug the lead-in cable into the antenna input of the radio and tune the radio to a weak station. Move the end of the antenna wire around the vehicle dash area. The sniffer is used to locate components that may not be properly shielded or grounded and can cause radio interference through the case (housing) of the radio itself.

FREQUENTLY ASKED QUESTION

What Does ESN Mean?

ESN means electronic serial number. This is necessary information to know when reviewing satellite radio subscriptions. Each radio has its own unique ESN, often found on a label at the back or bottom of the unit. It is also often shown on scan tools or test equipment designed to help diagnose faults in the units.

TECH TIP

The Separate Battery Trick

Whenever diagnosing sound system interference, try running separate 14 gauge wire(s) from the sound system power lead and ground to a separate battery outside of the vehicle. If the noise is still heard, the interference is *not* due to an alternator diode or other source in the wiring of the vehicle.

AUDIO NOISE CONTROL SYMPTOM CHART		
NOISE SOURCE	**WHAT IT SOUNDS LIKE**	**WHAT TO TRY**
Alternator	A whine whose pitch changes with engine speed	Install a capacitor to a ground at the alternator output
Ignition	Ticking that changes with engine speed	Use a sniffer to further localize the source of the problem
Turn signals	Popping in time with the turn signals	Install a capacitor across the turn signal flasher
Brake lights	Popping whenever the brake pedal is depressed	Install a capacitor across the brake light switch contacts
Blower motor	Ticking in time with the blower motor	Install a capacitor to ground at the motor hot lead
Dash lamp dimmer	A buzzy whine whose pitch changes with the dimmer setting	Install a capacitor to ground at the dimmer hot lead
Horn switch	Popping when the horn is sounded	Install a capacitor between the hot lead and horn lead at the horn relay
Horn	Buzzing synchronized with the horn	Install a capacitor to ground at each horn hot lead
Amplifier power supply	A buzz, not affected by engine speed	Ground the amplifier chassis using a braided ground strap

REAL WORLD FIX

Lightning Damage

A radio failed to work in a vehicle that was outside during a thunderstorm. The technician checked the fuses and verified that power was reaching the radio. Then the technician noticed the antenna. It had been struck by lightning. Obviously, the high voltage from the lightning strike traveled to the radio receiver and damaged the circuits. Both the radio and the antenna were replaced to correct the problem.

● **SEE FIGURE 61–26.**

FIGURE 61–26 The tip of this antenna was struck by lightning.

REAL WORLD FIX

The General Motors Security Radio Problem

A customer replaced the battery in a General Motors vehicle and now the radio display shows "LOC." This means that the radio is locked and there is a customer code stored in the radio.

Other displays and their meaning include:

"InOP" This display indicates that too many incorrect codes have been entered and the radio must be kept powered for one hour and the ignition turned on before any more attempts can be made.

"SEC" This display means there is a customer's code stored and the radio is unlocked, secured, and operable.

"---" This means there is no customer code stored and the radio is unlocked.

"REP" This means the customer's code has been entered once and the radio now is asking that the code be repeated to verify it was entered correctly the first time.

To unlock the radio, the technician used the following steps (the code number being used is 4321).

STEP 1 Press the "HR" (hour) button: "000" is displayed.
STEP 2 Set the first two digits using the hour button: "4300" is displayed.
STEP 3 Set the last two digits of the code using the "MIN" (minutes) button: "4321" is displayed.
STEP 4 Press the AM-FM button to enter the code. The radio is unlocked and the clock displays "1:00."

Thankfully, the owner had the security code. If the owner had lost the code, the technician would have to secure a scrambled factory backup code from the radio and then call a toll-free number to obtain another code for the customer. The code will only be given to authorized dealers or repair facilities.

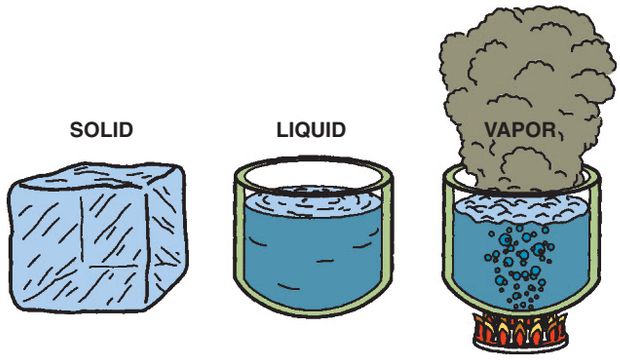
PURPOSE AND FUNCTION

Driver and passenger comfort is the primary purpose of the heating, ventilation, and air-conditioning system, often abbreviated **HVAC.** The heater is also needed in cold climates to prevent freezing or death.

PRINCIPLES INVOLVED On earth, matter is found in one of three different phases or states: solid, liquid, or vapor (gas). The state depends upon the nature of the substance, the temperature, and the pressure or force exerted on it. Water occurs naturally in all three states: solid ice, liquid water, and water vapor, depending upon the temperature and pressure of the location. ● **SEE FIGURE 62–1.**



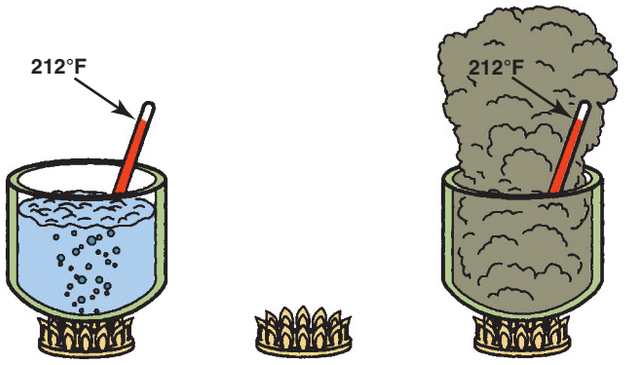


FIGURE 62–1 Water is a substance that can be found naturally in solid, liquid, and vapor states.

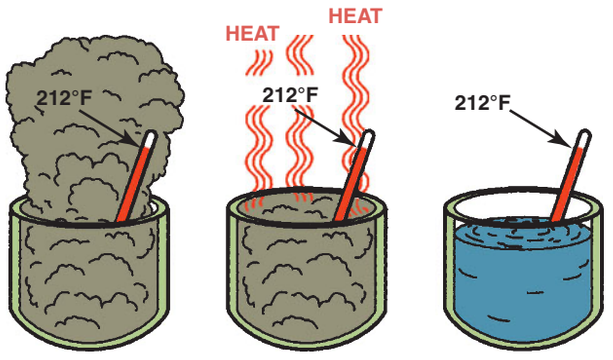
FREQUENTLY ASKED QUESTION



Why Is Liquid Sprayed from a Can Cold?

If you spray a can of liquid continuously, the can becomes cold, and the liquid being sprayed becomes cold. The can becomes cold because the pressure in the can is reduced while spraying, allowing the liquid propellant inside the can to boil and absorb heat. The liquid being sprayed has also been cooled by the liquid propellant. The propellant vapor is further cooled as it decompresses when it hits the open air. Rapid decompression results in a rapid temperature drop.

1 GRAM WATER + 540 CALORIES = 1 GRAM VAPOR
1 POUND WATER + 970 BTUs = 1 POUND VAPOR

FIGURE 62–2 The extra heat required to change a standard amount of water at its boiling point to a vapor is called **latent heat of vaporization.**

1 GRAM VAPOR + 540 CALORIES = 1 GRAM WATER
1 POUND VAPOR + 970 BTUs = 1 POUND WATER

FIGURE 62–3 The latent heat of vaporization that water vapor stores is given off when the vapor condenses to a liquid. The temperature stays the same.

CHANGES OF STATE

A **solid** is a substance that cannot be compressed and has strong resistance to flow. The molecules of a solid attract each other strongly, and resist changes in volume and shape.

A substance is solid at any temperature below its melting point. A melting point is a characteristic of a substance, and is related to the temperature at which a solid turns to a liquid. For water, the melting point is 32°F (0°C), which means that we can observe changes between liquid water and ice under normal weather conditions.

A **liquid** is a substance that cannot be compressed. A substance in a liquid state has a fixed volume, but no definite shape.

The **boiling point** is the temperature at which a liquid substance turns to a vapor. For water at normal sea level conditions, the boiling point is 212°F (100°C).

A **vapor** is a substance that can be easily compressed, has no resistance to flow, and no fixed volume. Since a vapor flows, it is considered a fluid just like liquids are.

A substance changes to a vapor if the temperature rises above its boiling point. A vapor condenses to liquid if the temperature falls below it. Just like melting and freezing, the boiling point and **condensation point** are the same temperature. Again, the difference is simply whether heat is being added or taken away. Boiling point and condensation point temperatures are not fixed; they vary with pressure.

HEAT AND TEMPERATURE

Molecules in a substance tend to vibrate rapidly in all directions, and this disorganized energy is called **heat.** The intensity of vibration depends on how much **kinetic energy,** or energy of motion, the atom or molecule contains. We measure the level of this energy as temperature.

Heat and temperature are not the same. Temperature is measured in degrees. Heat is measured in **calories (c).** The calorie is a metric unit that expresses the amount of heat needed to raise the temperature of one gram of water one degree Celsius.

Heat is also measured in British Thermal Units (BTU). One BTU is the heat required to raise the temperature of one pound of water 1°F at sea level. One BTU equals 252 calories.

LATENT HEAT

Latent heat is the "extra" heat that is needed to transform a substance from one state to another. Imagine that a solid or a liquid is being heated on a stove. When the solid reaches its melting point, or the liquid reaches its boiling point, their temperatures stop rising. The solid begins to melt, and the liquid begins to boil. This occurs without any change in temperature, even though heat is still being poured in from the burner.

The water in the container on the stove boils at a temperature of 212°F (100°C) at sea level, for as long as any liquid water remains. As you continue to add heat with the burner, it will all be absorbed in changing the state of the liquid to a vapor. This extra, hidden amount of energy necessary to change the state of a substance is called latent heat. ● **SEE FIGURES 62–2 AND 62–3.**

Latent heat is important in air-conditioning system operation because the cooling effect is derived from changing the state of liquid refrigerant to a vapor. The refrigerant absorbs latent heat of vaporization, cooling the air blown into the passenger compartment. Heat is taken away to cool the air.

TEMPERATURE, VOLUME, AND PRESSURE OF A VAPOR

Unlike a solid, a vapor has no fixed volume. Increasing the temperature of a vapor, while keeping the volume confined in the same space, increases the pressure. This happens as the vibrating vapor molecules collide more and more energetically with the walls of the container. Conversely, decreasing the temperature decreases the pressure. This relationship between temperature and pressure in vapor is why a can of nonflammable refrigerant can explode when heated by a flame—the pressure buildup inside the can will eventually exceed the can's ability to contain the pressure.

Increasing the pressure by compressing a vapor increases the temperature. Decreasing the pressure by permitting the vapor to expand decreases the temperature.

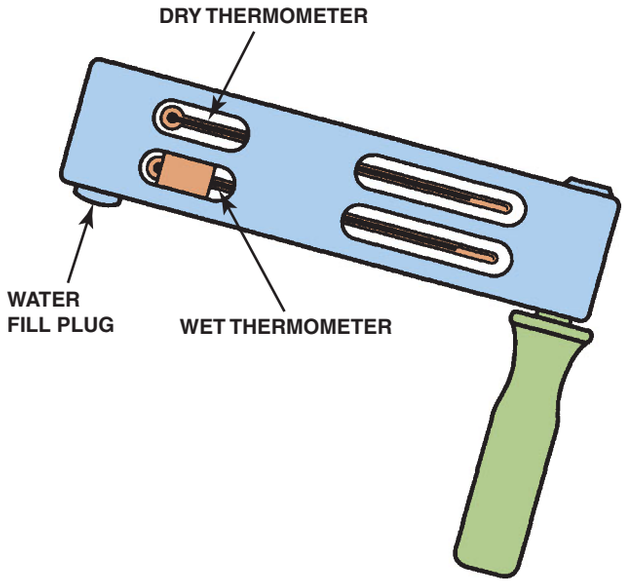


FIGURE 62–4 A sling psychrometer is used to measure relative humidity.

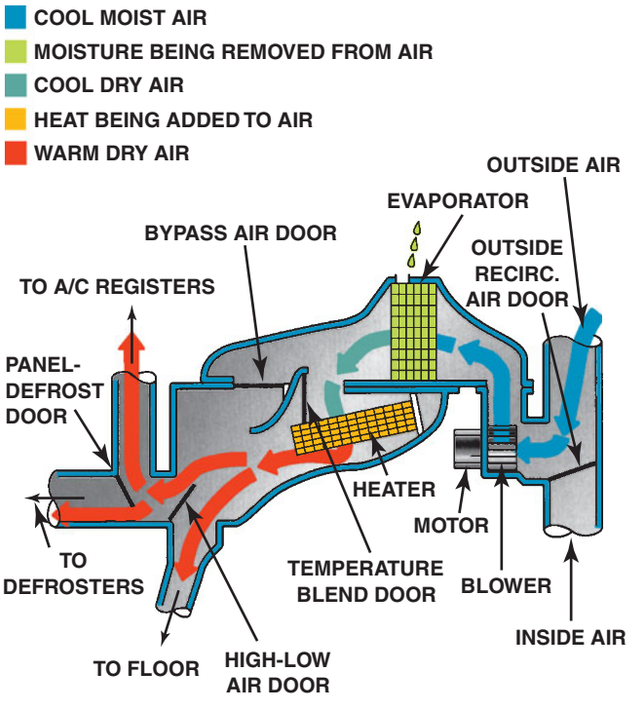

FIGURE 62–5 Typical flow of air through an automotive heat, ventilation, and air-conditioning system when placed in the heat position.

PRESSURE-TEMPERATURE RELATIONSHIPS

There are two aspects of the relationship between pressure and temperature that are important to understanding the operating of an HVAC system:

- The temperature at which a liquid boils (and vapor condenses) rises and falls with the pressure.
- Pressure in a sealed system that contains both liquid and vapor rises and falls with the temperature.

HUMIDITY

Water vapor is in the air in varying concentrations. **Humidity** refers to water vapor present in the air. The level of humidity depends upon the amount of water vapor present and the temperature of the air.

The amount of water vapor in the air tends to be higher near lakes or the ocean, because more water is available to evaporate from their surfaces. In desert areas with little open water, the amount of water vapor in the air tends to be low.

Absolute humidity is the measurement of the weight of the water vapor in a given volume of air. **Relative humidity** is the percentage of how much moisture is present in the air compared to how much moisture the air is capable of holding at that temperature.

Relative humidity is commonly measured with a **hygrometer** or a **psychrometer.** A hygrometer depends on a sensitive element that expands and contracts, based on the humidity. Hygrometers typically resemble a clock, with the scale reading from 0% to 100% relative humidity. Permanent-recording hygrometers may be constructed so that an ink pen or electric stylus makes a continuous record on a rotating paper disc or paper-covered drum.

A psychrometer uses two thermometers, one of which has the bulb covered in a cotton wick soaked in distilled water from a built-in reservoir. ● **SEE FIGURE 62–4**. The wick keeps the bulb of the "wet thermometer" wet so that it can be cooled by evaporation. To take a relative humidity reading, the psychrometer is placed in the airflow for a certain time. As the evaporator blows air, the wet bulb's temperature drops, and the dry bulb reads the temperature of the airflow. Sling psychrometers are spun around in the air a certain number of times. Water evaporates from the cotton wick at a rate inversely proportional to the relative humidity of the air; faster if the humidity is low, and slower if the humidity is high.

The "dry thermometer" registers ordinary air temperature. The higher the relative humidity, the closer the readings of the two thermometers, and the lower the humidity, the greater the difference. The different temperatures indicated by the wet and dry thermometers are compared to a chart, which gives the relative humidity.

HEATING SYSTEM

PURPOSE AND FUNCTION

All automotive and light-truck heater systems use the hot coolant from the engine to produce heat. The heater system is designed to provide passenger comfort and the heat needed to defrost windshield and front side windows in many vehicles. Therefore the heating system is a major safety system in the vehicle.

PARTS AND OPERATION

The engine coolant (antifreeze and water) flows through **heater hoses** and a **heater core.** The engine water pump supplies the force necessary to circulate the engine coolant through the heater core. The heater core is a small radiator with tubes and fins that help transfer the heat from the coolant to the air flowing through the heater core. ● **SEE FIGURE 62–5**. A **blower motor** with a squirrel cage-type fan is usually used to force air through the heater core and into the passenger compartment. ● **SEE FIGURE 62–6**. Before the heater can function correctly, the cooling system has to be functioning correctly. The following parts are also used to control the flow of coolant and therefore control the temperature of the passenger compartment.

1. Heater control valve.

? FREQUENTLY ASKED QUESTION

What Is an Auxiliary Electric Water Pump?

Some vehicles are equipped with an auxiliary electric water pump. The purpose and function of this pump is to help warm the interior of the vehicle by circulating coolant from the engine through the heater core when the engine is at idle speed. At idle speed, the water pump does not circulate a sufficient quantity of coolant through the heater core to warm the interior in freezing weather.

? FREQUENTLY ASKED QUESTION

How Does the Inside of the Vehicle Get Cooled?

The underlying principle involved in air-conditioning or refrigeration is that "cold attracts heat." Therefore, a cool evaporator attracts the hot air inside the vehicle. Heat always travels toward cold and when the hot air passes through the cold evaporator, the heat is absorbed by the cold evaporator, which lowers the temperature of the air. The cooled air is then forced into the passenger compartment by the blower through the air-conditioning vents.

AIR-CONDITIONING REFRIGERATION CYCLE

All automotive air-conditioning systems are closed and sealed. A refrigerant is circulated through the system by a **compressor** that is powered by the engine through an accessory drive belt. Older systems used a refrigerant, CFC-12, commonly referred to by its Dupont trade name of Freon or R-12. Starting in the early 1990s, vehicle manufacturers now all use HFC-134a, a refrigerant that is less harmful to the atmosphere. The basic principle of the refrigeration cycle is that as a liquid changes into a gas, heat is absorbed. The heat that is absorbed by an automotive air-conditioning system is the heat from inside the vehicle. This is how the system works:

1. The liquid refrigerant evaporates in a small radiator-type unit called the **evaporator.** As the refrigerant evaporates, it absorbs heat as it changes from a liquid to a gas. As the heat is absorbed by the refrigerant, the evaporator becomes cold. ● **SEE FIGURE 62–7**.
2. After the refrigerant has evaporated into a *low-pressure gas* in the evaporator, the refrigerant flows into the engine-driven compressor. The compressor compresses the low-pressure refrigerant gas into a high-pressure gas and forces the refrigerant through the system. ● **SEE FIGURE 62–8**.
3. This high-pressure gas flows into the condenser located in front of the cooling system radiator. The **condenser** looks like another radiator, and its purpose and function is the same as the cooling system radiator, to remove heat from the high-pressure gas. In the condenser, the high-pressure gas changes (condenses) to form a high-pressure liquid as the heat from the refrigerant is released to the air. ● **SEE FIGURE 62–9**.
4. The high-pressure liquid then flows through a device that meters the flow into the evaporator. When the high pressure of the liquid drops, it causes the refrigerant to vaporize.
5. Air is blown through the evaporator by the blower motor. The air is cooled as heat is removed from the air and transferred to the refrigerant in the evaporator. This cooled air is then directed inside the passenger compartment through vents.

EXPANSION VALVE SYSTEMS

An expansion valve is attached to the inlet to the evaporator and controls the amount of refrigerant flow into the evaporator. The expansion valve controls the flow of the refrigerant based on the

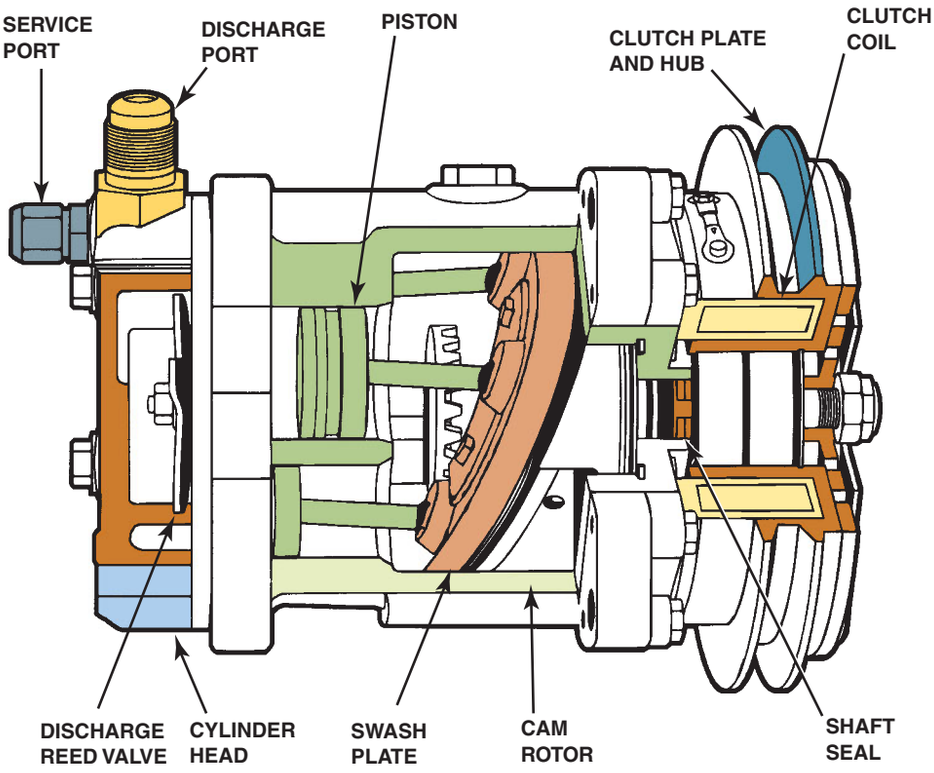

FIGURE 62–8 The compressor provides the mechanical force needed to pressurize the refrigerant.

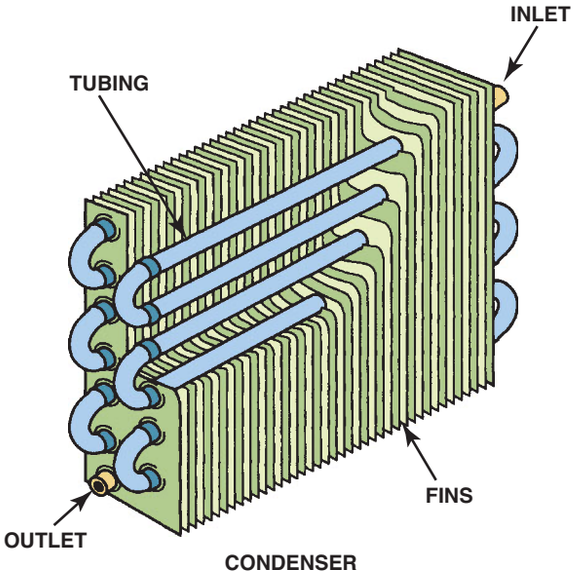

FIGURE 62–9 The condenser changes the refrigerant vapor into a liquid by transferring heat from the refrigerant to the air stream that flows between the condenser fins.

temperature at the outlet of the evaporator, which is measured by a temperature-sensing bulb and tube. When the outlet of the evaporator is warm, the opening of the expansion valve is increased. This opening allows refrigerant to flow into the evaporator. As the temperature at the outlet of the evaporator decreases, the sensing bulb and tube cause the expansion valve to restrict the flow of refrigerant into the evaporator. This type of system is called the **thermostatic expansion valve** system—usually abbreviated **TEV** or **TXV**. ● **SEE FIGURE 62–10**.

ORIFICE TUBE SYSTEMS

Many air-conditioning systems today use a fixed-orifice tube at the inlet to the evaporator. As refrigerant flows through this orifice (small hole), it expands inside the evaporator, where it absorbs heat and expands into a low-pressure gas. A pressure switch located in the low-pressure line at the outlet of the evaporator senses when the pressure is too low. Too low a pressure in the evaporator can cause the temperature of the evaporator to drop to below freezing. A cold evaporator can therefore cause the moisture in the air to freeze into ice, creating a blockage to air flow through the evaporator. Therefore, whenever the pressure drops below a certain pressure (typically about 3 to 33 PSI [214 to 228 kPa]), a pressure switch breaks the circuit to the air-conditioning compressor clutch, which stops the flow of refrigerant through the evaporator. Then, when the temperature (and pressure) increases in the evaporator, the pressure switch closes, restoring the electrical current flow to the compressor clutch and causing the compressor to start forcing refrigerant through the evaporator again. This type of system is commonly called a **cycling clutch orifice tube** (or **CCOT**) system. ● **SEE FIGURES 62–11 AND 62–12**.

THERMOSTATIC CONTROL

The lower the pressure of the refrigerant, the lower the temperature. If the pressure in the evaporator is above 30 PSI (220 kPa) for R-12 or 28 PSI (193 kPa) for an R-134a system, the temperature of the evaporator will remain about freezing, 32°F (0°C). Temperature control must be used to prevent the temperature of the evaporator from

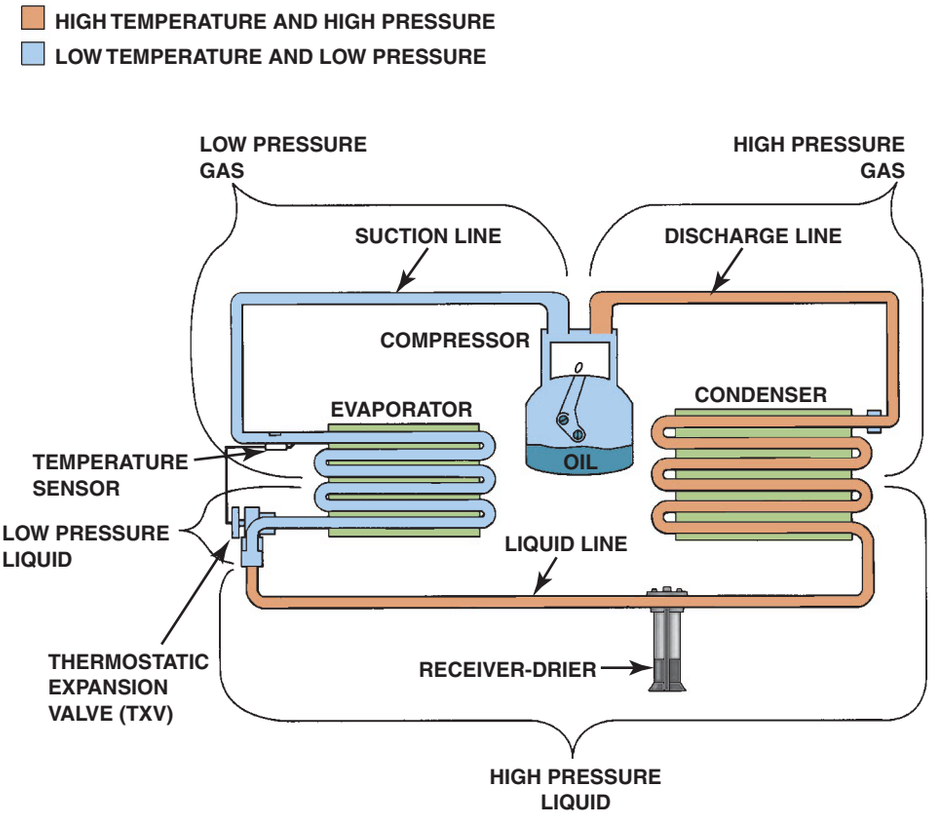

FIGURE 62–10 A typical air-conditioning system that uses an expansion valve. A temperature sensor bulb is attached to the outlet of the evaporator to control the amount of refrigerant allowed to flow into the evaporator.

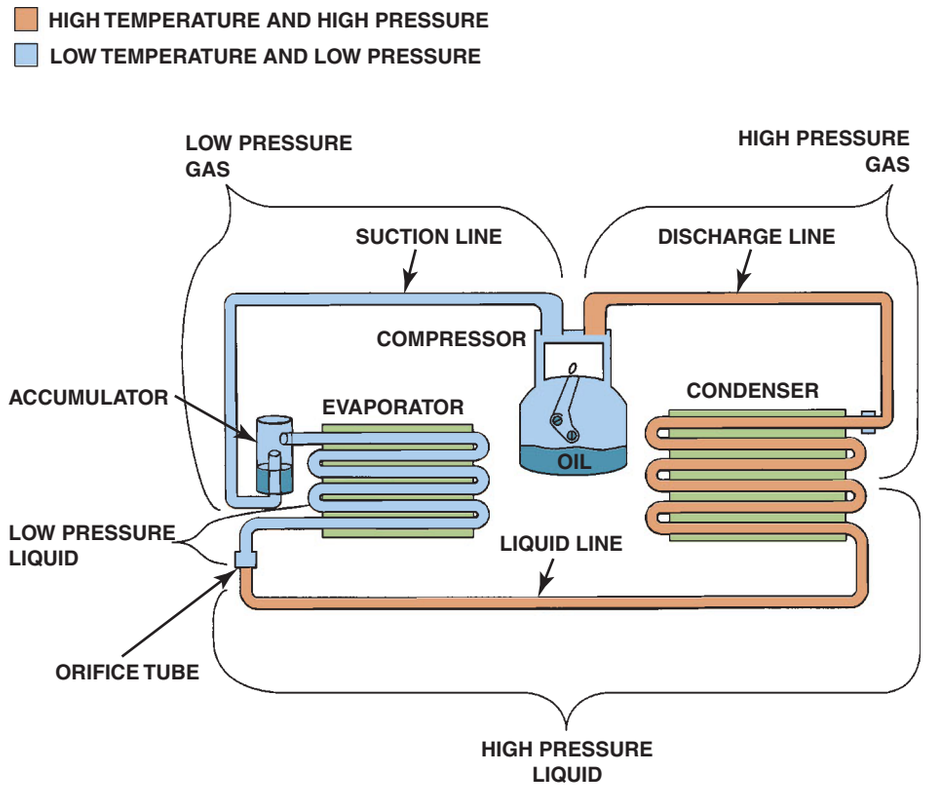

FIGURE 62–11 A typical automotive air-conditioning system that uses a cycling clutch and an orifice tube.

dropping below 32° F (0°C). At this temperature, the moisture in the air freezes. The resulting ice would clog the airflow through the evaporator. If air cannot flow through the evaporator, the air-conditioning system stops functioning and would be immediately noticed by the driver and any passengers. If the A/C is turned off, heat from the surrounding air will melt the ice and the air-conditioning system will again function until it ices up again.

A commonly used method to control evaporator temperature is to use a thermostat to control the compressor. Air-conditioning compressors use an **electromagnetic clutch.** ● **SEE FIGURE 62–13.**

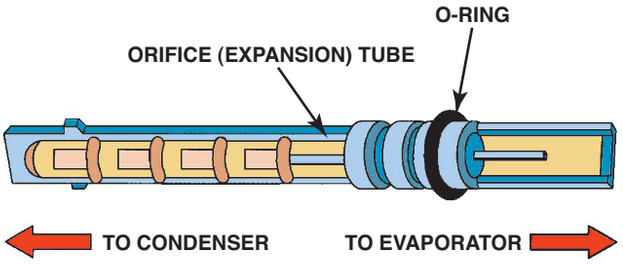

FIGURE 62–12 Typical orifice tube.

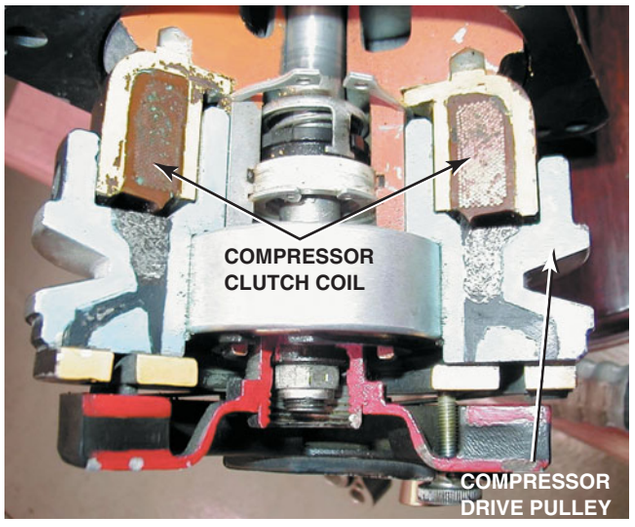

FIGURE 62–13 A cutaway of an air-conditioning compressor electromagnetic clutch.

When the thermostat senses that the temperature is near freezing, 32°F (0°C), the switch opens the electrical circuit to the compressor and the compressor stops circulating refrigerant. This thermostat switch is also called a **thermo switch, icing switch,** or **defrost switch**.

NOTE: Older vehicles used a system to control evaporator pressure when used with a continuously-operating compressor, including:

POA valve—A POA valve (meaning pilot operated absolute)
EPR valve—An evaporator pressure regulator valve maintains at least 30 psi in the evaporator to prevent evaporator freeze-up.

REFRIGERANTS

Air-conditioning refrigerant is used to transfer heat from the inside of the vehicle to the condenser located in the front of the vehicle. A refrigerant absorbs heat when it changes state from a liquid to a gas. One of the first refrigerants was **CFC-12,** commonly referred to as **R-12** or by its brand name **Freon,** a registered trade name of the DuPont Corporation. CFC-12 consists of one carbon atom surrounded by two chlorine (CL) and two fluorine (F) atoms and is therefore called a chlorofluorocarbon (CFC) compound. Its chemical name is dichlorodifluoromethane. It is the chlorine atoms that are believed to contribute to the destroying of the ozone layer in our upper atmosphere.

FIGURE 62–14 R-134a is available in 12 oz cans as well as larger 30-lb containers.

Another refrigerant, **HFC-134a,** also called **R-134a**, has been selected by vehicle manufacturers to replace the ozone-harming CFC. HFC-134a compound contains two carbon atoms and four fluorine atoms plus two hydrogen atoms and is therefore called a hydrofluorocarbon. Its chemical name is tetrafluorolthene, and Dupont calls it Suva®. ● **SEE FIGURE 62–14**. The boiling points and therefore the operation characteristics of CFC-12 and HFC-134a are similar.

HFC-134a is a smaller molecule than CFC-12. However, HFC-134a can more easily leak out through small holes or openings in the system. HFC-134a systems require that the inside layer of

the rubber refrigerant hoses contain a barrier to prevent penetration through the microscopic holes/standard rubber refrigerant holes.

NOTE: Look at the size of a blue HFC-134a 30-pound container compared to a white CFC-12 30-pound container. The blue R-134a container is larger because it requires more HFC-134a to achieve 30 pounds.

NOTE: Many vehicle manufacturers started using barrier-type refrigerant hoses on their vehicles in the late 1980s in anticipation of the conversion from CFC-12 to HFC-134a in future models.

REFRIGERANTS AND THE ENVIRONMENT

Air-conditioning refrigerants have been discovered to be harmful to the ozone layer. The ozone (O_3) layer is in the upper atmosphere and blocks out ultraviolet rays from the sun. ● **SEE FIGURE 62–15**. It has been discovered that certain chemicals, such as chlorofluorocarbon (CFC), are rapidly destroying this layer of ozone, which is 10 to 30 miles above Earth's surface. ● **SEE FIGURE 62–16** for how ozone is destroyed.

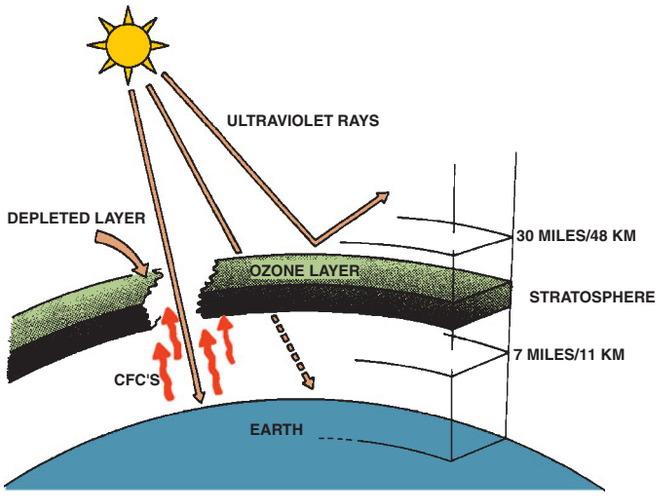

FIGURE 62–15 A depletion of the ozone layer allows more ultraviolet radiation from the sun to reach Earth's surface.

MONTREAL PROTOCOL A conference was held in Montreal, Canada, in 1987, where the United States and 22 other countries agreed to limit the production of ozone-depleting refrigerants. The Clean Air Act of 1990 specified that the production of R-12 refrigerant would cease at the end of 1995. **Section 609** of the Clean Air Act required the following:

- All technicians who service or repair automotive air-conditioning systems shall be properly trained and certified.
- Recovery and recycling equipment must be properly approved.
- Each shop that performs automotive air-conditioning service should comply to the Environmental Protection Agency (EPA) that it is using approved recycling equipment and that only properly trained and certified technicians are using the equipment.

? FREQUENTLY ASKED QUESTION

Is Carbon Dioxide the Next Refrigerant?

Not likely. While carbon dioxide (CO_2) (R744) is being used on prototype vehicles, such as the Toyota Fuel Cell Hybrid Vehicle (FCHV), it requires extremely high pressures, up to 2000 psi and is not as efficient as a refrigerant as R-134a. ● **SEE FIGURE 62–17**.

FIGURE 62–17 The label on a Toyota Fuel Cell Hybrid Vehicle (FCHV) showing that CO_2 is being used as the refrigerant.

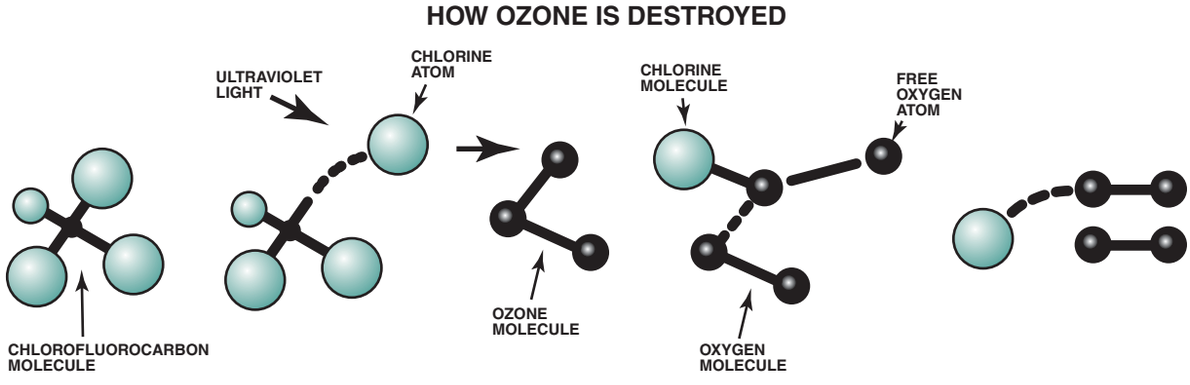

FIGURE 62–16 Chlorofluorocarbon molecules break apart in the atmosphere.

FIGURE 62–18 PAG oil used in Chrysler vehicles equipped with HFC-134a refrigerant. Notice that different oils are used for different systems depending primarily on the manufacturer of the compressor. Also notice that both PAG oils are in metal cans. PAG oil absorbs moisture so readily that it can even absorb moisture that is in the air through plastic—that is why metal containers are used.

FIGURE 62–19 Ester refrigerant oils are often specified for use when retrofitting an R-12 system to R-134a by companies who supply refit kits. Ester refrigerant oil is not recommended by many vehicle or air-conditioning compressor manufacturers. Always use the recommended refrigerant oil for the vehicle and system being serviced.

REFRIGERANT OILS

The oil carried by the refrigerant through the various components is often the only source of lubrication for the compressor. The oil used must be able to be mixed without separating in the refrigerant. This characteristic of being able to be mixed is called **miscible.** CFC-12 systems must use mineral oil. Mineral oil is not miscible in HFC-134a, and so such systems must use synthetic polyalkyline glycol, usually referred to as PAG oil. There are numerous different PAG oils, and each vehicle manufacturer (or air-conditioning compressor manufacturer) recommends which PAG to use. ● **SEE FIGURE 62–18**.

Another type of refrigerant oil is called **ester oil.** Ester is a classification of hydrocarbons and is specified for use in air-conditioning systems that have been charged (retrofitted) from CFC-12 to HFC-134a. Ester oil will mix with any remaining mineral oil and will work to lubricate the system even if some CFC-12 is still in the system. ● **SEE FIGURE 62–19**.

All refrigerant oils have a viscosity rating. Viscosity is the measure of the oil's thickness or resistance to flow. Always use the type and viscosity of oil specified by the manufacturer.

CAUTION: Failure to use the correct refrigerant oil in an air-conditioning system can cause serious (and expensive) damage to the air-conditioning compressor. Always use the refrigerant oil specified by the manufacturer.

CONDENSER

The condenser looks like a cooling system radiator. In fact, a condenser is a radiator because it is designed to radiate heat from the refrigerant to the outside air.

When the refrigerant leaves the compressor it is over 300°F (150°C) as it enters the condenser. Even on a hot 100°F (38°C) day, there is a difference in temperature between the outside air around the condenser and the temperature of the refrigerant inside the condenser. Heat always travels hot to cold. Therefore, the heat in the hot refrigerant has a natural tendency to radiate into the outside air. As the heat travels into the air, the high-pressure gas refrigerant changes state and becomes a high-pressure liquid. This is the reason the condenser is called by that name: as the heat leaves the refrigerant, it **condenses** from a gas (vapor) to a liquid. ● **SEE FIGURE 62–20**.

To help in the heat transfer, most vehicles are equipped with cooling fans driven either electrically or by the engine through an accessory drive belt. The fan draws air through the condenser and increases the heat transfer rate.

EVAPORATOR

The evaporator looks like a small radiator that is located in the evaporator housing on the passenger side of the bulkhead (firewall). The purpose of the evaporator is to transfer heat from the air to the refrigerant flowing through it. Heat from the air causes the low-pressure liquid inside the evaporator to evaporate into a low-pressure gas. As the refrigerant changes state from a liquid to a gas, it absorbs heat. A blower motor equipped with a squirrel cage–type fan circulates air through the evaporator and forces the cooler air into the passenger compartment.

Another benefit of the cooling of the air is a result of what happens to any moisture that may be in the air. Moisture in the air is called relative humidity and represents the percentage of water vapor that could be in the air to the actual amount in the air. High humidity feels uncomfortable. Because the evaporator is cold (usually just above the freezing point of 32°F (0°C)), any moisture in the air condenses on its cool surface. This removes the moisture from the air and lowers the relative humidity. The moisture that condenses

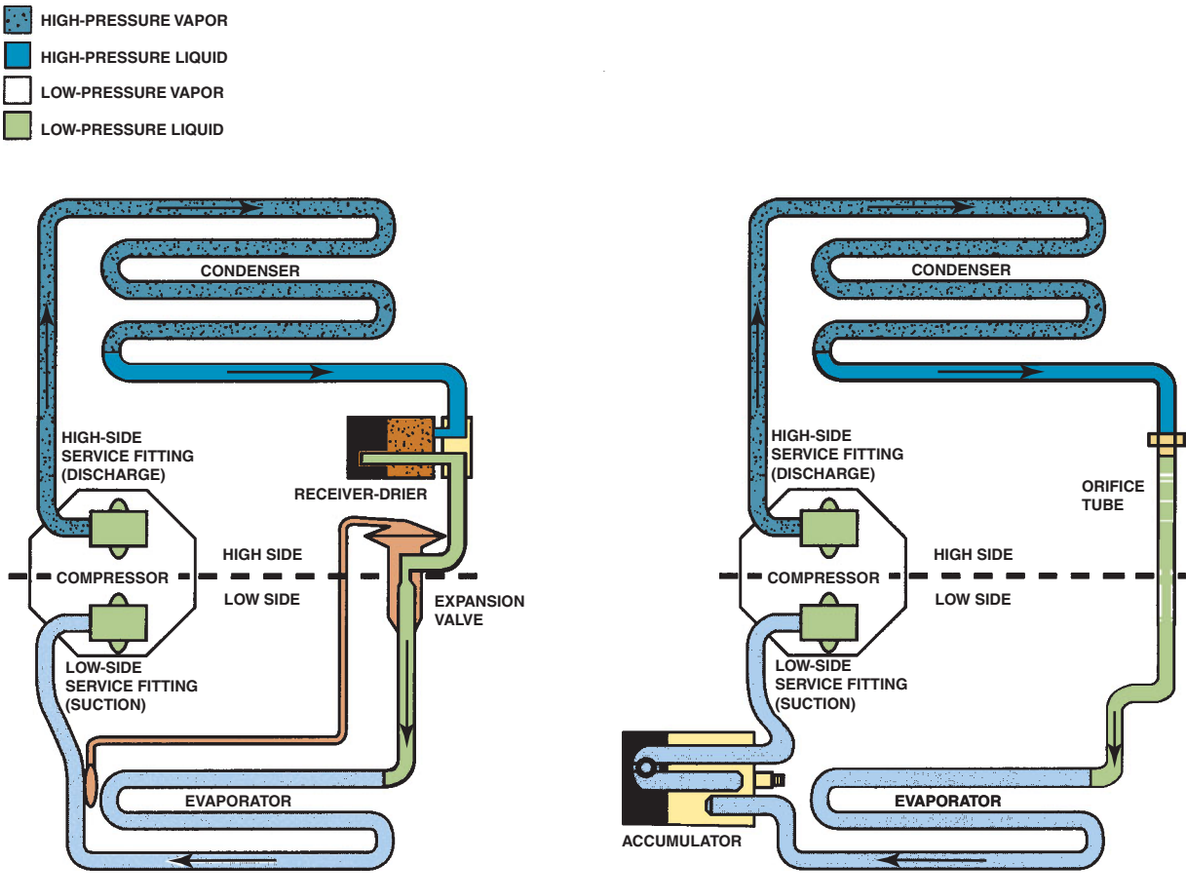

FIGURE 62–20 The condenser serves the same function for both the orifice-tube and the expansion valve–type air-conditioning system, and that is to remove the heat from the refrigerant and cause the hot refrigerant vapors to condense into a hot liquid.

TECH TIP

Broken Condenser Line? Check the Engine Mounts!

Most air-conditioning systems use aluminum and flexible rubber lines between the compressor and the condenser. Because the compressor is mounted on and driven by the engine and the condenser is mounted to the body, these lines can break if the engine mounts are defective. The rubber hoses attached between the aluminum fittings of the compressor and condenser are designed to absorb normal engine movement. Worn engine mounts would allow the engine to move too much. Aluminum lines cannot stand to be flexed without crushing and breaking.

Therefore, the wise technician will carefully inspect and replace any and all worn engine mounts if a broken aluminum condenser line is discovered to prevent a premature failure of a replacement condenser. ● **SEE FIGURE 62–21**.

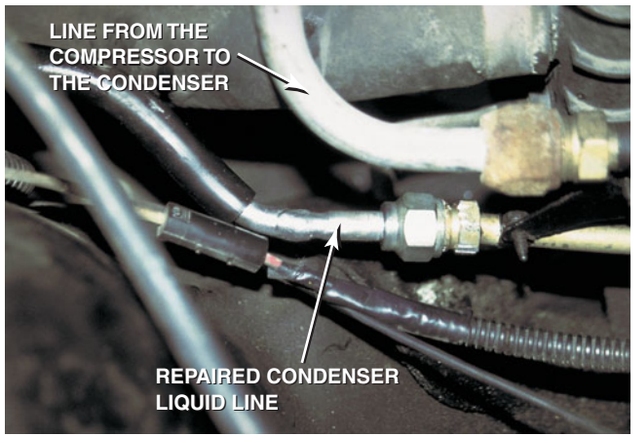

FIGURE 62–21 A repaired condenser refrigerant line.

out of the air then becomes water that is allowed to flow out of the evaporator housing and onto the ground. ● **SEE FIGURE 62–22**.

NOTE: If the carpet (or floor) of the vehicle is wet on the passenger side, the cause is often a clogged evaporator drain hose. The opening, called the condensate line, is frequently clogged with mud, road debris, or leaves. To check the drain opening, hoist the vehicle and insert a wire or screwdriver into the end of the hose opening at the bottom of the evaporator housing.

RECEIVER-DRIER

A receiver-drier is used on an air-conditioning system that uses an expansion valve. The receiver-drier is located between the condenser and the evaporator. This section of the air-conditioning system contains *high-pressure liquid refrigerant*. The purpose of the receiver is to provide temporary storage for the liquid refrigerant and it also usually includes a filter to trap debris and a desiccant to remove moisture. Many receiver-driers contain a sight glass that provides a view of the liquid refrigerant in the system.

A drier is needed to remove moisture from the system. The drier contains a **desiccant** (usually silica alumina or silica gel). A

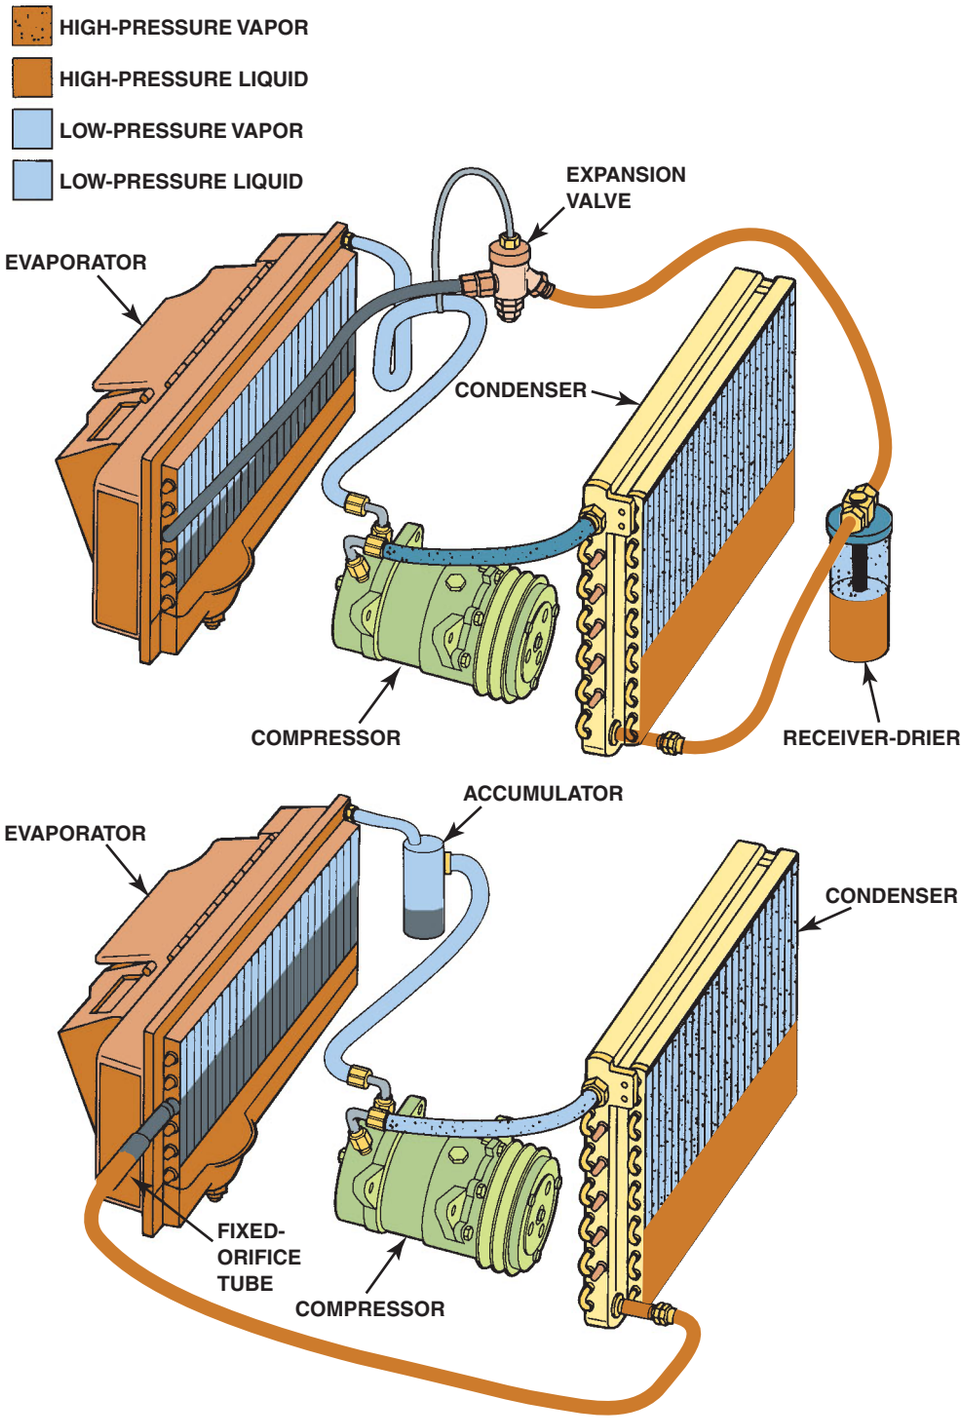

FIGURE 62–22 The evaporator serves the same function for both the orifice-tube and the expansion valve–type air-conditioning system, and that is to allow the liquid refrigerant to evaporate and absorb heat from the passenger compartment.

desiccant is a drying agent that absorbs any moisture (water) that gets into the air-conditioning refrigerant system. Moisture can combine with refrigerant to form an acid. Water can also freeze and form ice in the system.

The desiccant is classified as XH-5 for CFC-12 systems and XH-7 or XH-9 for HFC-134a systems. The desiccant used on a CFC-12 system is not compatible with HFC-134a systems. Therefore, whenever a system is changed (retrofitted) from CFC-12 to HFC-134a, the desiccant *must* be replaced.

The desiccant (accumulator or receiver-drier) should also be replaced on any air-conditioning system that has been left open to the atmosphere for any length of time (over 24 hours) or whenever the system has been left in a discharged condition. ● **SEE FIGURE 62–23**.

ACCUMULATOR

An accumulator is used on systems that use an orifice tube. It is located between the evaporator and the compressor. The refrigerant in this section of the refrigerant cycle is a *low-pressure gas*. The purposes of the accumulator include:

- Preventing liquid refrigerant from reaching the compressor

NOTE: A liquid cannot be compressed. If liquid refrigerant were to enter the compressor, the compressor would lock up and be damaged.

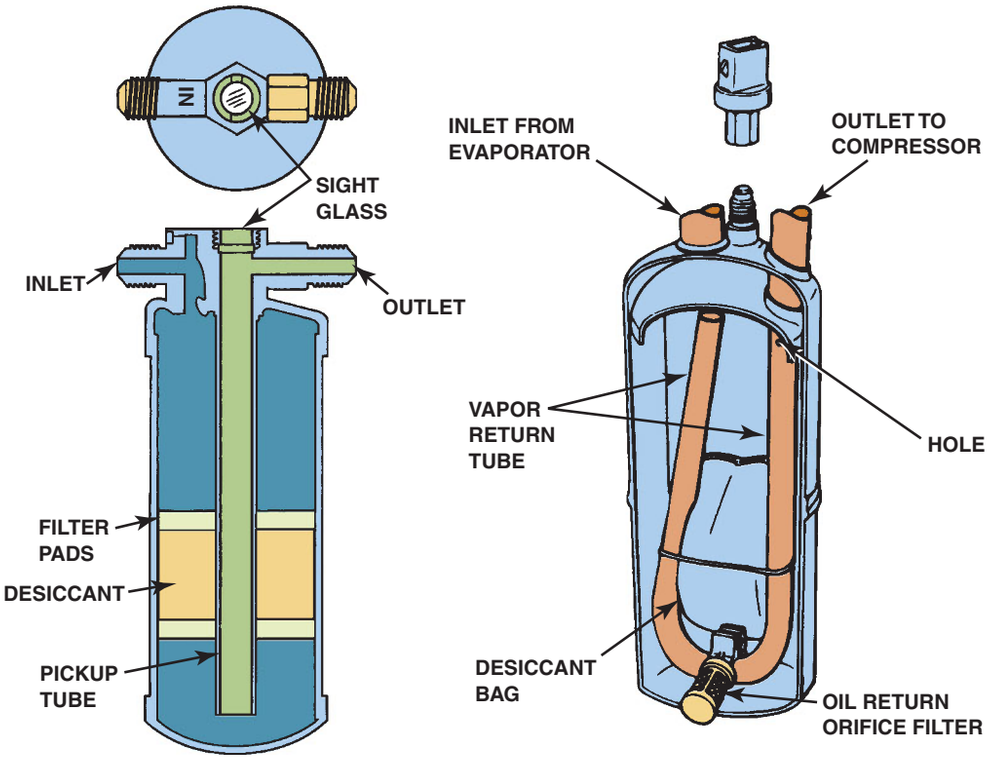

FIGURE 62–23 Expansion-valve systems store excess refrigerant in a receiver-drier, which is located in the high-side liquid section of the system, whereas orifice-tube systems store excess refrigerant in an accumulator located in the low-side vapor section of the system.

● **SEE FIGURE 62–24.**

REFRIGERANT LINES AND HOSES

Aluminum tubing is used to connect many stationary items together like the condenser to the receiver-drier and the receiver-drier to the evaporator. Rubber lines are usually used to and from the compressor. Because the compressor is attached to the engine and the engine is mounted on flexible rubber mounts, there is movement between the compressor and the other air-conditioning components that are attached to the body of the vehicle. These flexible refrigerant hoses are constructed from many layers of rubber and fabric. ● **SEE FIGURE 62–25**. Most hoses used on vehicles since the early 1990s use a nonpermeable inside layer of material that prevents the loss of refrigerant through the hose itself. These hoses, called **barrier hoses,** are required for use with HFC-134a refrigerant.

THERMOSTATIC EXPANSION VALVES

Thermostatic expansion valve (TXV) systems, as shown in **FIGURE 62–26**, use a temperature-sensitive bulb located on the evaporator outlet tube. The sensing bulb is insulated with a special tape, so it reacts only to temperature changes it senses from the outlet tube. The sensing bulb works in combination with a pressure-sensitive diaphragm inside the TXV body to control the size of the variable orifice. This regulates the rate at which liquid refrigerant flows into the evaporator.

The key to the operation of the expansion valve is the variable orifice. In these systems, the outlet from the high-pressure side to the low-pressure side is a variable-diameter hole. A **pintle valve** is a ball-and-seat valve used to increase or decrease the size of the opening. ● **SEE FIGURE 62–27**. The expansion valve uses the pintle valve to control how rapidly refrigerant enters the evaporator. The expansion valve controls the refrigerant flow in response to the temperature of the evaporator outlet, measured by the remotely mounted sensing bulb and **capillary tube.** ● **SEE FIGURE 62–28**. The sensing bulb may be clamped to the outlet pipe or mounted inside a passage near the outlet of the evaporator. The bulb and tube contain refrigerant. The rise or fall of the evaporator outlet

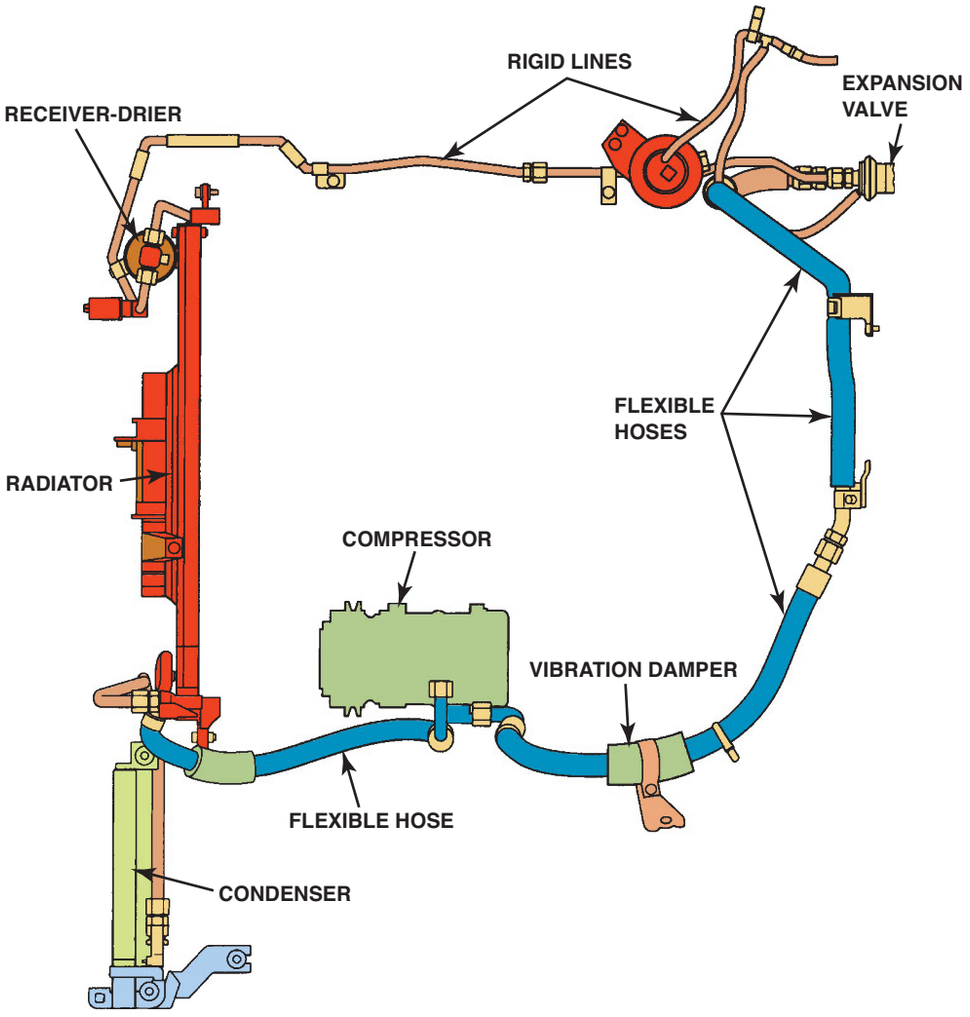

FIGURE 62–25 Rigid lines and flexible hoses are used throughout the air-conditioning system. The line to and from the compressor must be flexible because it is attached to the engine, which moves on its mounts during normal vehicle operation.

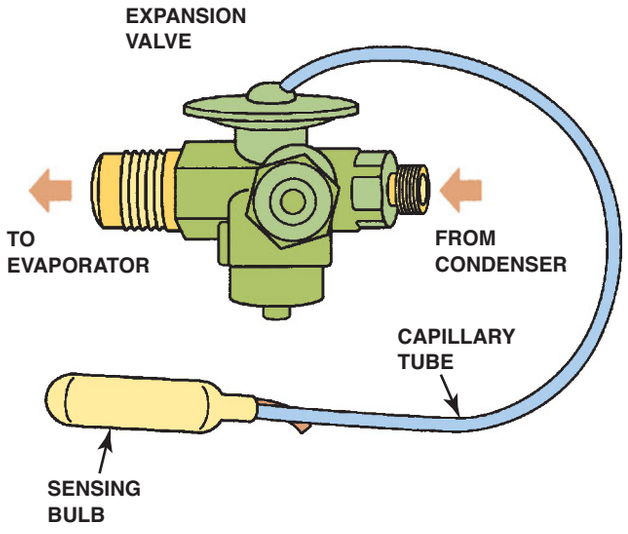

FIGURE 62–26 A typical expansion valve which uses an inlet and outlet attachment for the evaporator, and a temperature-sensing bulb that is attached to the evaporator outlet tube.

temperature causes the refrigerant in the bulb to expand or contract, resulting in a rise or fall of pressure inside the capillary.

This outlet-temperature-sensitive pressure is applied to one side of the spring-loaded diaphragm inside the expansion valve. ● **SEE FIGURE 62–29**. As the capillary tube warms, the refrigerant inside expands, forcing the diaphragm downward. The diaphragm magnifies this pressure and uses it to open the valve by pushing the pintle and ball away from its seat. This increases the size of the orifice and allows more refrigerant into the evaporator, increasing the cooling capacity.

When the evaporator cools in response to the boiling of the added refrigerant, the refrigerant in the capillary tube contracts. This relieves the pressure on the expansion valve diaphragm, which closes the pintle and ball, and reduces refrigerant flow.

Pressure on the top of the diaphragm is applied through the capillary tube. The equalizing pressure on the underside of the diaphragm can be internal (from the evaporator inlet) or external (from the evaporator outlet):

- An internally equalized expansion valve has a passage that permits evaporator inlet pressure to reach the underside of the diaphragm.
- An externally equalized expansion valve has an extra line mounted to the underside of the diaphragm housing. This line monitors the outlet pressure of the evaporator. The connection can be either at the outlet of the evaporator or at the outlet of the evaporator pressure control device.

In an expansion-valve system, the refrigerant vapor that leaves the evaporator is warmer than the liquid refrigerant that entered it. The heat that warms the refrigerant is referred to as **superheat.**

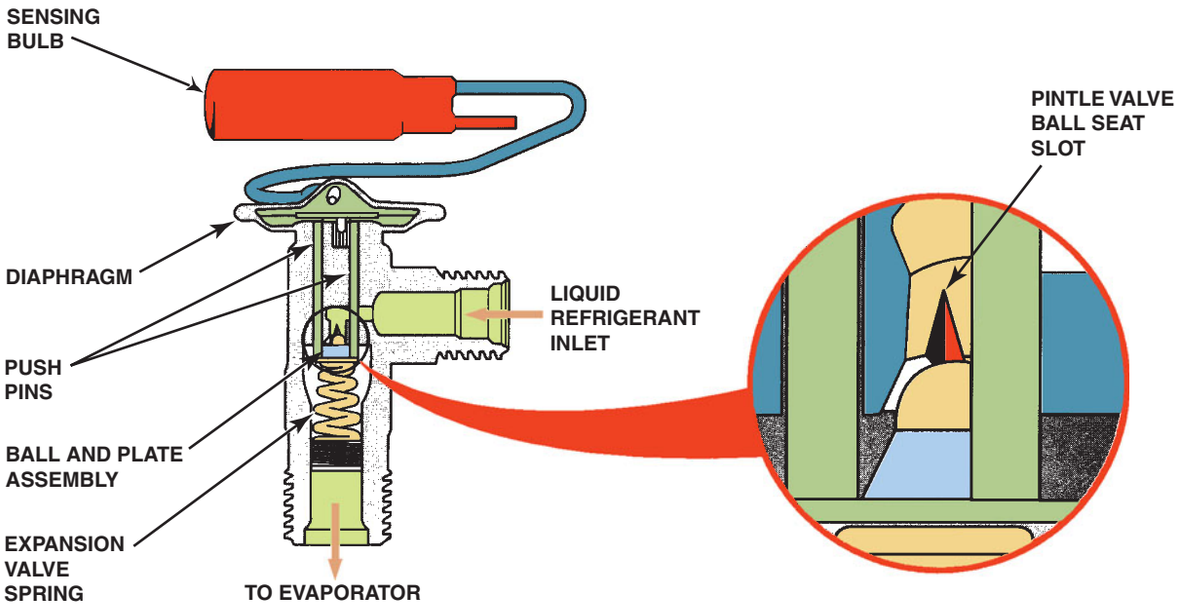

FIGURE 62–27 A slot cut in the ball seat inside the expansion valve permits a small amount of refrigerant and oil to pass through at all times, even when the valve is closed. This flow of oil through the system is necessary to make sure that the compressor receives the oil it needs for lubrication.

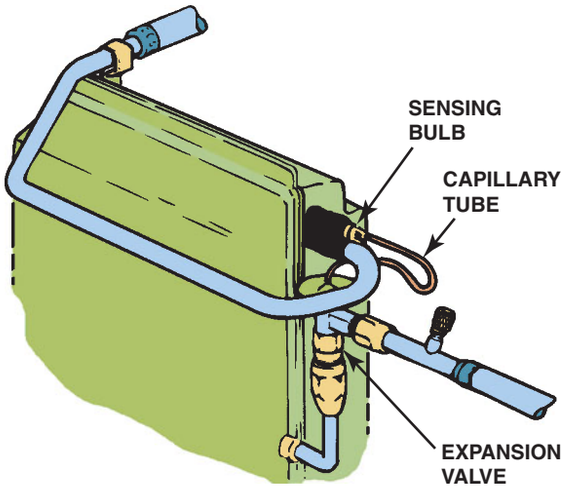

FIGURE 62–28 The sensing bulb is attached to the evaporator outlet tube. Refrigerant inside the bulb expands or contracts in response to the evaporator temperature.

Superheat is usually measured as the actual temperature difference between the boiling point of the refrigerant at the inlet and at the outlet of the evaporator. Typical values for superheat in an evaporator are between 4° and 16°F (3° and 10°C).

Superheat is important because it ensures that all (or almost all) of the refrigerant vaporizes before leaving the evaporator.

Chrysler uses a valve called an **H-valve.** It includes both the temperature-sensing and pressure-sensing functions of the expansion valve, but does not have any external tubes.

The H-valve has two refrigerant passages that form the legs of the "H" as shown in **FIGURES 62–30 AND 62–31**. The lower passage is the refrigerant line from the condenser to the evaporator, and contains the ball and spring valve. The upper passage is the refrigerant line from the evaporator to the compressor, and contains the temperature-sensing element. A pushrod connects the diaphragm of the temperature sensor located at the top of the block to the valve ball at the bottom.

The cycling-clutch switch, which senses the suction line, detects the evaporator outlet temperature and cycles the compressor clutch to control system cooling. This capillary device does not directly control the metering orifice. ● **SEE FIGURE 62–32**.

FIXED-ORIFICE TUBES

Liquid refrigerant flows from the condenser to the orifice tube. As with expansion valves, fixed-orifice tubes provide a restriction that separates the high-pressure from the low-pressure side of the system. ● **SEE FIGURE 62–33**. When it reaches the fixed-orifice tube, the refrigerant undergoes rapid expansion and changes from a warm, high-pressure liquid to a cold, low-pressure liquid and vapor mixture.

As it passes through the restriction to the low side, the refrigerant changes state from a liquid to a vapor because the pressure in the evaporator is so much lower than in the refrigerant line upstream from the orifice tube. The refrigerant begins to vaporize quickly as it absorbs the heat from the evaporator.

The orifice tube, located between the condenser and the evaporator inlet, may be inserted in the refrigerant line or may be part of the inlet refrigerant line assembly.

COMPRESSORS

The air-conditioning compressor is driven by the engine with an accessory drive belt. A magnetic clutch is usually used to connect and disconnect the drive pulley to the compressor as needed for cooling or defrosting. The compressor performs the following functions:

- Compresses the low-pressure gas refrigerant from the evaporator into a high-pressure gas that is then sent to the condenser

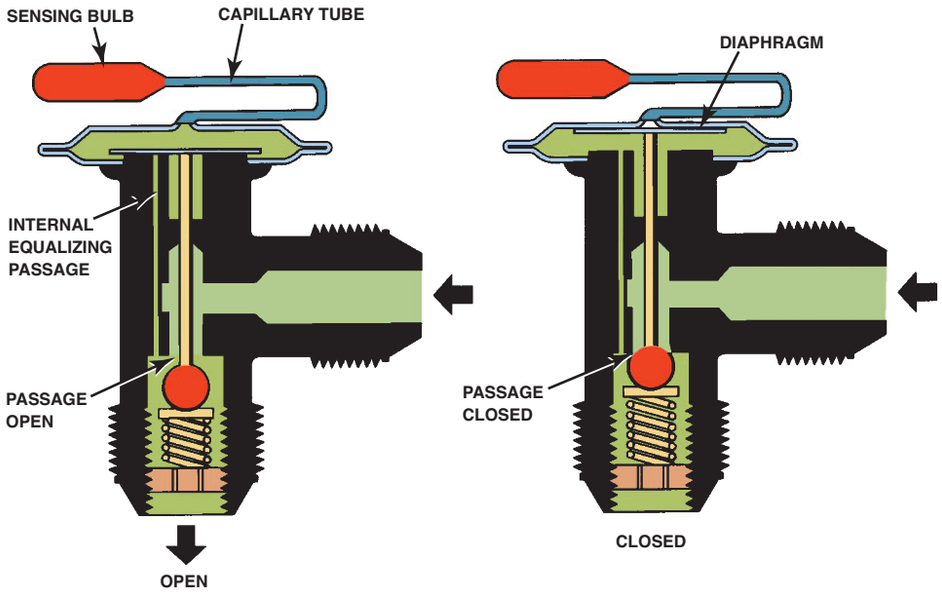

FIGURE 62–29 Pressure from the capillary tube pushes on the spring-loaded diaphragm to open the expansion valve. As the pressure in the capillary tube contracts, the reduced pressure on the diaphragm allows the valve to close.

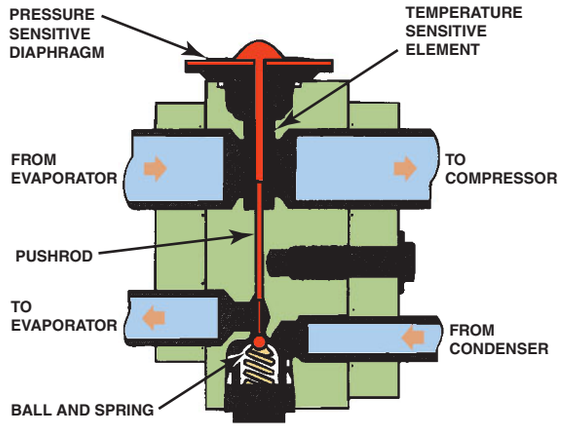

FIGURE 62–30 An H-valve (H-block) combines the temperature-sensing and pressure-regulating functions into a single assembly.

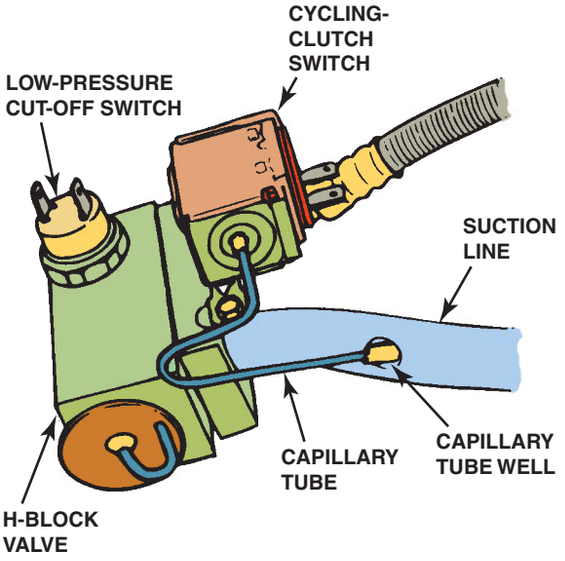

FIGURE 62–32 In this Chrysler system, a low-pressure cutoff switch and a cycling-clutch switch are mounted on the H-valve.

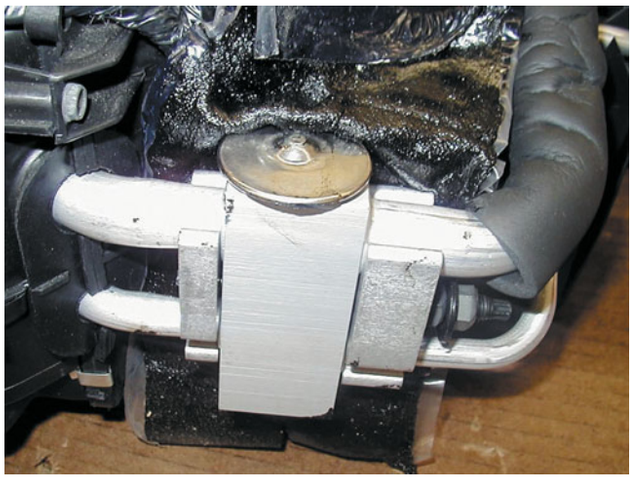

FIGURE 62–31 An H-valve as used on a Chrysler minivan.

- Raises the temperature of the gas so that there is a difference in temperature between the outside (ambient) air and the refrigerant in the condenser
- Acts as the pump used to circulate the refrigerant throughout the system
- Often switches on and off (cycles) to control evaporator temperatures
- Is the major reason why there is refrigerant oil in the system. The oil in the refrigerant lubricates the moving parts of the compressor.

POSITIVE-DISPLACEMENT PISTON COMPRESSORS

A **positive-displacement compressor** displaces a constant, uniform volume of refrigerant for each revolution or operating cycle. Most

automotive air-conditioner compressors are positive-displacement piston designs. These compressors have from one to 10 cylinders depending on manufacturer and application. Most of these compressors use a piston-in-cylinder arrangement with intake and discharge strokes to draw in, compress, and discharge refrigerant. ● **SEE FIGURE 62–34**.

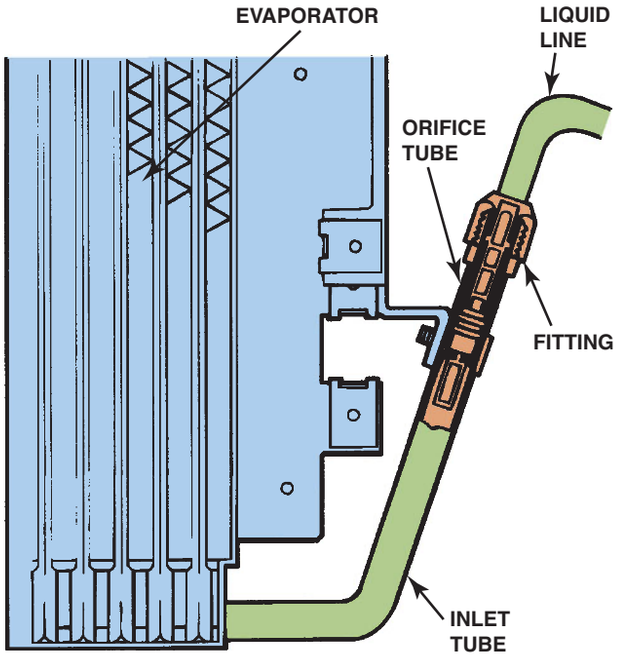

FIGURE 62–33 The orifice tube is usually located at the inlet tube to the evaporator.

The compressor intake stroke is also known as the suction stroke. The suction stroke of a positive-displacement compressor is like that of a two-stroke gasoline engine. Just as the intake stroke of an engine's piston creates a low-pressure area that draws the air–fuel mixture in through the cylinder head, the suction stroke of the compressor piston creates a low-pressure area to draw refrigerant vapor into the cylinder. However, the similarity ends here. In a two-stroke engine, the compression stroke compresses the air–fuel mixture inside a sealed cylinder, with both the intake and exhaust valves closed. In the two-stroke piston AC compressor, the discharge valve does not resist the refrigerant flow during the upward piston stroke. As the compressor operates, the maximum possible charge of refrigerant vapor has been drawn in at bottom dead center of the compressor piston's suction stroke. When the piston begins its discharge stroke, the pressure increases, shutting the suction valve and opening the discharge valve at the same time. The charge of refrigerant vapor is pushed out of the compressor into the high-side refrigerant line and travels toward the condenser. Therefore, the refrigerant vapor is compressed simultaneously throughout the entire high side of the air-conditioning system.

All piston compressors use one suction valve and one discharge valve for each piston. The typical valve used in compressors is the **reed valve:** a one-way, flap-type check valve that is built into the valve plate which seals one or more cylinders. ● **SEE FIGURE 62–35** on page 728. A reed valve flaps away from the valve plate to open, and toward the valve plate to close. Pressure pushes the valve in one direction or the other. The suction reed valve is located on the underside of the valve plate. When the suction created by the piston's downward stroke becomes strong enough, the suction reed valve bends, or flaps, off its seat. Low-pressure refrigerant vapor then flows into the compressor. The refrigerant vapor fills the partial vacuum created by the moving piston.

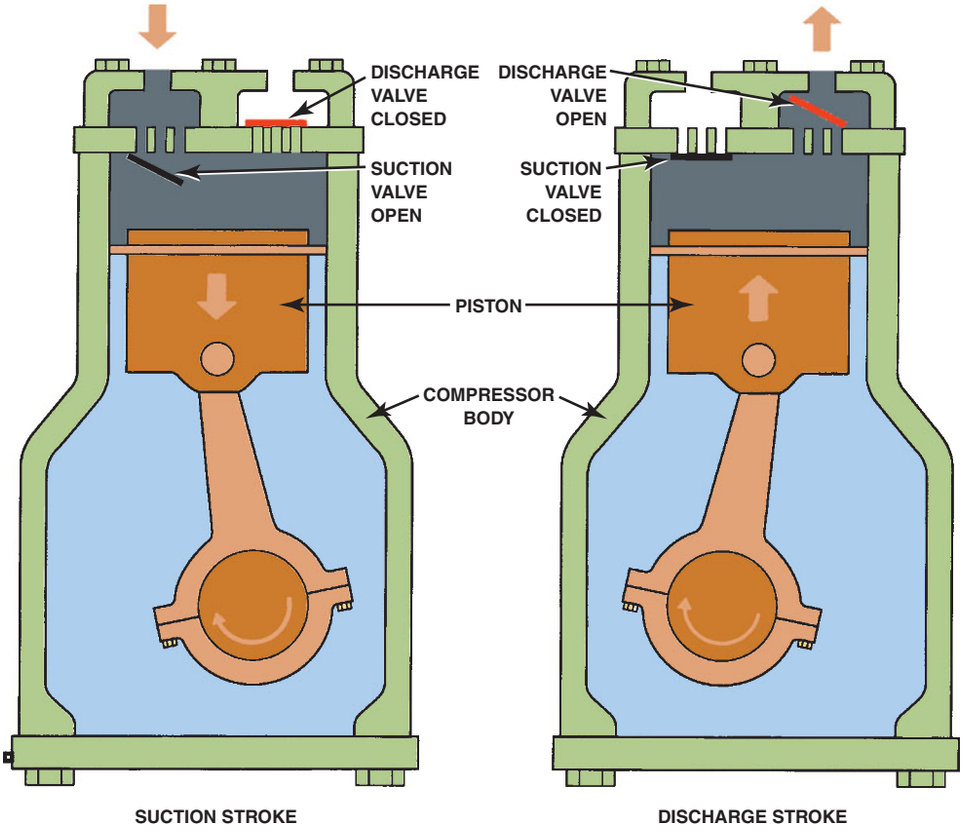

FIGURE 62–34 In a positive-displacement compressor, the descending piston creates a drop in pressure inside the cylinder. The resulting pressure differential allows low-side pressure to force the suction valve open. Refrigerant then flows into the cylinder. On the piston's discharge stroke, the pressure caused by the ascending piston closes the intake valve and forces the refrigerant out the discharge valve.

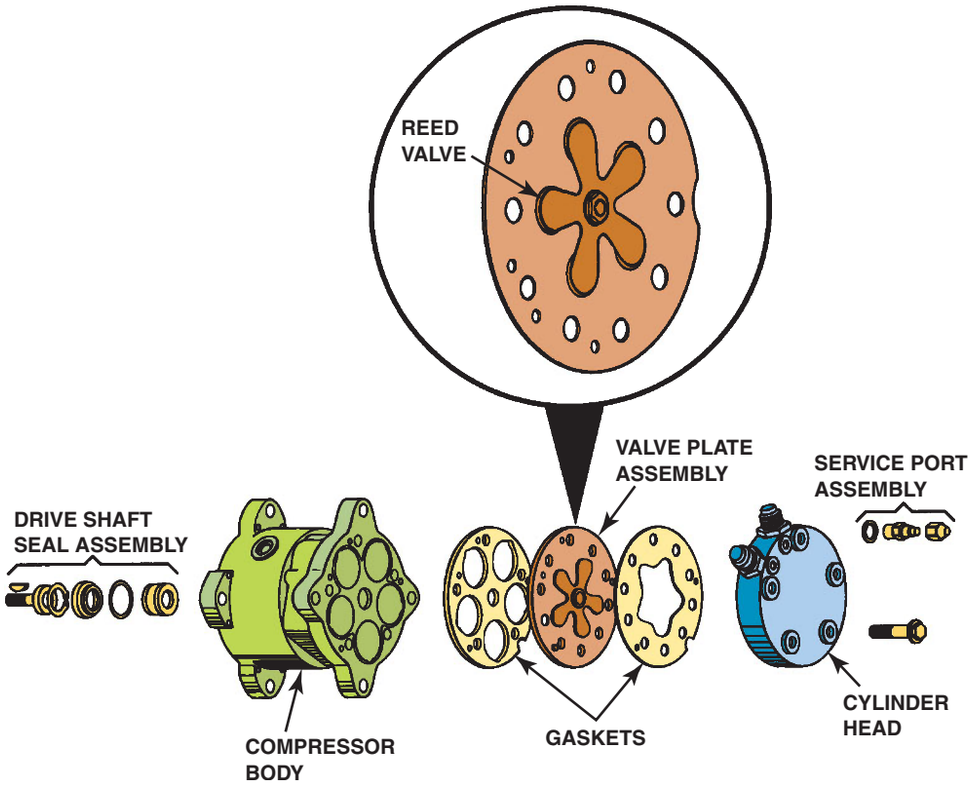

FIGURE 62–35 A reed valve is a one-way check valve that flaps away from the valve plate to open, and toward the valve plate to close.

The discharge reed valve is on the top side of the valve plate. The partial vacuum in the cylinder also pulls the discharge valve tightly against its seat, sealing off the system's high side from the cylinder during the suction stroke.

The reeds behave in exactly the opposite way during the piston's discharge stroke. The increasing cylinder pressure pushes the suction valve tightly against its seat, sealing off the system's low side. The discharge valve on the opposite side of the valve plate is unseated as the pressure in the cylinder increases as a result of the upward moving piston. The piston pushes the refrigerant through the discharge valve, out of the compressor, and into the air-conditioning system high side.

PISTONS AND RINGS

The basic two-stroke cycle depends upon the pistons and their sealing rings to provide an adequate seal against the high-side refrigerant pressure. Most piston compressors have from two to six cylinders.

Some compressors use a **swash plate,** or axial plate. This plate is rigidly mounted to the belt-driven shaft at an angle. ● **SEE FIGURE 62–36** on page 729. The pistons may be on one or both sides of the plate. The pistons are connected to the swash plate by means of a large ball bearing. As the pulley turns, the shaft and angled swash plate assembly rotate. This forces the pistons back and forth in their bores. In this way, the swash plate changes the rotating action of the shaft to a reciprocating action that provides driving force for each piston. Compressors that use a swash plate are often called **axial compressors.**

VARIABLE DISPLACEMENT COMPRESSOR

Some air-conditioning systems use variable displacement to control the amount of refrigerant flowing through the evaporator. The pressure difference between the high side and the low side causes the swash plate to move inside the compressor. As the swash plate changes its angle, the stroke of the piston is increased for more cooling or decreased to reduce the amount of cooling. ● **SEE FIGURE 62–37** on page 729.

TECH TIP

The Radio "POP" Trick

Most air-conditioning compressor clutch circuits contain a diode that is used to suppress the high-voltage spike that is generated whenever the compressor clutch coil is disengaged (turned off). If this diode were to fail, a high voltage (up to 400 volts!) could damage sensitive electronic components in the vehicle including the electronic air-conditioning compressor clutch control unit (if so equipped).

Another thing that can occur is that the radio will often turn off and then back on whenever the electronics inside the radio detect a high-voltage spike. This can create a "pop" in the radio that is very intermittent because it only occurs when the air-conditioning compressor clutch cycles off. To check this diode, simply tune the radio to a weak AM station near 1400 Hz and cycle the air-conditioning compressor on and off. If a "pop" is heard from the radio speaker(s), then the diode is defective and must be replaced.

NOTE: While some A/C compressor diodes can be replaced separately, some of these air-conditioning compressor clutch diodes are part of an entire wiring harness assembly.

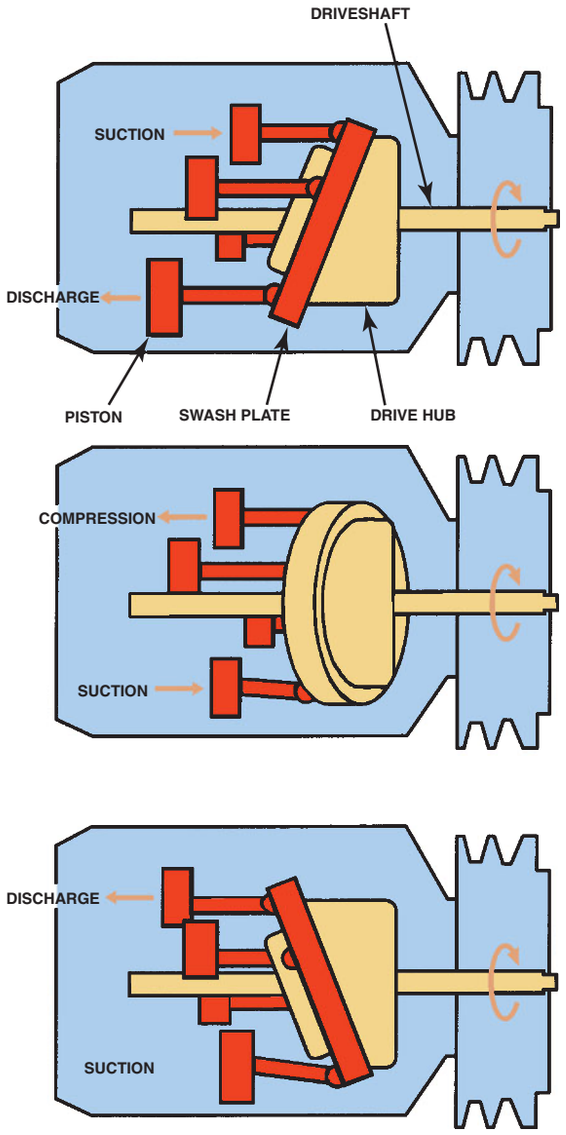

FIGURE 62–36 The swash plate, attached to the crankshaft at an angle, converts the pulley's rotary motion to axial motion, which drives the pistons in a reciprocating motion.

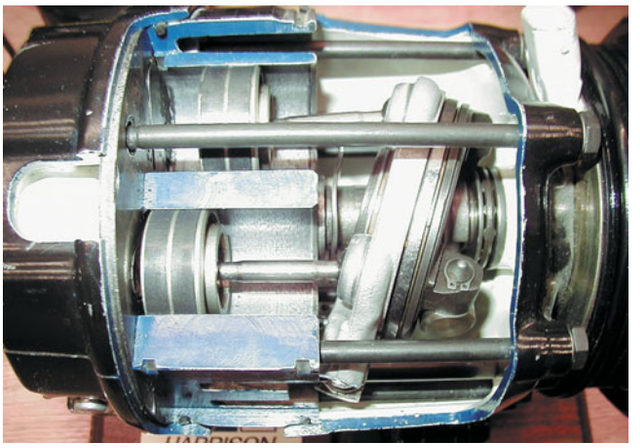

FIGURE 62–37 A V-5 variable displacement compressor. Internal pressures act on the swash plate, which changes the stroke of the piston and then displacement based on the pressures in the system.

COMPRESSOR CONTROLS

Most air-conditioning compressors use an electromagnetic clutch. A coil of wire inside the clutch creates a strong magnetic field that when activated connects the input shaft of the compressor to the drive pulley. Most electromagnetic coil assemblies have between 3 and 4 ohms of resistance. According to Ohm's law, about 3 to 4 amperes of current are required to energize the air-conditioning compressor clutch. All electrical circuits require three things to operate:

1. A voltage source
2. An electrical load (the air-conditioning compressor clutch)
3. A ground connection

All three of these must be in sync before current (amperes) can flow causing the compressor clutch to engage. Most vehicle manufacturers connect several components in series with the compressor clutch so that all have to be functioning before the compressor clutch can be engaged. The most commonly used switches include:

- **Low-pressure switch:** This pressure switch is electrically closed only if there is at least 25 psi of refrigerant pressure. This amount of pressure means that the system is sufficiently charged to provide lubrication for the compressor. This switch also prevents the air-conditioning compressor from being engaged when the temperature is low (low temperature means low refrigerant pressures). ● **SEE FIGURE 62–38.**
- **High-pressure switch:** This pressure switch is located in the high-pressure side of the air-conditioning system. If the pressure exceeds a certain level (typically 375 psi [2,600 kPa]), the pressure switch opens, thereby preventing possible damage to the air-conditioning system due to excessively high pressure.

REAL WORLD FIX

What Throttle Switch?

A service technician was tracing the cause of an inoperative air compressor on a Saab. The service manual showed a schematic of the air-conditioning compressor that indicated a number of switches that had to be closed for the compressor clutch to be supplied with battery voltage. Besides the low pressure switch (to assure that the system is charged so as not to damage the compressor), a throttle switch was shown on the schematic. Obviously, someone else had worked on the vehicle because the throttle switch was missing entirely—just two wires remained to indicate that anything had been installed. Connecting the two wires together provided voltage to the air-conditioning compressor clutch. The customer decided not to replace the throttle switch after learning that its purpose was to disconnect (open circuit) the air-conditioning compressor when the throttle was at wide open positive to allow the maximum power for passing.

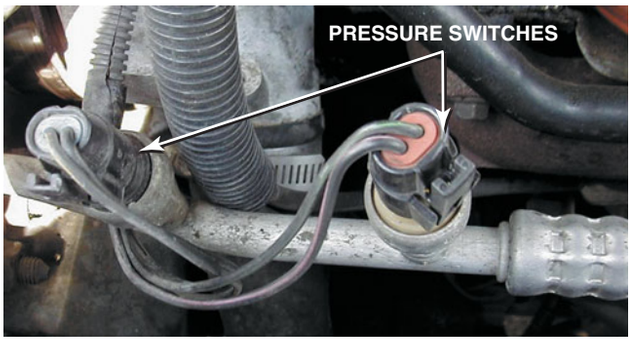

FIGURE 62–38 Typical air-conditioning pressure switches. A service manual would be needed to determine the function of each switch. One switch could be the low-pressure switch and the other a high-pressure switch.

- **Power steering pressure switch:** This switch is used on many vehicles, especially those with four-cylinder engines. It opens the circuit to the air-conditioning compressor clutch when the driver turns the steering wheel. This reduces the load on the engine at the same time power is needed by the power steering pump. Because the wheel is seldom held in a turning maneuver for a long period of time, this stoppage of the air-conditioning compressor has little, if any, effect on passenger cooling.

AIRFLOW MANAGEMENT

All automatic heating, ventilation, and air-conditioning (HVAC) systems use a combination of the following components to control airflow into the passenger compartment:

- Vents
- Ducts
- Air doors (also called flap doors or valves)

The use of these components allows the system to provide airflow under the following conditions:

1. Fresh outside air or recirculated air

? FREQUENTLY ASKED QUESTION

What Is "Afterblow"?

Afterblow is a term used to describe the operation of the blower motor after the ignition has been turned off. The purpose of afterblow is to dry the evaporator to help prevent the formation of mold and mildew in the evaporator case. The operation of the blower motor after the ignition is turned off has created some customer complaints. Check service information to be sure that the condition is normal or not on the vehicle being investigated. For example, in a typical General Motors system, the following conditions must be met for afterblow to occur:

1. The engine has been off for 30 minutes.
2. The outside air temperature is 70°F (21°C) or higher.
3. The battery voltage is 12 volts or higher.

If the above conditions exist, the afterblow is commanded to be on for 20 seconds, off for 10 seconds, and then back on for another 20 seconds.

Ventilation

- Temperature set to lowest temperature
- Air intake—select outside air
- Airflow—set to dash (panel) vents
- Air conditioning set to off
- Fan speed set to desired speed

Defogging or Defrosting the Inside of the Windshield

- Temperature set to high temperature
- Air intake set to outside air
- Airflow set to windshield
- Fan speed set to desired speed

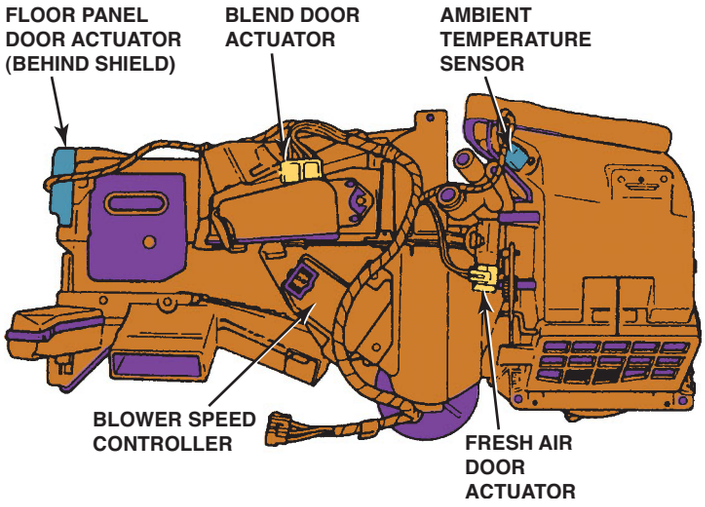

FIGURE 63–2 The ambient temperature sensor in this system is located in the fresh air intake duct for the HVAC system.

AUTOMATIC AIR CONDITIONING

Automatic air-conditioning systems are usually called **automatic temperature control (ATC) systems.** Automatic systems use many of the same components as a normally adjusted system but with additional sensors. These sensors and their purpose and function include:

OUTSIDE AIR TEMPERATURE (OAT) SENSOR This sensor is usually located at the front of the vehicle behind the grille but in front of the radiator. The purpose of this sensor is to detect the temperature of the outside air. This sensor is commonly called the **ambient air temperature sensor** and is also used to supply temperature information for the driver on a display. ● **SEE FIGURE 63–2**.

INSIDE VEHICLE TEMPERATURE SENSOR Many older ATC systems used a temperature sensor located behind the instrument panel. Air to the sensor was forced to flow past the sensor by using an **aspirator tube,** which was connected to the blower motor case.

DISCHARGE AIR TEMPERATURE SENSOR The **discharge air temperature (DAT) sensor** is located at the outlet of the vents. The purpose of this sensor is to inform the controller of the actual temperature at the discharge ducts.

EVAPORATOR OUTLET TEMPERATURE SENSOR This sensor is used to control the AC compressor to keep the evaporative temperature within the specified temperature range for most efficient operation.

SUNLOAD SENSOR Sunload sensors are mounted on the top of the dash so that they can adjust the temperature and the fan speed to match the increased heating through the windows from the sun. The most common type of sunload sensor is a **photo diode.** This type of sensor produces a voltage which is directly related to the amount of light received. The voltage varies from 0.3 volt (dash) to 3.0 volts (light).

NOTE: Some vehicles are equipped with a dual-zone sunload sensor that has two sensors included. This sensor allows the system to automatically adjust the airflow and air temperature based on the actual sun intensity experienced by both the driver and the passenger.

ACTUATORS

An actuator is a part that moves the vanes or valves. Actuators used in air-conditioning systems are either electric or vacuum operated and include three different types.

DUAL-POSITION ACTUATOR A **dual-position actuator** is able to move either open or closed. An example of this type of actuator is the recirculation door, which can be either open or closed.

THREE-POSITION ACTUATOR A **three-position actuator** is able to provide three air door positions, such as the bi-level door, which could allow defrost only, floor only, or a mixture of the two.

VARIABLE-POSITION ACTUATOR A **variable-position actuator** is capable of positioning a valve in any position. All variable-position actuators use a feedback potentiometer, which is used by the controller to detect the actual position of the door or valve. ● **SEE FIGURE 63–3**.

CABIN FILTERS

Most late-model air-conditioning systems include a **cabin filter,** which is an air filter in the outside air inlet. The purpose of the cabin filter is to filter dirt and dust from the air before it enters the interior of the vehicle. Cabin air filters can be accessed either in the dash, usually behind the glove box, or from under the hood. Cabin air filters should be replaced regularly, usually every two years during normal service and more often if the vehicle is driven in dusty areas. ● **SEE FIGURE 63–4**.

NOTE: Some cabin filters contain activated charcoal which absorbs hydrocarbons and helps to deodorize the air as it enters the interior. For best results, use the designated replacement filter.

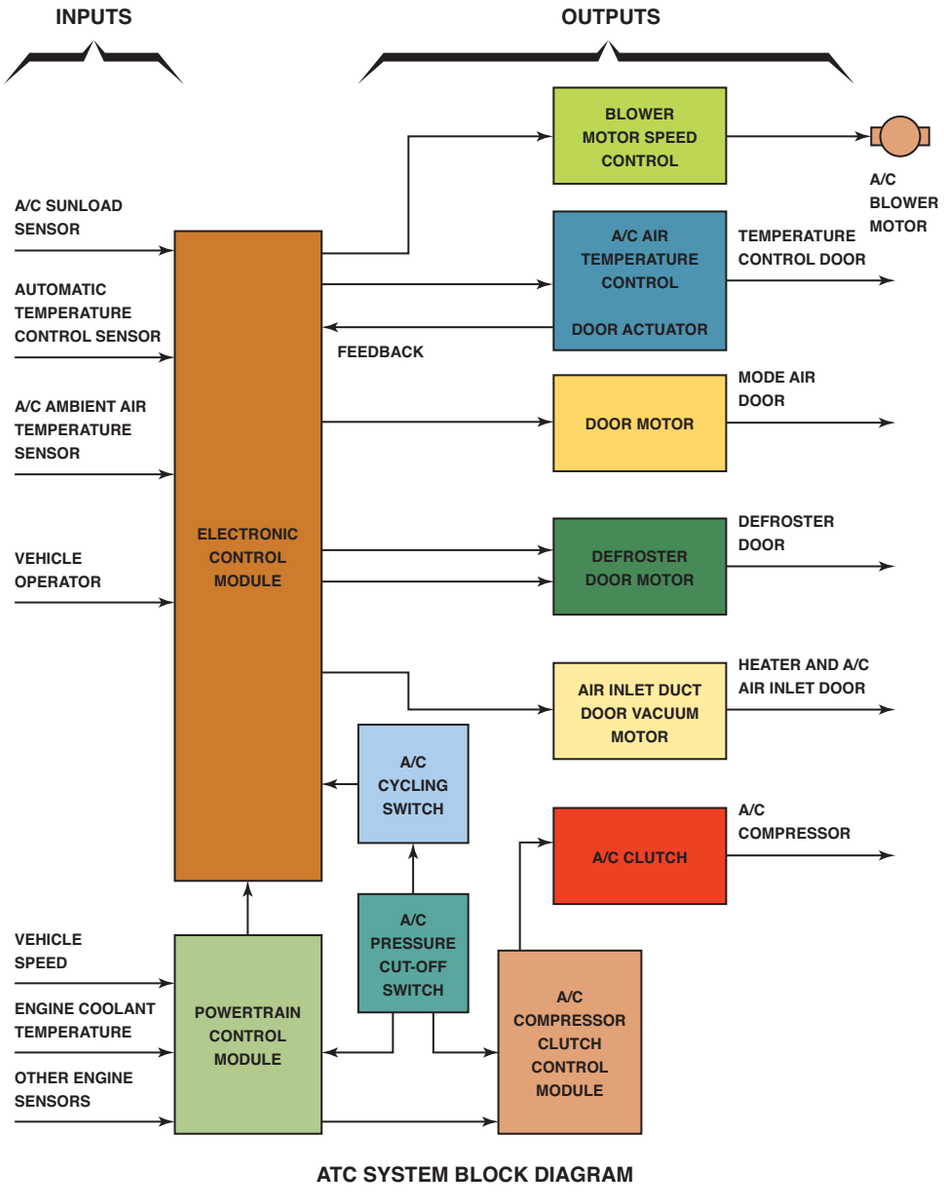

FIGURE 63–3 A block diagram showing the inputs to the electronic control assembly and the outputs; note that some of the outputs have feedback to the ECM.

FIGURE 63–4 A typical cabin filter being removed from behind the glove compartment.

VACUUM CONTROL CIRCUITS

Vacuum control circuits use vacuum created in the intake manifold of the engine. Because vacuum decreases to close to zero during heavy acceleration, a vacuum accumulator is used to store vacuum during the short periods of acceleration. ● **SEE FIGURE 63–5**.

ELECTRIC SERVOMOTOR CIRCUITS

Most HVAC systems use electric motors to move valves and doors. ● **SEE FIGURE 63–6** on page 734. Each servomotor contains a feedback potentiometer, which is used by the air conditioning control unit to indicate the actual position of the valve or door. If the commanded position and the actual position are not the same, then most systems are designed to store a diagnostic trouble code indicating which door is out of calibration. ● **SEE FIGURE 63–7** on page 734.

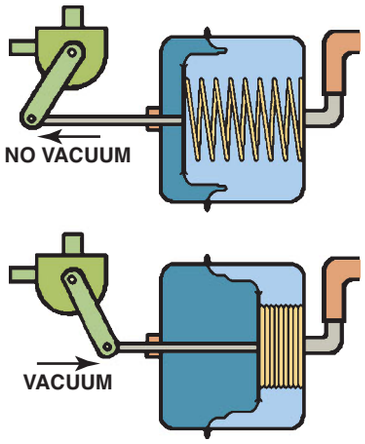

FIGURE 63–5 With no vacuum signal, the spring extends the actuator shaft to place the door in a certain position (top). A vacuum signal pulls the shaft inward and moves the door to the other position (bottom).

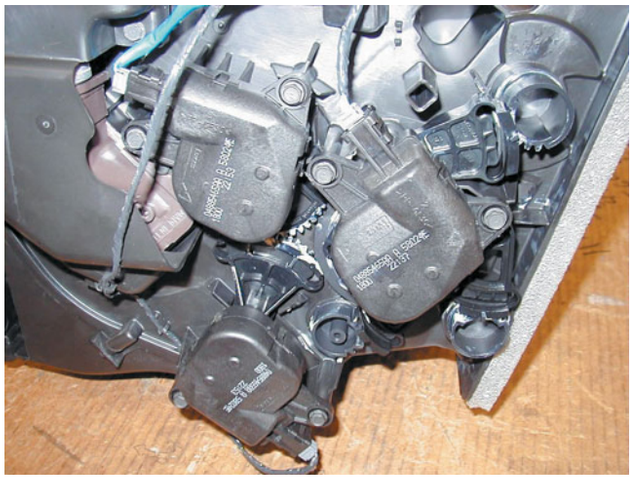

FIGURE 63–6 Three electric actuators can be easily seen on this demonstration unit. However, accessing these actuators in a vehicle can be difficult.

BLOWER MOTOR CONTROL

Blower motors are used to move air. The air is directed by the doors of the HVAC system. Most blower motors use resistors to control the speed of the motors by dropping the amount of current flow through the motor at the lower speed. The resistor lowers the voltage and the current to the motor. The control then allows full system voltage to be applied to the motor during high-speed operation. The blower motor resistor is always located in the plenum near the blower motor so that airflow past the resistor can help keep it cool. ● **SEE FIGURES 63–8 AND 63–9**.

DUAL-ZONE CLIMATE CONTROLS

Dual-zone climate controls allow the driver and the passenger to select different temperatures, as much as a 30°F (17°C) difference. In a dual-zone climate control system, the ducts and airflow are split and two air mix doors are used, with each door being controlled by its own actuator. ● **SEE FIGURE 63–10** on page 735.

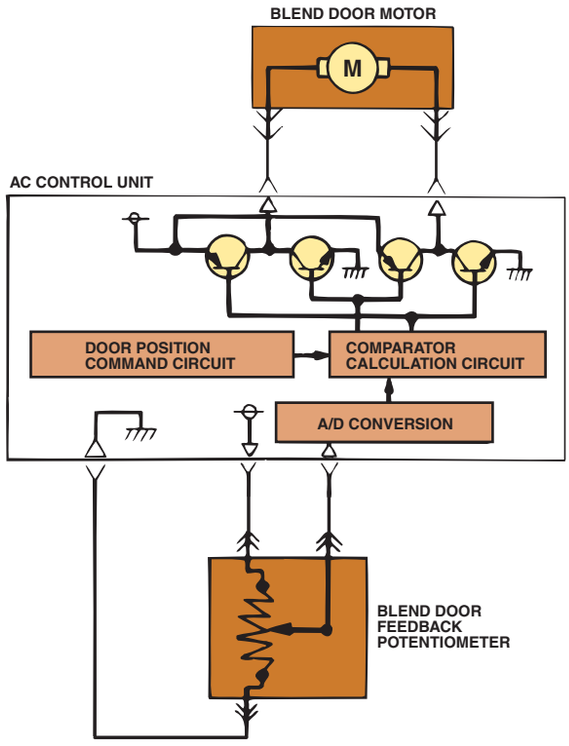

FIGURE 63–7 The feedback circuit signals the AC control unit with the blend door position.

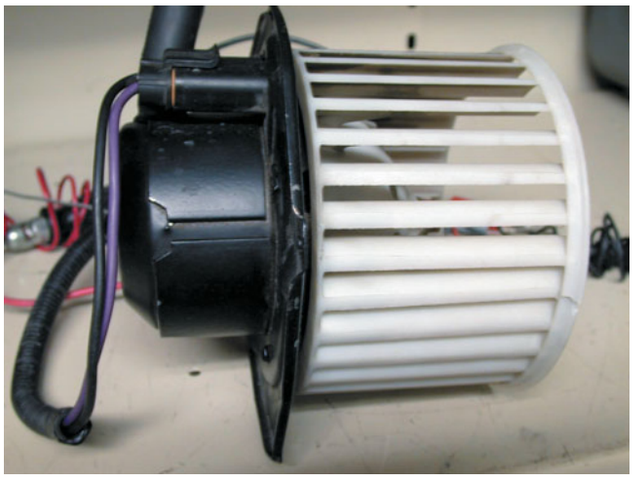

FIGURE 63–8 A typical blower motor assembly with attached squirrel cage blower. A replacement motor does not include the squirrel cage blower so it needs to be switched to the replacement motor.

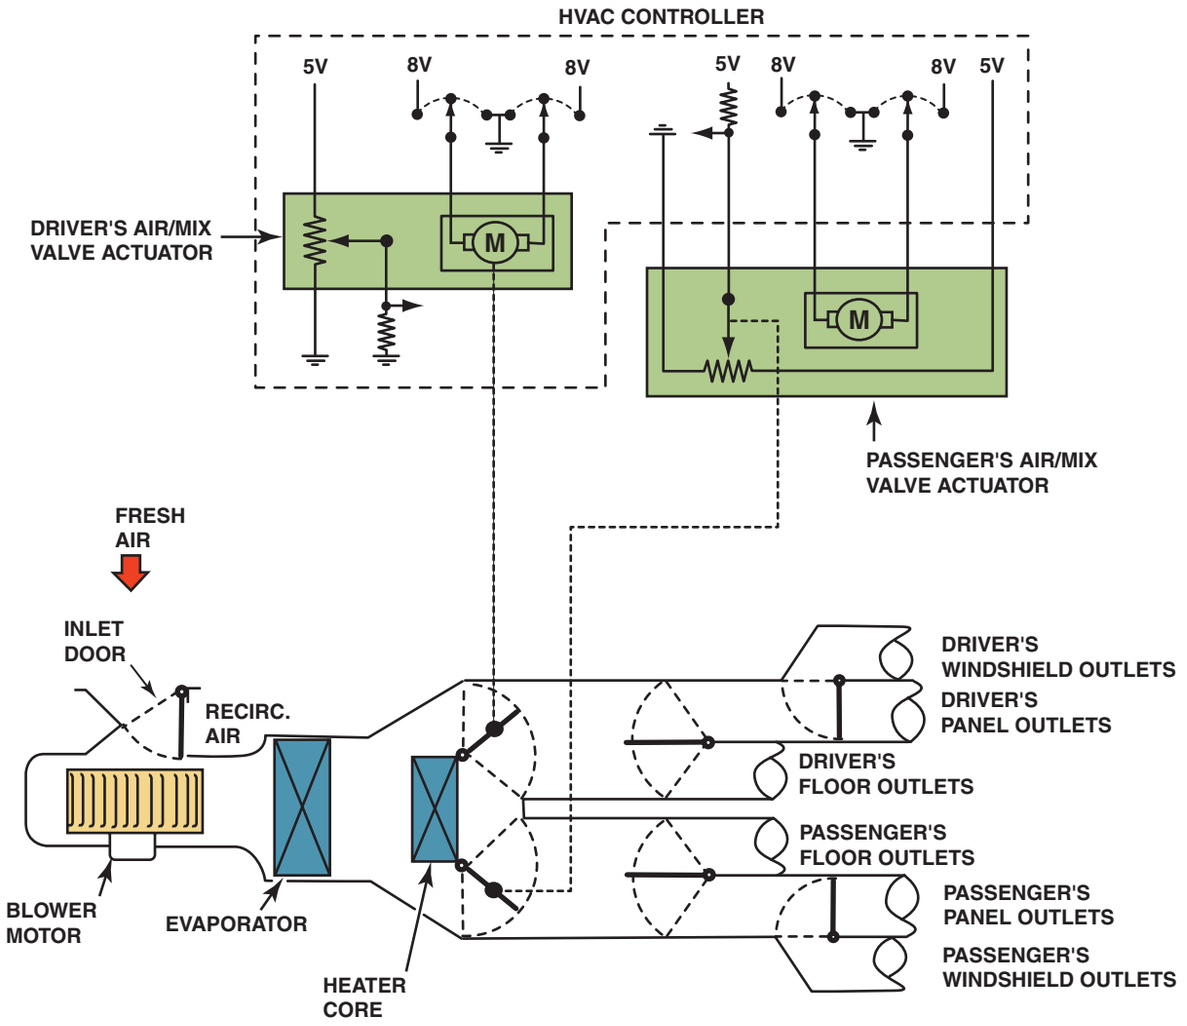

FIGURE 63–10 A dual climate control system showing the airflow and how it splits.

FIGURE 63–11 A typical dual-zone climate control panel showing left and right side temperature control levers.

REAR AIR-CONDITIONING SYSTEM

Many larger trucks, vans, and sport utility vehicles (SUVs) are equipped with rear heat and air-conditioning units. Many vehicles are equipped with ducts that route heated or cooled air to rear-seat passengers. ● **SEE FIGURE 63–11**. However, many larger vehicles require a separate heater core and air-conditioner evaporator in the rear to provide adequate heating and cooling. Most rear HVAC systems include the following components:

- A larger capacity air-conditioning compressor
- A second evaporator located at the rear of the vehicle
- A second heater core located at the rear of the vehicle
- A second blower motor and blower motor control at the rear of the vehicle
- Lines and fittings connecting the front heater and air-conditioning components to the rear system
- Rear controls for speed and temperature on some models

● **SEE FIGURE 63–12 AND FIGURE 63–13.**

RECIRCULATION OPERATION

When recirculation is selected, about 90% of the air is drawn from the passenger compartment and the other 10% is drawn from outside air. The purpose is to speed up the cooling of the inside of the vehicle.

However, the body control module may also select recirculation operation if the high-side air-conditioning system pressures exceed 320 PSI (2,200 kPa) to help lower the high-side pressure using cooler inside air through the evaporator. This condition should not normally occur, but if it does, this could cause a customer concern because the blower noise is greatly increased in the recirculation position.

FIGURE 63–12 Heated or cooled air is supplied to the rear seat passengers of most vehicles through ducts that run under the front seats.

FIGURE 63–13 A rear heat and air conditioning system on a Honda Odyssey minivan.

HYBRID ELECTRIC VEHICLE HEATING AND COOLING SYSTEMS

Hybrid electric vehicle (HEV) systems need to be different than conventional systems because the engine stops when at idle if the engine is warm. As a result, the engine-driven air-conditioning compressor will also stop. To allow idle-stop mode and still provide air conditioning, several methods are used depending on the exact vehicle. These methods include:

1. Idle-stop mode is disabled if max cooling is selected.
2. Honda uses a hybrid compressor which has a smaller capacity part of the compressor being operated by an electric motor, which is powered by the high-voltage (HV) batteries.
3. Toyota uses an air-conditioning compressor that is entirely driven by the high-voltage batteries and is therefore capable of providing cooling under all conditions, including when the engine is not operating.

Toyota uses electric heating devices called positive temperature coefficient (PTC) thermistor installed in the heater core to provide heat to the passenger compartment. These heaters are powered by the high-voltage electric system.

chapter 64 HEATING AND AIR-CONDITIONING SYSTEM DIAGNOSIS

OBJECTIVES: **After studying Chapter 64, the reader will be able to:** • Prepare for ASE Heating and Air Conditioning (A7) certification test content area "A" (Air Conditioning System Diagnosis and Repair), content area "B" (Refrigeration System Component Diagnosis and Repair), content area "C" (Heating and Engine Cooling Systems Diagnosis and Repair), content area "D" (Operating Systems and Related Controls Diagnosis and Repair), and content area "E" (Refrigeration, Recovery, Recycling, and Handling). • Diagnose lack of heat problems. • List the air-conditioning system performance check procedures. • Discuss methods used to locate the source of an air-conditioning system leak. • Describe how to recover, evacuate, and recharge an air-conditioning system. • Discuss what is necessary to retrofit a CFC-12 system to be able to use HFC-134a refrigerant.

KEY TERMS: Bleeder valves 739 • High-side pressure 741 • Low coolant level 740 • Low-side pressure 741

HVAC DIAGNOSTIC PROCEDURE

When diagnosing a heating and air-conditioning system problem, most vehicle manufacturers recommend that the following steps be performed.

STEP 1 **Verify the customer complaint (concern).** Sometimes the customer does not understand how the system is supposed to work or does not explain the fault clearly. Verifying the fault also means that the technician can verify that the problem has been corrected after the service procedure has been performed.

STEP 2 **Do a thorough visual inspection.** Heating and air-conditioning problems are often found by looking carefully at all of the components, checking for obvious faults or damage due to an accident or road debris.

STEP 3 **Check for diagnostic trouble codes.** Many heating and air-conditioning systems use sensors and actuators, which are computer controlled and will set diagnostic trouble codes in the event of component failure.

STEP 4 **Check for related technical service bulletins (TSBs).** If there has been a bulletin released to solve a known problem, it saves a lot of time to know what to do rather than spend a lot of time trying to find and correct a problem.

STEP 5 **Determine the root cause.** Be sure to find and correct the root cause of the problem. A low refrigerant level means that there was a leak in the system. Finding and correcting the leak that caused the low refrigerant level is correcting the root cause.

STEP 6 **Verify the repair.** Drive the vehicle under similar conditions which caused the customer to complain and verify that the concern has been corrected.

HEATER DIAGNOSIS

Most of the heat absorbed from the engine by the cooling system is wasted. Some of this heat, however, is recovered by the vehicle heater. Heated coolant is passed through tubes in the small core of the heater. Air is passed across the heater fins and is then sent to the passenger compartment. In some vehicles, the heater and air

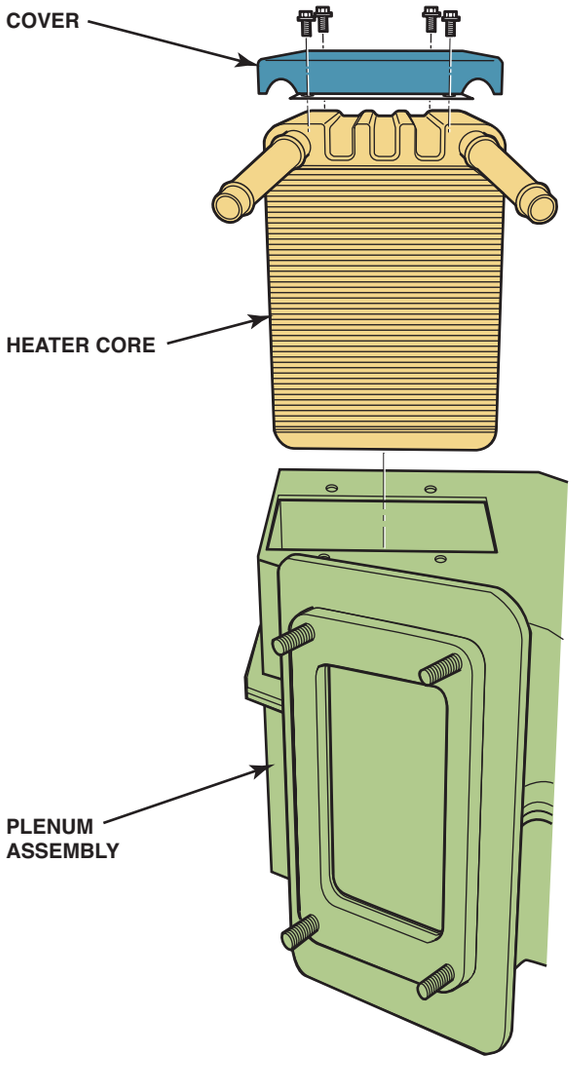

FIGURE 64–1 The heater core is mounted inside a heater plenum chamber where air passes over it to absorb heat from the warmed engine coolant.

conditioning work in series to maintain vehicle compartment temperature. ● **SEE FIGURE 64–1**.

THERMOSTAT DIAGNOSIS

When the vehicle's heater does not produce the desired amount of heat, many owners and technicians replace the thermostat before doing any other troubleshooting. While it is true that a defective thermostat can be the reason for the engine not to reach normal operating temperatures, there are many other causes that can result in lack of heat from the heater. To determine the exact cause, follow this procedure:

STEP 1 After the engine has been operating for 15 minutes, feel the upper radiator hose. If the engine is up to proper operating temperature, the upper radiator hose should be too hot for you to keep your hand on it. The hose should also be pressurized.

a. If the hose is not hot enough, replace the thermostat.

b. If the hose is not pressurized, pressure test the cooling system with a pressure tester to locate leaks. Replace the radiator pressure cap if it will not hold the specified pressure.

c. If okay, see step 2.

TECH TIP

Water on the Carpet? Check the Evaporator Water Drain

If the evaporator water drip tube becomes clogged with mud, leaves, or debris, water will build up inside the evaporator housing and spill out onto the carpet on the passenger side. Customers often think that the windshield or door seals are leaking. Most evaporator water drains are not visible unless the vehicle is hoisted.

STEP 2 With the engine running, feel both heater hoses. (The heater should be set to the maximum heat position.) Both hoses should be too hot to hold. If both hoses are warm (not hot) or cool, check the heater control valve, if equipped, for proper operation. If one hose is hot and the other (return) is just warm or cool, remove both hoses from the heater core or engine and flush the heater core with water from a garden hose.

HEATER TROUBLE DIAGNOSIS

A lack of heat from the heater or having heat coming out of the wrong vents can be a dangerous and uncomfortable problem. The first step in the diagnostic process is to perform a thorough visual inspection and perform simple tests. This includes the following:

- **Check the coolant level.** Low coolant level can cause a lack of heat from the heater. Low coolant level can also cause occasional loss of heat.

  CAUTION: Do not remove the radiator cap when the engine is hot. Allow the vehicle to sit several hours before removing the pressure cap to check the radiator coolant level.

- **Carefully touch the upper radiator hose with the engine running.** On most vehicles, the temperature of the hose should be so hot that you cannot keep your hand on it (between 190° to 220°F [88° to 104°C]).

  NOTE: An infrared thermometer (pyrometer) can be used to measure the temperature of the upper radiator hose and the area around the thermostat housing.

- **Results:** If the upper radiator hose is not too hot to hold, then the engine thermostat is defective. If the radiator hose is too hot to handle, then the lack of heat from the heater is not due to a lack of hot water in the engine.

● **SEE FIGURE 64–2**.

- **Results:** (a) If neither heater hose is hot to the touch, it is likely there is an air pocket in the heater that is preventing the flow of coolant into the heater core. (b) If only one heater hose is hot to the touch, then the heater core is likely to be clogged or partially clogged. A clogged heater core would prevent enough hot coolant from circulating through the heater core to provide adequate heat to the passenger compartment.

VISUAL INSPECTION

The diagnosis of a heater problem or concern should start with a visual inspection. The following items should be checked or tested:

TECH TIP

Defrost All the Time? Check the Vacuum

A common problem involves airflow from the defroster ducts even though the selector lever is in other positions. The defrost setting is the default position in the event of a failure with the vacuum supply. The defrost position is used because it is the *safest* position. For safety, the windshield must remain free from frost. Heat is also supplied to the passenger compartments not only through defrost ducts but also through the heater vents at floor level.

If the airflow is mostly directed to the windshield, check under the hood for a broken, disconnected, or missing vacuum hose. Check the vacuum reserve container for cracks or rust (if metal) that could prevent the container from holding vacuum. Check all vacuum hose connections at the intake manifold and trace each carefully, inspecting for cracks, splits, or softened areas that may indicate a problem.

HINT: This problem of incorrect airflow inside the vehicle often occurs after another service procedure has been performed, such as spark plug replacement. The movement of the technician's body and arms can cause a hose to be pulled loose or a vacuum fitting to break without the service technician being aware that anything wrong has occurred.

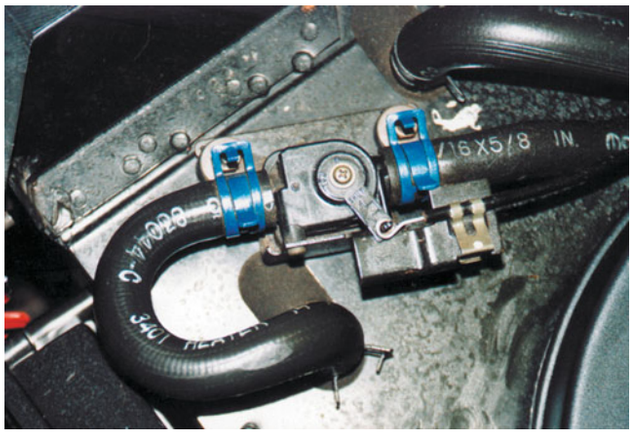

FIGURE 64–2 A cable controlled heater control valve. This valve is normally open, allowing engine coolant to flow through the heater core. When the air conditioning is switched to maximum cooling, the valve shuts off the flow of coolant to the heater.

TECH TIP

The Hand Test

To check a radiator or condenser for possible clogged or restricted areas, simply touch the outside of the unit with your hand. Any cool spots indicate that the radiator or condenser is clogged in that cool area.

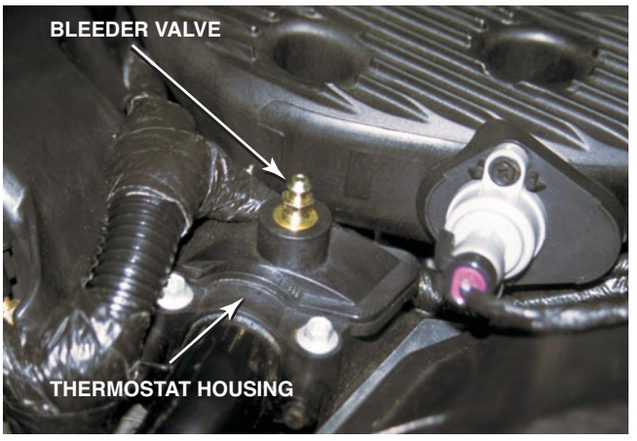

FIGURE 64–3 Many engines are equipped with a bleeder valve to permit a technician to bleed any trapped air from the cooling system. The valve is loosened as coolant is poured into the system. Because air is lighter than coolant, the air tends to float toward the highest part of the cooling system.

FREQUENTLY ASKED QUESTION

How Can You Easily Burp Air from the Cooling System?

The first step in being certain there is no air in the cooling system is to try to avoid getting air into the system in the first place during cooling system service. If the engine is equipped with **bleeder valves** near the high spots of the cooling system, these valves should be open when refilling the radiator. ● **SEE FIGURE 64–3**. Any trapped air will always travel to the highest portion of the cooling system and escape out of these bleeder openings. Close the valves as soon as coolant is observed coming out of the valve opening.

If the cooling system is not equipped with bleeder valves, fill the cooling system as full as possible and then start the engine. With the radiator cap removed, the coolant level will often rise as the trapped air is expanding, then drop down as the trapped air escapes out of the radiator neck opening. Air can still remain trapped. To help speed up the process, try installing the radiator cap just to the first notch. (In this position the radiator cap is closed, but will not seal enough to allow pressure to build in the cooling system.) To help force any trapped air from the cooling system, simply drive the vehicle normally for several miles. By driving the vehicle under load, the engine will warm up faster and the thermostat will open allowing the coolant to flow from the engine and through the radiator. Any trapped air is then released into the radiator where it can easily escape through the unsealed radiator cap. After filling the radiator, securely tighten the radiator cap and test-drive the vehicle to verify proper operation. Always check service information for the exact procedure to follow when replacing coolant.

NOTE: An air bubble could be lodged in the heater core. This is a common occurrence especially if the coolant (antifreeze) has been recently replaced. Failure to properly "burp" the air from the cooling system can cause a pocket of air to remain trapped in the heater core, preventing coolant from flowing through. See Frequently Asked Question "How Can You Easily Burp Air from the Cooling System?"

TECH TIP

Hot/Cold/Hot/Cold Heater Diagnosis

A common customer complaint is a lack of heat from the heater but only while driving, even though there seems to be plenty of heat when the engine is at idle speed and the vehicle is stopped. This is a classic symptom of **low coolant level.** The lower than normal coolant level in the radiator prevents enough flow to supply the heater core. When the engine speed is reduced, the water pump turns slower and coolant can more easily flow through the heater core resulting in heat from the heater. As the engine speed increases, the water pump speed also increases. Because there is less than the proper amount of coolant in the system, the water pump will only be able to supply coolant through the engine (a path of lower resistance).

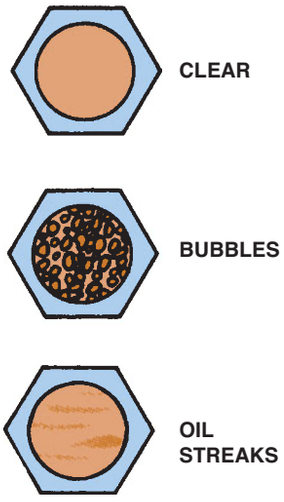

FIGURE 64–4 Many older CFC-12 systems are equipped with a sight glass either on or near the receiver-drier. A fully-charged (or completely empty) system is indicated by a clear sight glass. Bubbles or foam indicate that the system is not fully charged. An empty system may have oil streaks on the sight glass being moved by the vapor remaining in the system.

CHECKING A/C SYSTEM PERFORMANCE

The first step in the diagnosis of any cooling system problem is to verify the complaint (concern).

STEP 1 Start the engine and turn the A/C system to maximum with the engine operating between 1500 and 2000 RPM with the doors open. Operate the system for 5 to 10 minutes.

STEP 2 Verify by visual inspection that the A/C compressor clutch is engaged. Check the sight glass if the vehicle is so equipped, as shown in ● **FIGURE 64–4**.

HINT: If the A/C compressor clutch cannot be observed, have an assistant turn the air conditioning on and then off and listen for the "click" of the A/C compressor clutch.

STEP 3 Place an air-conditioning thermometer in the A/C vent near the center of the vehicle. Wait several minutes to allow the system to reach maximum output and observe the thermometer.

- *If 35° to 45°F (2° to 7°C)*, the system is functioning okay. Continue a thorough visual inspection looking for any faults that may cause an intermittent problem.
- *If over 45°F (7°C)*, continue with pressure gauge testing (Step 4).

STEP 4 *Identify the refrigerant*. Before connecting the pressure gauges or performing any other service to an automotive air-conditioning system, verify the refrigerant that is presently in the system. Connect a refrigerant identification machine to the system. ● **SEE FIGURE 64–5**.

STEP 5 *Connect both high-pressure and low-pressure gauges to the service ports*. Start the engine and turn the air conditioning system on and set to maximum cooling. The low-side pressure should be about 25 to 35 PSI. The high-side pressure should be about 150 to 200 PSI. Compare your readings to the normal and abnormal readings in the following chart. ● **SEE FIGURES 64–6 AND 64–7**.

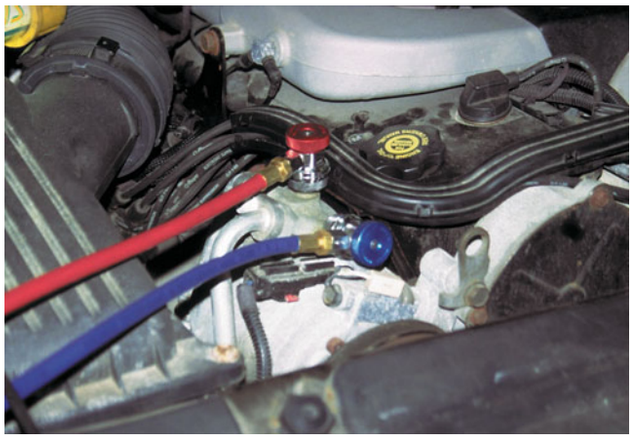

FIGURE 64–5 A typical refrigerant identification machine. The readout indicates what kind of refrigerant is in the system. If a blend or some other contaminated refrigerant is discovered, it should be recovered and stored in a separate container to keep it from contaminating fresh refrigerant.

Low	Low	Low refrigerant charge level
Low	High	Restriction in high-side line
High	High	System is overcharged. Expansion valve stuck open

TEMPERATURE AND PRESSURE MEASUREMENTS

Temperature and pressure are directly related in AC systems. As the ambient temperature increases, the high-side pressure must also increase to have a heat transfer at the condenser. The temperature

(a)

(b)

FIGURE 64–6 (a) Both high-pressure (red) and low-pressure (blue) hoses have been attached to the vehicle. (b) High-side pressure can be compared to the temperature of the outlet from the compressor. Here a service technician is using an infrared pyrometer to measure the temperature.

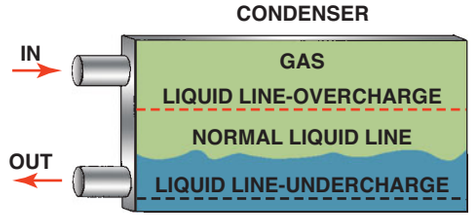

FIGURE 64–7 Hot refrigerant condenses in the condenser when it loses its heat to the outside air. Note how the level of the liquid line changes when undercharged or overcharged.

of the vapor must be higher than the ambient temperature to allow enough heat to be removed for condensation. Also, higher ambient temperatures, and high humidity, usually mean a higher heat load on the evaporator. This means a larger quantity of heat has to be removed at the condenser.

The **high-side pressure** is directly related to the amount of heat that needs to be removed, and the heat transfer at the condenser. **Low-side pressure** indicates the boiling point of the temperature of the evaporator. If the pressure is too high, the boiling point of the refrigerant and temperature of the evaporator are too high. Low-side pressure that is too low indicates the evaporator is too cold and may ice, or that there is not enough boiling refrigerant in the evaporator to remove an adequate amount of heat. ● **SEE FIGURE 64–8**.

The heat transfer at the condenser is usually the cause of high-side pressure that is too high. The number one cause of poor heat transfer is lack of airflow across the condenser. The vehicle is dependent upon fans to move enough air when you are testing in a stall. It may be necessary to drive the vehicle at 30 mph to get the ram air necessary to determine if lack of airflow is the reason for the poor heat transfer.

Another cause of excessive high-side pressure is contamination with a different refrigerant. Mixing R-12 and R-134a raises the condensing pressure of the mixture. If the system is contaminated with R22, the pressures can become extremely high. At 150°F, the pressure of R-12 is 235 PSI (1,620 kPa), R-134a is 263 PSI (1,813 kPa), and R-22 is 381 PSI (2,627 kPa). This is an important reason to use a refrigerant identifier.

As compressor efficiency is reduced, the high side decreases, and the low side increases. The function of the compressor is to pull down the low side and push up the high side. When the compressor is failing, it does not do either job well. Always look at both the high- and low-side pressures when diagnosing a problem. ● **SEE FIGURES 64–9 THROUGH 64–11**.

? **FREQUENTLY ASKED QUESTION**

What's Wrong When the A/C Compressor Clutch Cycles On and Off Rapidly?

This is a common occurrence on a vehicle equipped with a cycling clutch orifice tube (CCOT) system that is low on refrigerant charge. With a normal charge, the low-side pressure should be 15 to 35 PSI and the clutch should be on for 45 to 90 seconds and be off for only about 15 to 30 seconds.

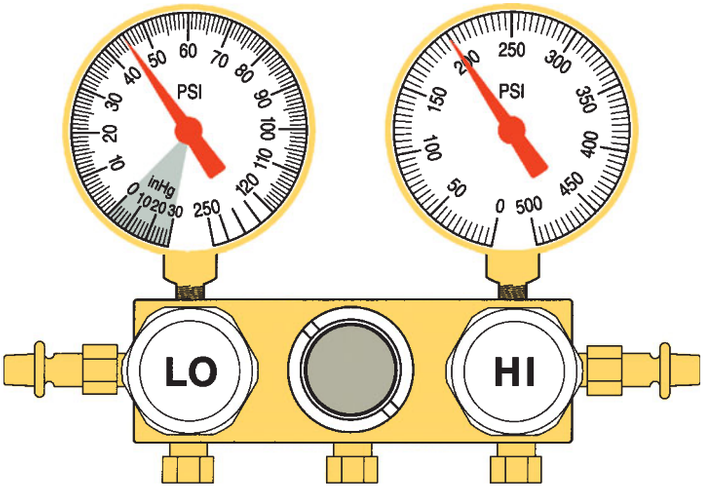

FIGURE 64–10 Both low- and high-side pressures higher than normal indicate that the system is overcharged with refrigerant.

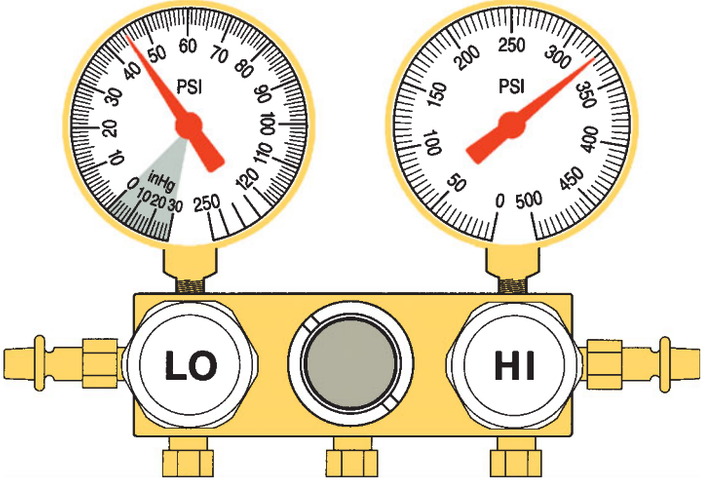

FIGURE 64–11 Lack of proper airflow across the condenser is usually the cause of this condition.

FIGURE 64–12 A clogged orifice tube.

TECH TIP

High-Side Pressure Tip

A quick and easy way to determine the correct high-side pressure is to add 100 to the ambient air temperature in Fahrenheit.

For example: 85°F outside air temperature

$$\begin{array}{r} +100 \\ \hline 185 \text{ PSI} = \text{typical normal high-side pressure} \end{array}$$

TECH TIP

Clogged Orifice Tube Test

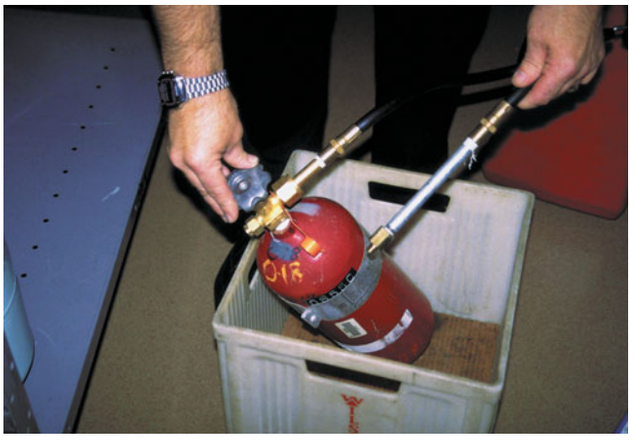
A clogged orifice tube is a common air-conditioning system failure. When the orifice tube becomes clogged, it blocks the flow of refrigerant through the evaporator, which causes a reduced cooling of the passenger compartment. To check for a possible restriction in the system, follow these easy steps:

STEP 1 Connect the A/C pressure gauge to both low- and high-side pressure fittings.

STEP 2 Operate the A/C system for 5 to 10 minutes.

STEP 3 Shut off the A/C system and watch the pressure gauges. If the pressures do not equalize quickly, then there is a restriction in the system. ● **SEE FIGURES 64–12 AND 64–13.**

NOTE: To locate a restriction anywhere in the system, feel along the system lines. The restriction exists at the point of greatest temperature difference. "Frosting" is a good indication of a restriction.



TECH TIP

The Fire Extinguisher Test

To test the expansion valve, start the engine and allow the A/C system to function with the control set to "recirculate." Using a CO_2 fire extinguisher, blast the expansion valve with CO_2. The valve should close and the low-side pressure should go into a vacuum. If the low-side pressure does not go into a vacuum, the expansion valve is faulty and should be replaced. ● **SEE FIGURE 64–14.**

FIGURE 64–13 Assortment of orifice tubes. Note that each is color coded and identified on the lid of the assortment. Even though some technicians have purposely installed an orifice tube with a larger opening in an attempt to increase cooling, it is always safe to use the exact orifice tube specified for the vehicle being serviced.

REAL WORLD FIX

The Clogged Evaporator Problem

The owner of an older Buick complained that the blower motor must be defective because the air no longer flowed from the air-conditioning vents as it should. A check of the blower motor circuit revealed that the blower motor was working. To confirm the operation of the blower, the resistor pack was removed and air flowed out of the opening. Then the technician discovered the cause of the lack of airflow—the evaporator was covered with oily dirt. The technician recovered the refrigerant and removed the evaporator. Apparently, the evaporator had a small refrigerant leak that allowed the refrigerant oil to coat the fins of the evaporator. Any dirt in the air stuck to the evaporator until the dirt almost completely blocked the airflow. Replacing the evaporator and recharging the system fixed the blower motor problem. ● **SEE FIGURE 64–15**.

TECH TIP

The Touch, Feel Test

A quick-and-easy test to check the state of charge of an orifice tube system is to use one hand and touch the evaporator side of the orifice tube. Touch your other hand to the inlet to the accumulator. The following conditions can be determined by noticing the temperature of these two locations. ● **SEE FIGURE 64–16**.

Normal operation—both temperatures about the same

Undercharged condition—accumulator temperature higher (warmer) than the orifice tube temperature

Just remember: High pressure means that the temperature of the component or line will also be high (hot). Low pressure means that the temperature of the component or line will also be low (cold). For example, the inlet to the compressor (low pressure) should always be cool whereas the outlet of the compressor (high pressure) should always be hot.

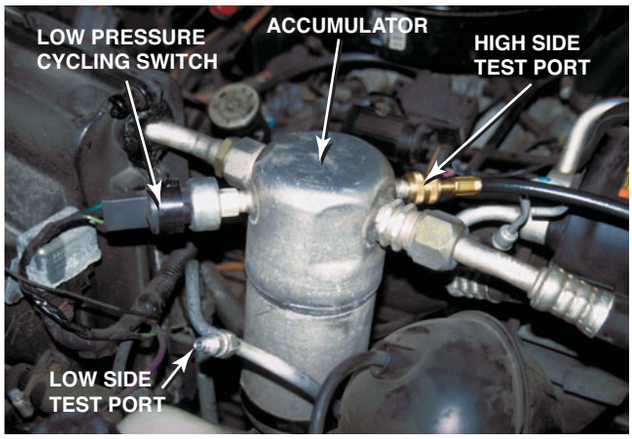

FIGURE 64–16 If the system is fully charged, the outlet temperature of the line leaving the evaporator should be about the same as the temperature of the line entering the evaporator after the expansion valve. The low-pressure cycling switch usually has to be disconnected and a jumper wire used to connect the two electrical terminals allowing the compressor to run if the system is low on charge.

TECH TIP

The Smell Test

Many air-conditioning systems form mildew inside the evaporator housing due to the moist condition that exists in this area. If a "wet" smell is noticed, the mold and mildew may be the cause and a biocide will need to be used to correct the problem.

TECH TIP

Leak-Testing the Evaporator

A quick-and-easy test to check whether the evaporator is leaking refrigerant is to remove the blower motor resistor pack. The blower motor resistor pack is almost always located directly "downstream" and near the blower motor. Removing the blower motor resistor pack gives access to the area near the evaporator. Inserting the probe of a leak detector into this open area allows the detector to test the air close to the evaporator. If the vehicle does not use a blower motor resistor or if it is difficult to access, hoist the vehicle and insert the sniffer probe in the condensate tube.

FIGURE 64–17 Typical electronic refrigerant leak detector. Many are capable of detecting either CFC-12 or HFC-134a.

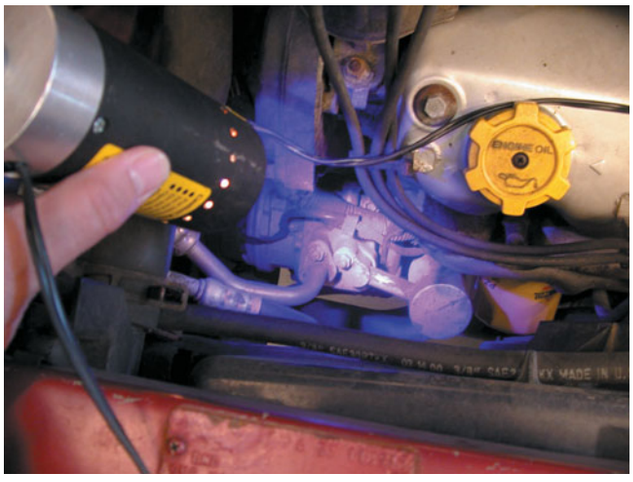

FIGURE 64–18 A black light being used to look for refrigerant leaks after a fluorescent dye was installed in the system.

LEAK DETECTION

If the A/C system is low on a charge of refrigerant, the sources of the leak should be found and corrected. Several different methods of leak detection are available including:

- **Visual inspection.** Look for oily areas that are formed when refrigerant leaks and some refrigerant oil is lost. It is this oil that indicates a refrigerant leak.
- **Electronic leak detector.** Many of these units can detect both CFC-12 and HFC-134a. The detector will sound a tone if a leak is detected. ● **SEE FIGURE 64–17**.
- **Dye in the refrigerant.** A dye is added to some refrigerant to help the technician visually spot a leak in the refrigerant system. This method works well except for leaks in the evaporator, which are usually not visible. ● **SEE FIGURE 64–18**.
- **Soap solution.** Mix a few drops of liquid soap or detergent into a small glass of water. Using a small brush or a small spray bottle, apply the soapy solution to all fittings and other areas such as the condenser and compressor, which often are sources of leaks. If the system is empty, pressurize the system with dry nitrogen.

BLOWER MOTOR SERVICE

Blower motor related services include the following components and operation:

- **Blower motor and construction.** If the blower motor is not functioning, the switch, resistors, or blower motor itself may need to be replaced. If the resistors are found to be defective, then double-check that the current draw of the blower motor is within factory specifications. One of the most common reasons for a defective blower motor resistor is a defective blower motor that has worn bushings and draws more than normal current (amperes).
- **Relays and switches.** Switches and relays can be tested by proper operation and replaced if needed. Always follow the vehicle manufacturer's recommended replacement procedures.
- **Mechanical, electrical, and vacuum components.** Electrical wiring or terminals can often be repaired. Check service information for the recommended procedures to follow. If a component has been found to be defective, follow the vehicle manufacturer's recommended component replacement procedures.

See Chapter 59 for details on blower motor diagnosis.

COOLING SYSTEM SERVICE

COOLING SYSTEM THERMOSTAT REPLACEMENT

A defective (stuck open) thermostat can cause a lack of heat from the heater. If heat "comes and goes," check for proper coolant level in the radiator before replacing the thermostat. When replacing the thermostat, always follow the vehicle manufacturer's recommended procedures and use the designated coolant.

HEATER HOSE REPLACEMENT

Check heater hoses for signs of deterioration and replace as needed. ● **SEE FIGURE 65–1.** Follow the vehicle manufacturer's recommended procedures.

COOLING FAN

Inspect the cooling fan for dents, nicks, or other faults that can cause a vibration or reduce airflow through the radiator. Check the viscous fan clutch for leakage of silicone fluid and replace if needed.

See chapter 21 for details on cooling fan-relayed diagnosis and service procedures.

REFRIGERANT RECOVERY PROCEDURES

LEAK REPAIR PROCEDURES

After a leak has been found, the refrigerant should be recovered and the faulty part repaired or replaced. Leaks at joints may need a replacement O-ring. Often, the leak is at a component such as the evaporator, condenser, or refrigerant line. Leaking components are usually replaced rather than repaired.

FIGURE 65–1 Some heater hoses are best inspected by hoisting the vehicle and inspecting them from underneath the vehicle as shown.

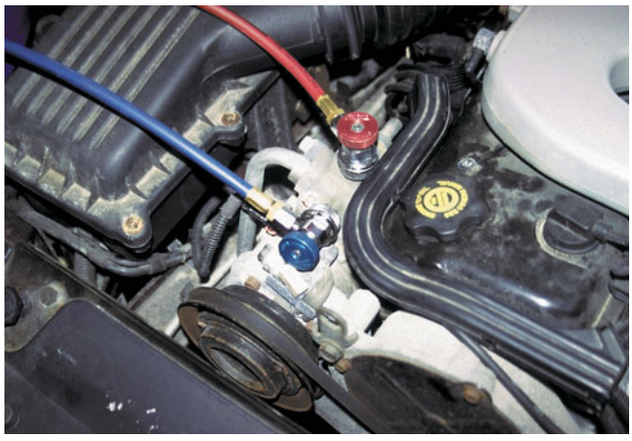
TECH TIP

Use the Same Length Heater Hoses

Heater hoses are designed to supply warm coolant from the engine's cooling system to the small radiator called the heater core inside the vehicle. Because the heater hoses attach to the engine and the engine moves on its mounts during operation, the heater hoses are long enough to allow the engine to move without causing stress to be applied to the heater core. The extra length also helps to prevent engine vibration from being transmitted to the heater core and the interior of the vehicle. When replacing heater hoses, always use the old hoses as a guide and use the same length hoses. Also, route the replacement hoses in the same manner as originally designed, again, to help reduce the stress to the heater core.

TECH TIP

Check the Air Dam If Overheating Occurs



The **air dam** under the front of the vehicle is designed to force air to flow upward and through the radiator rather than travel underneath the vehicle. If this air dam is broken or damaged due to contact with a parking block or other object, the engine may overheat.

REFRIGERANT RECOVERY

Refrigerant should be recovered and not allowed to be discharged into the atmosphere. A refrigerant recovery unit should be used to remove the refrigerant from the vehicle, and it should be stored in a container until it can be recycled. ● **SEE FIGURES 65–2 AND 65–3.**

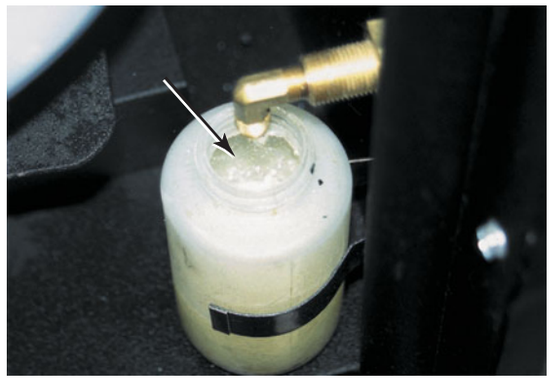
(a)

(b)

FIGURE 65–2 (a) A typical automotive air-conditioning service machine that is capable of handling both CFC-12 and HFC-134a systems. (b) HFC-134a systems use quick-disconnect fittings that are larger than those used for CFC-12 systems.

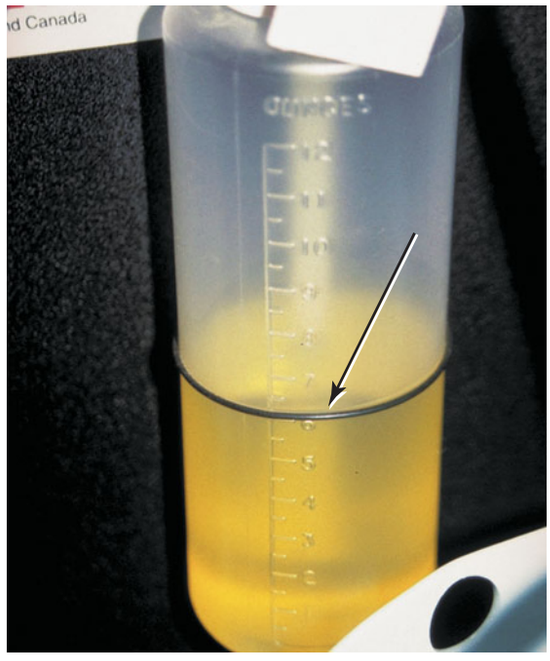
REFRIGERANT IDENTIFICATION

All refrigerant should be identified before it is recovered. Many also can detect sealers that may have been used in an attempt to stop a refrigerant leak. Sealers in refrigerant would contaminate the refrigerant and make it unsuitable for recycling.



Always follow the operating instructions for machine being used.

Most recovery units are capable of drawing a slight vacuum on the system (about 5 in. Hg) to assure that all refrigerant is removed from the system. During the recovery process, any refrigerant oil removed is separated from the refrigerant and allowed to flow into a container where it can be measured. This is important because the correct total amount of lubricating refrigerant oil must be added to the system when recharged to protect the compressor.



REPAIRS OR REPLACEMENT OF COMPONENTS

After all refrigerant has been removed from the system, repairs can be accomplished. For example, the evaporator can now be removed from the vehicle and replaced. If the system has been opened to the atmosphere for a length of time (over 24 hours), most experts recommend replacing the drier to help prevent the possibility of damaging moisture being trapped in the system. After all repairs are completed, the system should then be evacuated.

NOTE: Be sure to follow all instructions regarding the amount of oil that needs to be added to the system if components have been replaced.

(a)

(b)

FIGURE 65–3 (a) Refrigerant oil must be retrieved and measured when the refrigerant is recovered from the system. (b) A rubber O-ring is used to indicate the level of refrigerant oil already in the container. The exact same amount of refrigerant oil must be installed as was removed when the system is recharged.

REFRIGERANT LINE CONNECTIONS

Refrigerant lines have connections at each end so they can be removed during system repair. Refrigerant line connections must meet three requirements:

- The connection must be vapor tight.
- The connection must be easy to disconnect and reconnect.
- The seals must withstand rapid and extreme temperature changes.

The **O-ring seal,** ● **FIGURE 65–4,** is part of a fitting that holds the ends of two refrigerant lines or hoses together inside a connector. The O-ring forms the seal between the lines or hoses and the connector. The O-rings usually are made of highly saturated nitriles (HSN) or neoprene rubber and remain flexible over a wide range of temperatures. The O-ring must be lubricated with clean refrigerant oil before assembly to ensure a good seal. Be careful not to crimp the O-ring during installation.

Replace the O-ring seals at all connections when you retrofit a system to R-134a. This ensures any traces of R-12 or its oil

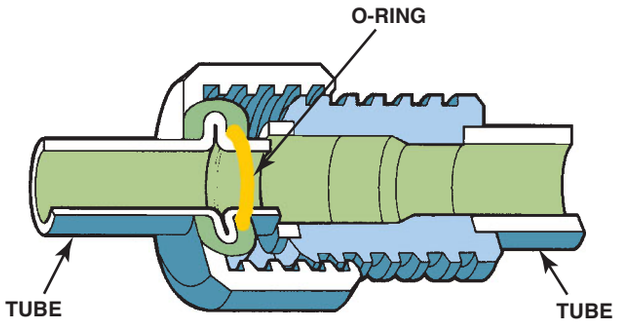


FIGURE 65–4 O-rings are usually made of neoprene rubber or highly saturated nitriles (HSN) to withstand high temperatures and flexing. O-rings should be changed during a retrofit procedure.

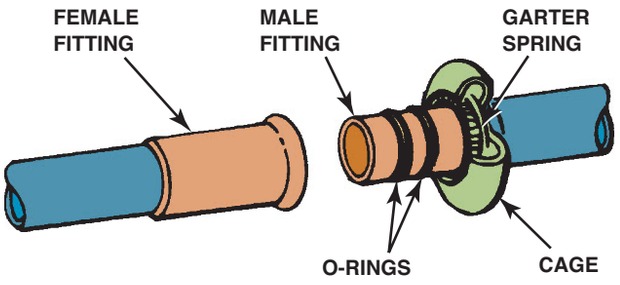

FIGURE 65–5 A Ford spring-lock coupling.

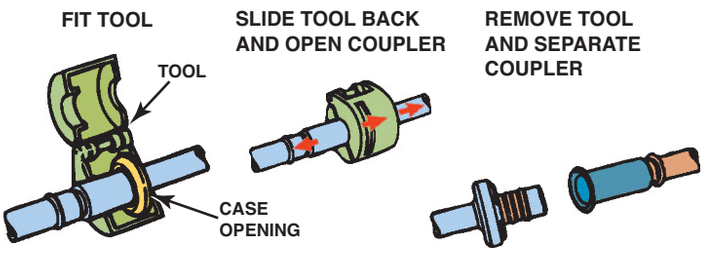

FIGURE 65–6 A special tool is needed to remove and install the Ford spring-lock coupling.

SAFETY TIP

Refrigerant Can Be Hazardous

Always wear safety glasses and protective gloves when servicing any automotive air-conditioning system. If any refrigerant escapes, it can cause skin to freeze or cause blindness if liquid refrigerant were to get into the eyes.

absorbed in the O-ring cannot enter the new system. Replace all gaskets as well.

A variation on the O-ring seal is Ford's spring-lock coupling. ● **SEE FIGURE 65–5.** It uses two O-rings mounted on the small end of the refrigeration line. The end of the joining refrigeration line is flared to slide over the two O-rings. A circular garter spring holds the connection together. You need a special tool to disconnect the coupling. ● **SEE FIGURE 65–6.**

SERVICE VALVES Service valves provide entry to the system when it is necessary to add or discharge refrigerant. The Schrader valve is used on R-12 systems. **Quick-disconnect valves** are used on R-134a systems. Each type of refrigerant has its own unique fitting. This prevents accidental use of the wrong service equipment and/or the introduction of the wrong refrigerant. Service valves are found almost anywhere on the system. They may be located on the receiver-drier, accumulator, compressor, muffler, or in the lines themselves.

All service valves have plastic coverings called **service caps.** ● **SEE FIGURE 65–7.** Along with preventing dirt from entering the system, service valve caps have O-rings which become the primary seal if a valve leaks. Always reattach the caps after any service has been performed, and replace them if you come across a system with missing service caps. Another built-in precaution is the refrigerant cut-off valve, which keeps the refrigerant in the service hose instead of allowing it to vent to the atmosphere. All service equipment hoses are required to have a cut-off valve within 12 inches of the end of the hose.

SCHRADER VALVES For years, R-12 systems have used the **Schrader valve.** A Schrader valve is similar to a tire valve. Internal pressure holds Schrader valves closed. There is also a small spring to keep the valve seated if the internal pressure becomes insufficient. When the service connection is made, the depressor in the end of the service hose or service coupling, presses on a small pin inside the valve, forcing the valve open. ● **SEE FIGURE 65–8.** The valve opens only when the service line connection is nearly complete, preventing contamination of the system or the unnecessary release of refrigerant.

The high-side service valve on R-12 systems is smaller and has different threads than the low-side service valve. This prevents incorrect connections that may result in damage to the system and to your service equipment. Some Ford systems use different sizes of quick-disconnect fittings, similar to an air-hose coupling. Adapters are available for use with standard manifold gauge sets.

EVACUATION PROCEDURES

Evacuation means that a vacuum will be applied to the system to vaporize any moisture that may be in the system. Although water boils at 212°F (100°C) at sea level, it can boil at much lower temperatures when the pressure is reduced. In other words, if a vacuum is applied to the air-conditioning system, the low pressure will cause any trapped moisture in the system to vaporize (boil). This water vapor is then removed from the system through the vacuum pump and released into the atmosphere. It is important to evacuate the system to at least 26 in. Hg of vacuum for at least 45 minutes to be assured that all of the moisture has been removed. For best results, the vacuum should be higher than 29 in. Hg. Just remember, the higher the vacuum and the longer that it is allowed to evacuate, the better.

NONCONDENSABLE GASES

Refrigerant should be checked for the presence of air, which is called a **noncondensable gas.** This means that the air will not condense into a liquid when pressurized like refrigerant. If air is present in the container of refrigerant, it is considered to be a contaminate and will reduce the cooling efficiency if installed into an air-conditioning

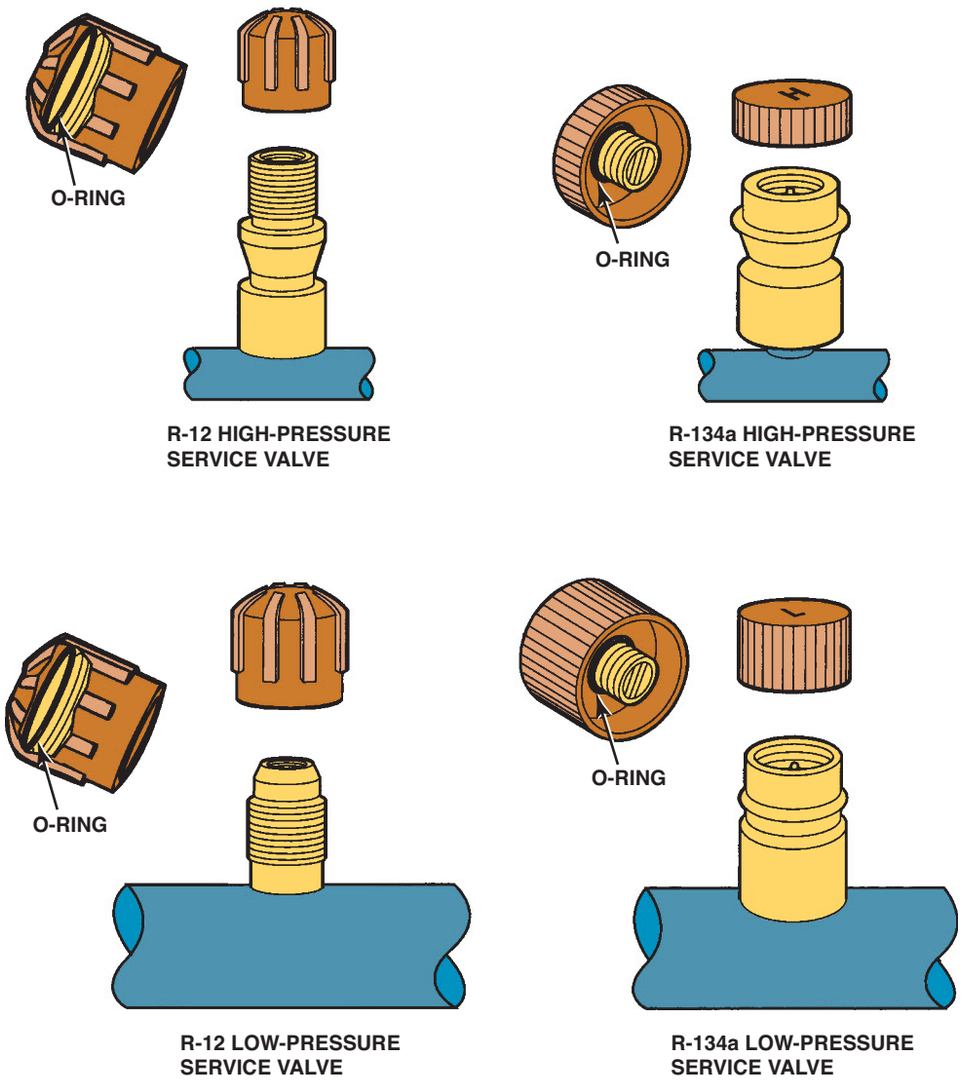

FIGURE 65–7 The service cap O-ring becomes the primary seal if the service valve leaks.

TECH TIP

Use a Micron Vacuum Gauge for Best Results

A typical vacuum gauge reads in inches of Mercury (in. Hg) and the recommended vacuum level needed to remove moisture from the system is considered to be 27 in. Hg or less. However, many experts recommend using a vacuum gauge that measures the amount of air remaining in the system. This type of gauge measures vacuum in microns. A micron is one millimeter of a meter and there are about 760,000 microns of air at atmospheric pressure. A vacuum reading of 29.72 in. Hg is about 5,000 microns. Many experts recommend that the micron level be 500 or less for best results. This is particularly important when evacuating a dual-climate control system where two evaporators are used and there are long lengths of refrigerant lines. ● **SEE FIGURE 65–9.**

system. There are two ways to determine if there is air (noncondensable gas) in the refrigerant, including:

- **Use a refrigerant identifier.** Most refrigerant identifiers will display the amount of air present.
- **Measure the temperature and pressure of the refrigerant.** Compare the measurement to a temperature/pressure chart.

If the only contaminate is air, it can be purged from the refrigerant. Always follow the instructions on the recycling machine for the procedure to follow.

REFRIGERANT RECYCLING

After refrigerant has been recovered, it needs to be recycled for further use. Most air-conditioning machines include the ability to recycle the refrigerant to the following SAE J1991 specification:

- **Moisture**—A maximum of 15 parts per million (ppm) by weight
- **Refrigerant oil**—A maximum of 4,000 parts per million (ppm) by weight
- **Noncondensable gases (air)**—A maximum of 330 parts per million (ppm) by weight

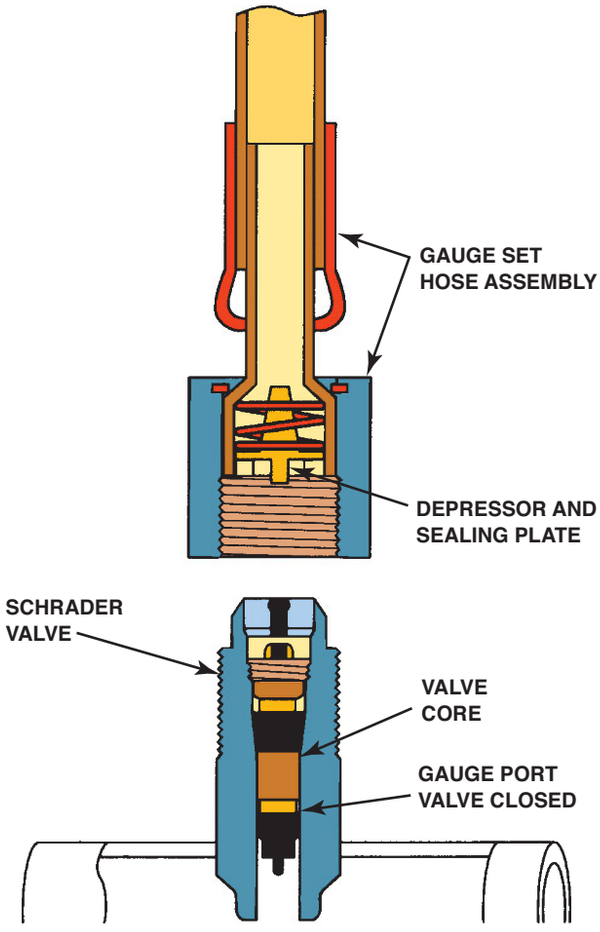

FIGURE 65–8 A depressor pin on the gauge set opens the Schrader valve when the connection is almost completely tightened. This prevents accidental refrigerant discharge.

RECHARGING A SYSTEM

After the system has been evacuated, it can be recharged with refrigerant. Most vehicles have a placard or sticker that indicates the correct amount of refrigerant to use. ● **SEE FIGURES 65–10 AND 65–11.** Follow the operating instructions for the equipment you are using.

FIGURE 65–11 A temperature and humidity gauge is a useful tool for air-conditioning work. The higher the relative humidity, the more difficult it is for the air-conditioning system to lower the temperature inside the vehicle.

REAL WORLD FIX

The Cadillac Story

When servicing an older Cadillac equipped with an automatic air-conditioning system (C-68), it was discovered that the compressor would not engage. The vehicle owner stated that a message had been warning him that the system was low on charge. The technician tightened a slightly loose Schrader valve and then added about one pound of R-12 to the system, yet the controller (computer) would not engage the clutch. The technician then remembered that if a diagnostic trouble code (DTC) has been set, the computer will not allow the compressor clutch to be engaged. This is a precaution to prevent possible compressor damage if the system is low on charge and not able to transfer the lubricating refrigerant oil through the system that the compressor needs for lubrication. The technician disconnected the negative (−) battery cable and waited several minutes and then reconnected it. After starting the engine and turning on the A/C controls, the compressor clutch engaged and the service technician was able to complete charging the system.

TECH TIP

Because It Fits, Does Not Mean It Is Correct!

Many air-conditioning systems use orifice tubes that look similar if not identical. They are usually color coded for identification. Always use the recommended orifice tube for the vehicle you are servicing. Some examples of the various colors and sizes available include:

Make	Color	Orifice Size (Inches)
Chrysler	purple	0.0605
Ford	red	0.0605
Ford	orange	0.0560
Ford	brown	0.0470
Ford	green	0.0505
GM	yellow	0.0605

NOTE: Always use the specified amount of refrigerant. Reduced cooling can occur if the system is either undercharged or overcharged. Air-conditioning service is definitely not a situation where "more is better."

RETROFITTING A CFC-12 SYSTEM TO A HFC-134A SYSTEM

Due to environmental and cost concerns, many service technicians are retrofitting (adapting) CFC-12 systems to HFC-134a systems. Whenever making the change, several tasks have to be performed, including:

- Specific service fittings must be installed.
- Retrofit labels must be attached to the vehicle in a visible location.
- PAG or ester oil must be used instead of the mineral oil in a CFC-12 system.
- A high-pressure shutoff switch must be installed that opens the compressor clutch circuit if the pressure exceeds 410 PSI.

Other changes that may or may not be necessary include:

- Replacing hoses
- Replacing O-rings
- Replacing the receiver-drier or accumulator
- Replacing pressure switches and calibrating them for use with an HFC-134a system
- Replacing the condenser or compressor as required by some vehicle manufacturers

All of the required parts necessary to retrofit a particular vehicle are often included in a kit for easy use. **SEE FIGURE 65–12.** When the system is recharged, the amount of HFC-134a is usually 90% of the CFC-12 amount minus 4 ounces. In other words, if 30 ounces is the normal charge of CFC-12, then 23 ounces of HFC-134a should be used (30 ounces × 90% = 27 ounces minus 4 ounces = 23 ounces).

(a)

(b)

FIGURE 65–12 (a) When a system is retrofitted from CFC-12 to HFC-134a, the proper service fittings have to be used to help assure that cross-contamination does not occur. (b) An underhood sticker is also installed indicating that the system was retrofitted to HFC-134a and when it was done and by whom.

COMPRESSOR SERVICE

COMPRESSOR DRIVE BELT Always check the compressor drive belt(s) whenever servicing the air-conditioning system and replace as needed. If some chunks are missing from the belt ribs or pieces of rubber are embedded in the pulleys, a noise that is often misinterpreted as coming from a defective compressor can occur.

COMPRESSOR CLUTCH SERVICE If the compressor clutch has been slipping, it will be blue, indicating that excessive heat has

FIGURE 65–13 A special tool is needed to remove and install the magnetic clutch on the air-conditioning compressor.

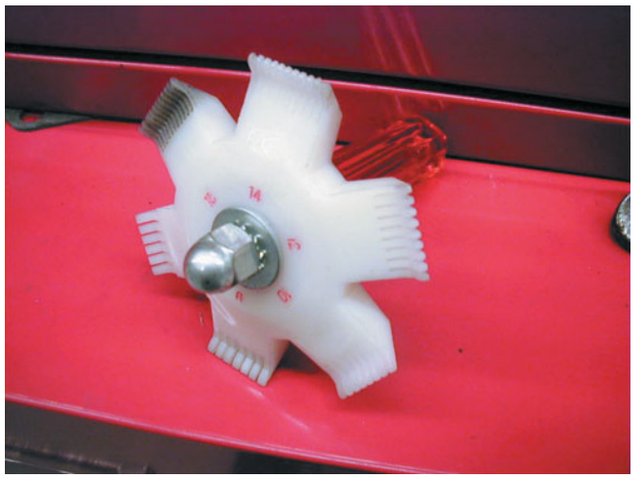

FIGURE 65–14 A fin comb is used to straighten the fins on the condenser to help increase airflow and heat transfer.

TECH TIP

An Additional Filter Is Insurance

If the air-conditioning compressor is found to be damaged mechanically, many experts recommend that an additional filter be installed in the refrigerant line to trap any debris that may have gotten into the system. This additional filter will help prevent the new compressor from being harmed by the debris as it circulates through the system.

TECH TIP

Might as Well Do It Now

Whenever an evaporator is being replaced, many service technicians also recommend that the heater core also be replaced. This is especially true if the vehicle had a neglected cooling system. Most heater cores are close to or even have to be removed to replace an evaporator. The only additional cost to the vehicle owner is the cost of the heater core itself.

been generated by the slipping clutch. Replace the clutch and adjust the air gap according to service information instructions. ● **SEE FIGURE 65–13.**

If replacement is needed, determine the quantity of oil that may be trapped in the old unit so that the proper amount can be added to the system after the new compressor has been installed.

COMPRESSOR REMOVAL If testing indicates that the air-conditioning compressor has failed, it should be removed from the vehicle after all of the refrigerant has been evacuated from the system. The steps specified by service information usually include the following:

STEP 1 Remove the refrigerant from the system.

STEP 2 Disconnect the compressor drive belt.

STEP 3 Disconnect sensors and compressor clutch wiring connections and label them if needed.

STEP 4 Disconnect the suction and discharge hoses.

STEP 5 Seal the hoses to help keep moisture and dirt from entering the system.

STEP 6 Remove the compressor mounting fasteners.

STEP 7 Drain and measure the refrigerant oil from the compressor.

STEP 8 Inspect the hoses, lines, fittings, O-rings, seals, muffler, and service valves for proper operation and repair or replace as needed as part of the compressor service.

CONDENSER SERVICE

Inspect the condenser for airflow restriction and clean as needed. Often a **"fin comb"** is needed to straighten the fins of the condenser, which may have been bent by road debris. ● **SEE FIGURE 65–14.**

If replacement is needed, determine the quantity of oil that may be trapped in the old unit so that the proper amount can be added to the system after the new condenser has been installed.

EVAPORATOR SERVICE

If the evaporator has been tested and found to be clogged or leaking, it has to be replaced. In most vehicles this is a major job involving disassembly of the dash.

RECEIVER/DRIER OR ACCUMULATOR/ DRIER SERVICE

Most experts recommend that the receiver/drier or accumulator/drier be replaced anytime the refrigerant system is opened and other repairs or services are being performed. Before replacing

FIGURE 65–15 Always be sure that the service valves are snug before evacuating the system. They are a common place for small refrigerant leaks.

the receiver/drier or accumulator/drier, determine the quantity of refrigerant oil so that the proper amount can be added to the system when it is recharged. Always follow the vehicle manufacturer's recommended service and repair procedures. ● **SEE FIGURE 65–15.**

ORIFICE TUBE/EXPANSION VALVE SERVICE

If the orifice tube is found to be clogged or the expansion valve has been determined to be not operating correctly, they will require replacement. Always follow the vehicle manufacturer's recommended replacement procedures and adhere to all precautions.

GASOLINE

DEFINITION **Gasoline** is a term used to describe a complex mixture of various hydrocarbons refined from crude petroleum oil for use as a fuel in engines. Gasoline and air burns in the cylinder of the engine and produces heat and pressure, which is converted to rotary motion inside the engine and eventually powers the drive wheels of a vehicle. When combustion occurs, carbon dioxide and water are produced if the process is perfect and all of the air and all of the fuel are consumed in the process.

CHEMICAL COMPOSITION Gasoline is a combination of hydrocarbon molecules that have between five and 12 carbon atoms. The names of these various hydrocarbons are based on the number of carbon atoms and include:

- **Methane**—one carbon atom
- **Ethane**—two carbon atoms
- **Propane**—three carbon atoms
- **Butane**—four carbon atoms
- **Pentane**—five carbon atoms
- **Hexane**—six carbon atoms

- **Heptane**—seven carbon atoms (Used to test octane rating–has an octane rating of zero)
- **Octane**—eight carbon atoms (A type of octane is used as a basis for antiknock rating)

REFINING

TYPES OF CRUDE OIL

Refining is a complex combination of interdependent processing units that can separate crude oil into useful products such as gasoline and diesel fuel. As it comes out of the ground, **petroleum** (meaning "rock oil") crude can be as thin and light colored as apple cider or as thick and black as melted tar. A barrel of crude oil is 42 gallons, not 55 gallons as commonly used for industrial barrels. Typical terms used to describe the type of crude oil include:

- Thin crude oil has a high American Petroleum Institute (API) gravity, and therefore, is called *high-gravity* crude.
- Thick crude oil is called *low-gravity* crude. High-gravity-type crude contains more natural gasoline and its lower sulfur and nitrogen content makes it easier to refine.
- Low-sulfur crude oil is also known as "sweet" crude.
- High-sulfur crude oil is also known as "sour" crude.

DISTILLATION

In the late 1800s, crude was separated into different products by boiling in a process called **distillation.** Distillation works because crude oil is composed of hydrocarbons with a broad range of boiling points.

In a distillation column, the vapor of the lowest-boiling hydrocarbons, propane and butane, rises to the top. The straight-run gasoline (also called naphtha), kerosene, and diesel fuel cuts are drawn off at successively lower positions in the column.

CRACKING

Cracking is the process where hydrocarbons with higher boiling points could be broken down (cracked) into lower-boiling hydrocarbons by treating them to very high temperatures. This process, called *thermal cracking*, was used to increase gasoline production starting in 1913.

Instead of high heat, today cracking is performed using a catalyst and is called **catalytic cracking.** A catalyst is a material that speeds up or otherwise facilitates a chemical reaction without undergoing a permanent chemical change itself. Catalytic cracking produces gasoline of higher quality than thermal cracking.

Hydrocracking is similar to catalytic cracking in that it uses a catalyst, but the catalyst is in a hydrogen atmosphere. Hydrocracking can break down hydrocarbons that are resistant to catalytic cracking alone, and it is used to produce diesel fuel rather than gasoline.

Other types of refining processes include:

- Reforming
- Alkylation
- Isomerization
- Hydrotreating
- Desulfurization

SEE FIGURE 66–1.

FIGURE 66–2 A gasoline testing kit, including an insulated container where water at 100°F is used to heat a container holding a small sample of gasoline. The reading on the pressure gauge is the Reid vapor pressure (RVP).

SHIPPING The gasoline is transported to regional storage facilities by railway tank car or by pipeline. In the pipeline method, all gasoline from many refiners is often sent through the same pipeline and can become mixed. All gasoline is said to be **fungible,** meaning that it is capable of being interchanged because each grade is created to specification so there is no reason to keep the different gasoline brands separated except for grade. Regular grade, mid-grade, and premium grades are separated in the pipeline and the additives are added at the regional storage facilities and then shipped by truck to individual gas stations.

VOLATILITY

DEFINITION OF VOLATILITY

Volatility describes how easily the gasoline evaporates (forms a vapor). The definition of volatility assumes that the vapors will remain in the fuel tank or fuel line and will cause a certain pressure based on the temperature of the fuel.

REID VAPOR PRESSURE (RVP)

Reid vapor pressure (RVP) is the pressure of the vapor above the fuel when the fuel is at 100°F (38°C). Increased vapor pressure permits the engine to start in cold weather. Gasoline without air will not burn. Gasoline must be vaporized (mixed with air) to burn in an engine. ● **SEE FIGURE 66–2.**

SEASONAL BLENDING

Cold temperatures reduce the normal vaporization of gasoline; therefore, winter-blended gasoline is specially formulated to vaporize at lower temperatures for proper starting and driveability at low ambient temperatures. The **American Society for Testing and Materials (ASTM)** standards for winter-blend gasoline allow volatility of up to 15 pounds per square inch (PSI) RVP.

At warm ambient temperatures, gasoline vaporizes easily. However, the fuel system (fuel pump, carburetor, fuel-injector nozzles, etc.) is designed to operate with liquid gasoline. The volatility of summer-grade gasoline should be about 7.0 PSI RVP. According to ASTM standards, the maximum RVP should be 10.5 PSI for summer-blend gasoline.

DISTILLATION CURVE

Besides Reid vapor pressure, another method of classifying gasoline volatility is the **distillation curve.** A curve on a graph is created by plotting the temperature at which the various percentage of the fuel evaporates. A typical distillation curve is shown in ● **FIGURE 66–3.**

? FREQUENTLY ASKED QUESTION

Why Do I Get Lower Gas Mileage in the Winter?

Several factors cause the engine to use more fuel in the winter than in the summer, including:

- Gasoline that is blended for use in cold climates is designed for ease of starting and contains fewer heavy molecules, which contribute to fuel economy. The heat content of winter gasoline is lower than summer-blended gasoline.
- In cold temperatures, all lubricants are stiff, causing more resistance. These lubricants include the engine oil, as well as the transmission and differential gear lubricants.
- Heat from the engine is radiated into the outside air more rapidly when the temperature is cold, resulting in longer run time until the engine has reached normal operating temperature.
- Road conditions, such as ice and snow, can cause tire slippage or additional drag on the vehicle.

DRIVEABILITY INDEX

A distillation curve shows how much of a gasoline evaporates at what temperature range. To predict cold-weather driveability, an index was created called the **driveability index,** also called the *distillation index*, and abbreviated **DI**.

The DI was developed using the temperature for the evaporated percentage of 10% (labeled T10), 50% (labeled T50), and 90% (labeled T90). The formula for DI is:

$$\mathbf{DI = 1.5 \times T10 + 3 \times T50 + T90}$$

The total DI is a temperature and usually ranges from 1,000°F to 1,200°F. The lower values of DI generally result in good cold-start and warm-up performance. A high DI number is less volatile than a low DI number.

NOTE: Most premium-grade gasoline has a higher (worse) DI than regular-grade or midgrade gasoline, which could cause poor cold-weather driveability. Vehicles designed to operate on premium-grade gasoline are programmed to handle the higher DI, but engines designed to operate on regular-grade gasoline may not be able to provide acceptable cold-weather driveability.

VOLATILITY-RELATED PROBLEMS

At higher temperatures, liquid gasoline can easily vaporize, which can cause **vapor lock.** Vapor lock is a *lean* condition caused by vaporized fuel in the fuel system. This vaporized fuel takes up space normally occupied by liquid fuel. Bubbles that form in the fuel cause vapor lock, preventing proper operation of the fuel-injection system.

Heat causes some fuel to evaporate, thereby causing bubbles. Sharp bends cause the fuel to be restricted at the bend. When the fuel flows past the bend, the fuel can expand to fill the space after the bend. This expansion drops the pressure, and bubbles form in the fuel lines. When the fuel is full of bubbles, the engine is not being supplied with enough fuel and the engine runs lean. A lean engine will stumble during acceleration, will run rough, and may stall. Warm weather and alcohol-blended fuels both tend to increase vapor lock and engine performance problems.

If winter-blend gasoline (or high-RVP fuel) is used in an engine during warm weather, the following problems may occur:

1. Rough idle
2. Stalling
3. Hesitation on acceleration
4. Surging

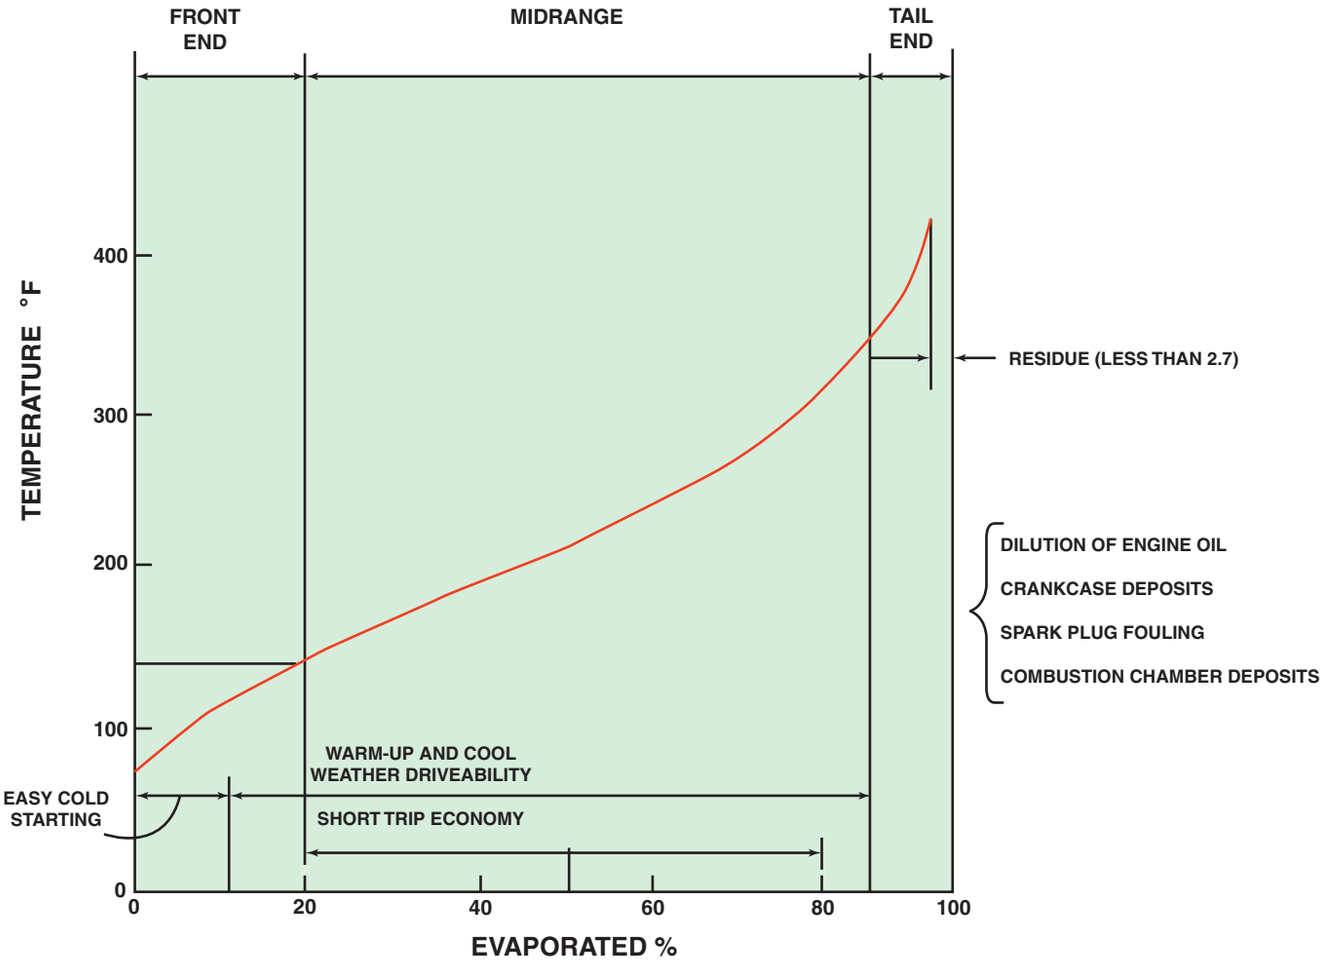

FIGURE 66–3 A typical distillation curve. Heavier molecules evaporate at higher temperatures and contain more heat energy for power, whereas the lighter molecules evaporate easier for starting.

GASOLINE COMBUSTION PROCESS

CHEMICAL REACTIONS

The combustion process involves the chemical combination of oxygen (O_2) from the air (about 21% of the atmosphere) with the hydrogen and carbon from the fuel. In a gasoline engine, a spark starts the combustion process, which takes about 3 ms (0.003 sec) to be completed inside the cylinder of an engine. The chemical reaction that takes place can be summarized as follows: hydrogen (H) plus carbon (C) plus oxygen (O_2) plus nitrogen (N) plus spark equals heat plus water (H_2O) plus carbon monoxide (CO) (if incomplete combustion) plus carbon dioxide (CO_2) plus hydrocarbons (HC) plus oxides of nitrogen (NO_X) plus many other chemicals. In an equation format it looks like this:

$$\mathbf{H + C + O_2 + N + Spark = Heat + CO_2 + HC + NO_x}$$

HEAT ENERGY

The heat produced by the combustion process is measured in **British thermal units (BTUs).** One BTU is the amount of heat required to raise one pound of water one Fahrenheit degree. The metric unit of heat is the *calorie* (cal). One calorie is the amount of heat required to raise the temperature of one gram (g) of water one Celsius degree:

Gasoline—About 130,000 BTUs per gallon

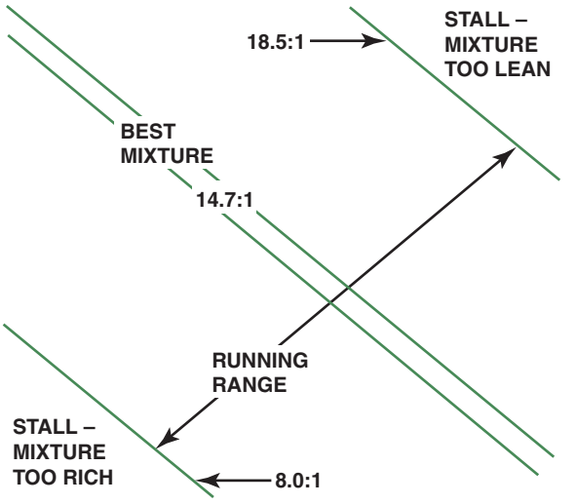

FIGURE 66–4 An engine will not run if the air-fuel mixture is either too rich or too lean.

AIR-FUEL RATIOS

Fuel burns best when the intake system turns it into a fine spray and mixes it with air before sending it into the cylinders. In fuel-injected engines, the fuel becomes a spray and mixes with the air in the intake manifold. There is a direct relationship between engine airflow and fuel requirements; this is called the **air-fuel ratio.**

The air-fuel ratio is the proportion by weight of air and gasoline that the injection system mixes as needed for engine combustion. The mixtures, with which an engine can operate without stalling, range from 8 to 1 to 18.5 to 1. ● **SEE FIGURE 66–4.**

These ratios are usually stated by weight, such as:

- 8 parts of air by weight combined with 1 part of gasoline by weight (8:1), which is the richest mixture that an engine can tolerate and still fire reliably.
- 18.5 parts of air mixed with 1 part of gasoline (18.5:1), which is the leanest practical ratio. Richer or leaner air-fuel ratios cause the engine to misfire badly or not run at all.

STOICHIOMETRIC AIR-FUEL RATIO The ideal mixture or ratio at which all of the fuel combines with all of the oxygen in the air and burns completely is called the **stoichiometric** ratio, a chemically perfect combination. In theory, this ratio for gasoline is an air-fuel mixture of 14.7 to 1. ● **SEE FIGURE 66–5.**

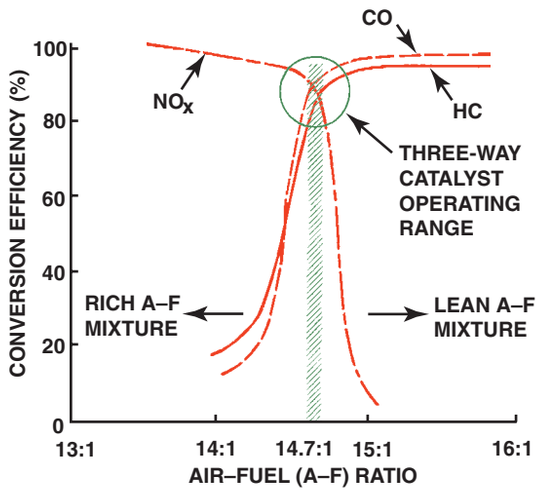

FIGURE 66–5 With a three-way catalytic converter, emission control is most efficient with an air-fuel ratio between 14.65 to 1 and 14.75 to 1.

In reality, the exact ratio at which perfect mixture and combustion occurs depends on the molecular structure of gasoline, which can vary. The stoichiometric ratio is a compromise between maximum power and maximum economy.

NORMAL AND ABNORMAL COMBUSTION

The **octane rating** of gasoline is the measure of its antiknock properties. *Engine knock* (also called **detonation, spark knock,** or **ping**) is a metallic noise an engine makes, usually during acceleration, resulting from abnormal or uncontrolled combustion inside the cylinder.

Normal combustion occurs smoothly and progresses across the combustion chamber from the point of ignition. ● **SEE FIGURE 66–6.**

Normal flame-front combustion travels between 45 and 90 mph (72 and 145 km/h). The speed of the flame front depends on the air-fuel ratio, combustion chamber design (determining amount of turbulence), and temperature.

During periods of spark knock (detonation), the combustion speed increases by up to 10 times to near the speed of sound. The increased combustion speed also causes increased temperatures and pressures, which can damage pistons, gaskets, and cylinder heads. ● **SEE FIGURE 66–7.**

One of the first additives used in gasoline was **tetraethyl lead (TEL).** TEL was added to gasoline in the early 1920s to reduce the tendency to knock. It was often called ethyl or high-test gasoline.

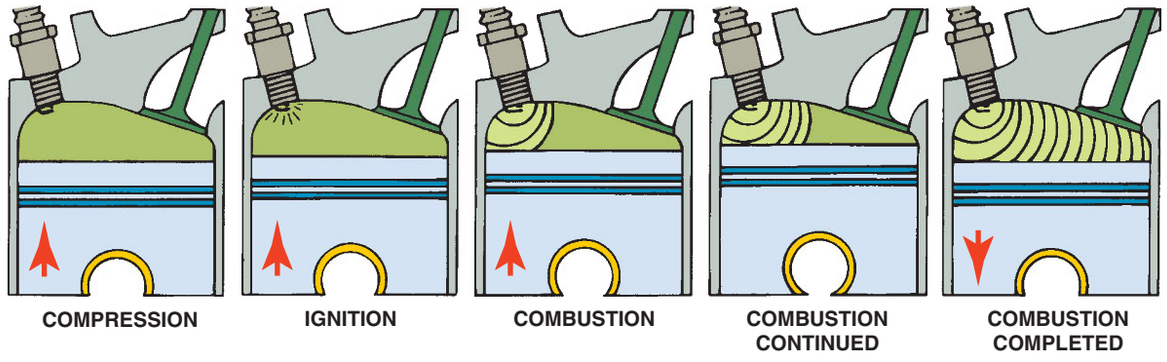

FIGURE 66–6 Normal combustion is a smooth, controlled burning of the air-fuel mixture.

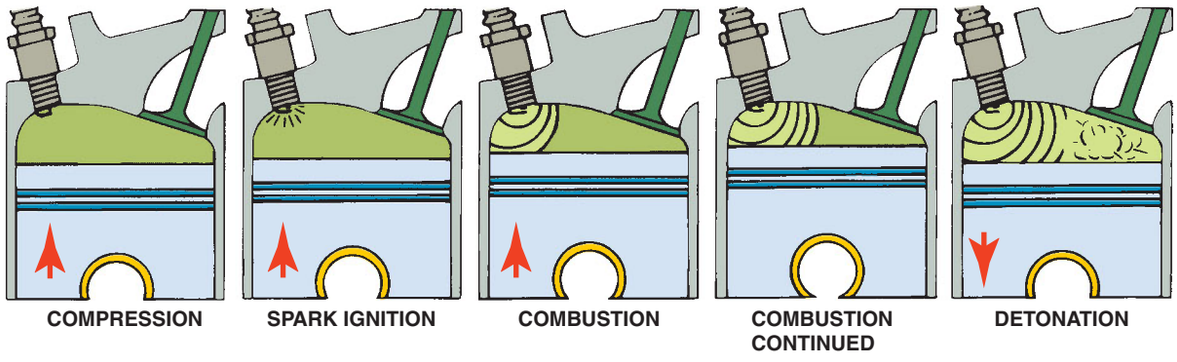

FIGURE 66–7 Detonation is a secondary ignition of the air-fuel mixture. It is also called spark knock or pinging.

FREQUENTLY ASKED QUESTION

What Grade of Gasoline Does the EPA Use When Testing Engines?

Due to the various grades and additives used in commercial fuel, the government (EPA) uses a liquid called indolene. Indolene has a research octane number of 96.5 and a motor method octane rating of 88, which results in an R + M ÷ 2 rating of 92.25.

TECH TIP

Horsepower and Fuel Flow

To produce 1 hp, the engine must be supplied with 0.50 lb of fuel per hour (lb/hr). Fuel injectors are rated in pounds per hour. For example, a V-8 engine equipped with 25 lb/hr fuel injectors could produce 50 hp per cylinder (per injector) or 400 hp. Even if the cylinder head or block is modified to produce more horsepower, the limiting factor may be the injector flow rate.

The following are flow rates and resulting horsepower for a V-8 engine:

30 lb/hr: 60 hp per cylinder or 480 hp
35 lb/hr: 70 hp per cylinder or 560 hp
40 lb/hr: 80 hp per cylinder or 640 hp

Of course, injector flow rate is only one of many variables that affect power output. Installing larger injectors without other major engine modification could decrease engine output and drastically increase exhaust emissions.

OCTANE RATING

The antiknock standard or basis of comparison is the knock-resistant hydrocarbon isooctane, chemically called trimethylpentane (C_8H_{18}), also known as 2-2-4 trimethylpentane. If a gasoline tested had the exact same antiknock characteristics as isooctane, it was rated as 100-octane gasoline. If the gasoline tested had only 85% of the antiknock properties of isooctane, it was rated as 85 octane. Remember, octane rating is only a comparison test.

The two basic methods used to rate gasoline for antiknock properties (octane rating) are the *research method* and the *motor method*. Each uses a model of the special cooperative fuel research (CFR) single-cylinder engine. The research method and the motor method vary as to temperature of air, spark advance, and other parameters. The research method typically results in readings that are 6 to 10 points higher than those of the motor method. For example, a fuel with a research octane number (RON) of 93 might have a motor octane number (MON) of 85.

The octane rating posted on pumps in the United States is the average of the two methods and is referred to as (R + M) ÷ 2, meaning that, for the fuel used in the previous example, the rating posted on the pumps would be

$$\frac{\text{RON} + \text{MON}}{2} = \frac{93 + 85}{2} = 89$$

The pump octane is called the **antiknock index (AKI).**

FIGURE 66–8 A pump showing regular with a pump octane of 87, plus rated at 89, and premium rated at 93. These ratings can vary with brand as well as in different parts of the country.

GASOLINE GRADES AND OCTANE NUMBER The posted octane rating on gasoline pumps is the rating achieved by the average of the research and the motor methods. ● **SEE FIGURE 66–8.**

Except in high-altitude areas, the grades and octane ratings are as follows:

Grades	Octane rating
Regular	87
Midgrade (also called Plus)	89
Premium	91 or higher

HIGH-ALTITUDE OCTANE REQUIREMENTS

As the altitude increases, atmospheric pressure drops. The air is less dense because a pound of air takes more volume. The octane rating of fuel does not need to be as high because the engine cannot take in as much air. This process will reduce the combustion (compression) pressures inside the engine. In mountainous areas, gasoline (R + M) ÷ 2 octane ratings are two or more numbers lower than normal (according to the SAE, about one octane number lower per 1,000 ft or 300 m in altitude). ● **SEE FIGURE 66–9.**

A secondary reason for the lowered octane requirement of engines running at higher altitudes is the normal enrichment of the air-fuel ratio and lower engine vacuum with the decreased air density. Some problems, therefore, may occur when driving out of high-altitude areas into lower-altitude areas where the octane rating must be higher. Most computerized engine control systems can compensate for changes in altitude and modify air-fuel ratio and ignition timing for best operation.

Because the combustion burn rate slows at high altitude, the ignition (spark) timing can be advanced to improve power. The amount of timing advance can be about 1 degree per 1,000 ft over 5,000 ft. Therefore, if driving at 8,000 ft of altitude, the ignition timing can be advanced 3 degrees.

High altitude also allows fuel to evaporate more easily. The volatility of fuel should be reduced at higher altitudes to prevent vapor from forming in sections of the fuel system, which can cause driveability and stalling problems. The extra heat generated in climbing

FIGURE 66–9 The posted octane rating in most high-altitude areas shows regular at 85 instead of the usual 87.

? FREQUENTLY ASKED QUESTION

Can Regular-Grade Gasoline Be Used If Premium Is the Recommended Grade?

Maybe. It is usually possible to use regular-grade or midgrade (plus) gasoline in most newer vehicles without danger of damage to the engine. Most vehicles built since the 1990s are equipped with at least one knock sensor. If a lower octane gasoline than specified is used, the engine ignition timing setting will usually cause the engine to spark knock, also called detonation or ping. This spark knock is detected by the knock sensor(s), which sends a signal to the computer. The computer then retards the ignition timing until the spark knock stops.

NOTE: Some scan tools will show the "estimated octane rating" of the fuel being used, which is based on knock sensor activity.

As a result of this spark timing retardation, the engine torque is reduced. While this reduction in power is seldom noticed, it will reduce fuel economy, often by 4 to 5 miles per gallon. If premium gasoline is then used, the PCM will gradually permit the engine to operate at the more advanced ignition timing setting. Therefore, it may take several tanks of premium gasoline to restore normal fuel economy. For best overall performance, use the grade of gasoline recommended by the vehicle manufacturer.

to higher altitudes plus the lower atmospheric pressure at higher altitudes combine to cause vapor lock problems as the vehicle goes to higher altitudes.

GASOLINE ADDITIVES

DYE Dye is usually added to gasoline at the distributor to help identify the grade and/or brand of fuel. In many countries, fuels are required to be colored using a fuel-soluble dye. In the United States and Canada, diesel fuel used for off-road use and not taxed is required to be dyed red for identification. Gasoline sold for off-road use in Canada is dyed purple.

? FREQUENTLY ASKED QUESTION

What Is Meant by "Phase Separation?"

All alcohols absorb water, and the alcohol–water mixture can separate from the gasoline and sink to the bottom of the fuel tank. This process is called *phase separation*. To help avoid engine performance problems, try to keep at least a quarter tank of fuel at all times, especially during seasons when there is a wide temperature span between daytime highs and nighttime lows. These conditions can cause moisture to accumulate in the fuel tank as a result of condensation of the moisture in the air.

OCTANE IMPROVER ADDITIVES When gasoline companies, under federal EPA regulations, removed tetraethyl lead from gasoline, other methods were developed to help maintain the antiknock properties of gasoline. Octane improvers (enhancers) can be grouped into three broad categories:

1. Aromatic hydrocarbons (hydrocarbons containing the benzene ring) such as xylene and toluene
2. Alcohols such as ethanol (ethyl alcohol), methanol (methyl alcohol), and tertiary butyl alcohol (TBA)
3. Metallic compounds such as methylcyclopentadienyl manganese tricarbonyl (MMT)

NOTE: MMT has been proven to be harmful to catalytic converters and can cause spark plug fouling. However, MMT is currently one of the active ingredients commonly found in octane improvers available to the public and in some gasoline sold in Canada. If an octane boost additive has been used that contains MMT, the spark plug porcelain will be rust colored around the tip.

Propane and butane, which are volatile by-products of the refinery process, are also often added to gasoline as octane improvers. The increase in volatility caused by the added propane and butane often leads to hot-weather driveability problems.

OXYGENATED FUEL ADDITIVES **Oxygenated fuels** contain oxygen in the molecule of the fuel itself. Examples of oxygenated fuels include methanol, ethanol, methyl tertiary butyl ether (MTBE), tertiary-amyl methyl ether (TAME), and ethyl tertiary butyl ether (ETBE).

Oxygenated fuels are commonly used in high-altitude areas to reduce carbon monoxide (CO) emissions. The extra oxygen in the fuel itself is used to convert harmful CO into carbon dioxide (CO_2). The extra oxygen in the fuel helps ensure that there is enough oxygen to convert all CO into CO_2 during the combustion process in the engine or catalytic converter.

METHYL TERTIARY BUTYL ETHER (MTBE). MTBE is manufactured by means of the chemical reaction of methanol and isobutylene. Unlike methanol, MTBE does not increase the volatility of the fuel and is not as sensitive to water as are other alcohols. The maximum allowable volume level, according to the EPA, is 15% but is currently being phased out because of health concerns, as well as MTBE contamination of drinking water if spilled from storage tanks.

FIGURE 66–10 This refueling pump indicates that the gasoline is blended with 10% ethanol (ethyl alcohol) and can be used in any gasoline vehicle. E85 contains 85% ethanol and can be used only in vehicles specifically designed to use it.

FIGURE 66–11 A container with gasoline containing alcohol. Notice the separation line where the alcohol–water mixture separated from the gasoline and sank to the bottom.

TERTIARY-AMYL METHYL ETHER. Tertiary-amyl methyl ether (TAME) contains an oxygen atom bonded to two carbon atoms and is added to gasoline to provide oxygen to the fuel. It is slightly soluble in water, very soluble in ethers and alcohol, and soluble in most organic solvents including hydrocarbons.

ETHYL TERTIARY BUTYL ETHER. ETBE is derived from ethanol. The maximum allowable volume level is 17.2%. The use of ETBE is the cause of much of the odor from the exhaust of vehicles using reformulated gasoline.

ETHANOL. **Ethanol,** also called *ethyl alcohol* is drinkable alcohol and is usually made from grain. Adding 10% ethanol (ethyl alcohol or grain alcohol) increases the (R + M) ÷ 2 octane rating by three points. The alcohol added to the base gasoline, however, also raises the volatility of the fuel about 0.5 PSI. Most automobile manufacturers permit up to 10% ethanol if driveability problems are not experienced.

The oxygen content of a 10% blend of ethanol in gasoline, called **E10,** is 3.5% oxygen by weight. ● **SEE FIGURE 66–10.**

Keeping the fuel tank full reduces the amount of air and moisture in the tank. ● **SEE FIGURE 66–11.**

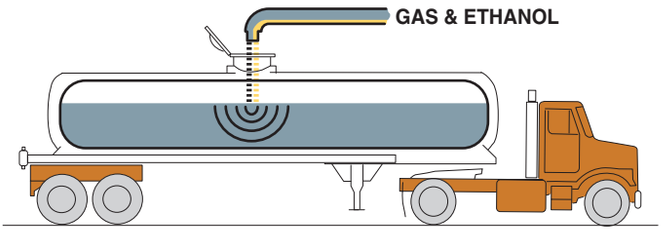

FIGURE 66–12 In-line blending is the most accurate method for blending ethanol with gasoline because computers are used to calculate the correct ratio.

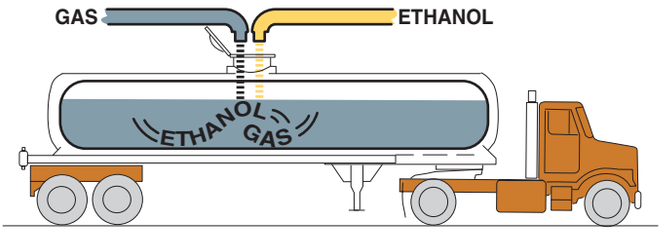

FIGURE 66–13 Sequential blending uses a computer to calculate the correct ratio as well as the prescribed order in which the products are loaded.

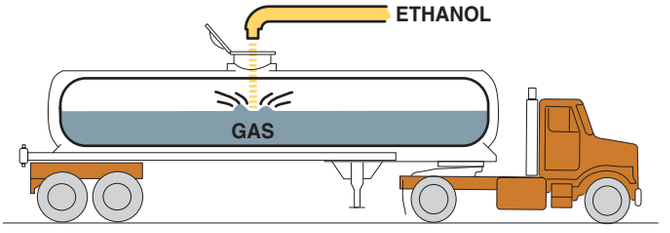

FIGURE 66–14 Splash blending occurs when the ethanol is added to a tanker with gasoline and is mixed as the truck travels to the retail outlet.

GASOLINE BLENDING

Gasoline additives, such as ethanol and dyes, are usually added to the fuel at the distributor. Adding ethanol to gasoline is a way to add oxygen to the fuel itself. Gasoline containing an addition that has oxygen is called *oxygenated fuel*. There are three basic methods used to blend ethanol with gasoline to create E10 (10% ethanol, 90% gasoline):

1. **In-line blending.** Gasoline and ethanol are mixed in a storage tank or in the tank of a transport truck while it is being filled. Because the quantities of each can be accurately measured, this method is most likely to produce a well-mixed blend of ethanol and gasoline. ● **SEE FIGURE 66–12.**
2. **Sequential blending.** This method is usually performed at the wholesale terminal and involves adding a measured amount of ethanol to a tank truck followed by a measured amount of gasoline. ● **SEE FIGURE 66–13.**
3. **Splash blending.** Splash blending can be done at the retail outlet or distributor and involves separate purchases of ethanol and gasoline. In a typical case, a distributor can purchase gasoline, and then drive to another supplier and purchase ethanol. The ethanol is then added (splashed) into the tank of gasoline. This method is the least-accurate method of blending and can result in ethanol concentration for E10 that should be 10% to range from 5% to over 20% in some cases. ● **SEE FIGURE 66–14.**

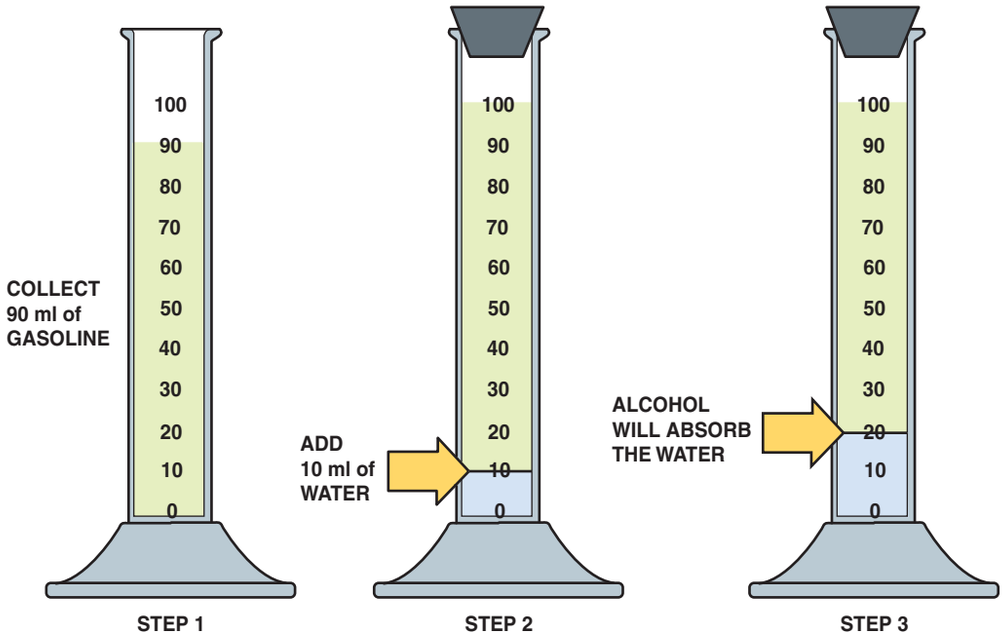

FIGURE 66–15 Checking gasoline for alcohol involves using a graduated cylinder and adding water to check if the alcohol absorbs the water.

FREQUENTLY ASKED QUESTION

Is Water Heavier Than Gasoline?

Yes. Water weighs about 8.3 pounds per gallon, whereas gasoline weighs about 6 pounds per gallon. The density as measured by specific gravity includes:

Water = 1.000 (the baseline for specific gravity)
Gasoline = 0.730 to 0.760

This means that any water that gets into the fuel tank will sink to the bottom.

REFORMULATED GASOLINE

Reformulated gasoline (RFG) is manufactured to help reduce emissions. The gasoline refiners reformulate gasoline by using additives that contain at least 2% oxygen by weight and reducing the additive benzene to a maximum of 1% by volume. Two other major changes done at the refineries are as follows:

1. **Reduce light compounds.** Refineries eliminate butane, pentane, and propane, which have a low boiling point and evaporate easily. These unburned hydrocarbons are released into the atmosphere during refueling and through the fuel tank vent system, contributing to smog formation. Therefore, reducing the light compounds from gasoline helps reduce evaporative emissions.
2. **Reduce heavy compounds.** Refineries eliminate heavy compounds with high boiling points such as aromatics and olefins. The purpose of this reduction is to reduce the amount of unburned hydrocarbons that enter the catalytic converter, which makes the converter more efficient, thereby reducing emissions.

Because many of the heavy compounds are eliminated, a drop in fuel economy of about 1 mpg has been reported in areas where reformulated gasoline is being used. Formaldehyde is formed when RFG is burned, and the vehicle exhaust has a unique smell when reformulated gasoline is used.

TESTING GASOLINE FOR ALCOHOL CONTENT

Take the following steps when testing gasoline for alcohol content:

WARNING

Do not smoke or run the test around sources of ignition!

1. Pour suspect gasoline into a graduated cylinder.
2. Carefully fill the graduated cylinder to the 90-mL mark.
3. Add 10 mL of water to the graduated cylinder by counting the number of drops from an eyedropper.
4. Put the stopper in the cylinder and shake vigorously for 1 minute. Relieve built-up pressure by occasionally removing the stopper. Alcohol dissolves in water and will drop to the bottom of the cylinder.
5. Place the cylinder on a flat surface and let it stand for 2 minutes.
6. Take a reading near the bottom of the cylinder at the boundary between the two liquids.
7. For percent of alcohol in gasoline, subtract 10 from the reading.

   For example,

   The reading is 20 mL: 20 − 10 = 10% alcohol

If the increase in volume is 0.2% or less, it may be assumed that the test gasoline contains no alcohol. ● **SEE FIGURE 66–15.** Alcohol content can also be checked using an electronic tester. See the step-by-step sequence at the end of the chapter.

FIGURE 66–16 The gas cap on a Ford vehicle notes that BP fuel is recommended.

TECH TIP

The Sniff Test

Problems can occur with stale gasoline from which the lighter parts of the gasoline have evaporated. Stale gasoline usually results in a no-start situation. If stale gasoline is suspected, sniff it. If it smells rancid, replace it with fresh gasoline.

NOTE: If storing a vehicle, boat, or lawnmower over the winter, put some gasoline stabilizer into the gasoline to reduce the evaporation and separation that can occur during storage. Gasoline stabilizer is frequently available at lawnmower repair shops or marinas.

FREQUENTLY ASKED QUESTION

How Does Alcohol Content in the Gasoline Affect Engine Operation?

In most cases, the use of gasoline containing 10% or less of ethanol (ethyl alcohol) has little or no effect on engine operation. However, because the addition of 10% ethanol raises the volatility of the fuel slightly, occasional rough idle or stalling may be noticed, especially during warm weather. The rough idle and stalling may also be noticeable after the engine is started, driven, then stopped for a short time. Engine heat can vaporize the alcohol-enhanced fuel causing bubbles to form in the fuel system. These bubbles in the fuel prevent the proper operation of the fuel injection system and result in a hesitation during acceleration, rough idle, or in severe cases repeated stalling until all the bubbles have been forced through the fuel system, replaced by cooler fuel from the fuel tank.

FREQUENTLY ASKED QUESTION

Why Should I Keep the Fuel Gauge Above One-Quarter Tank?

The fuel pickup inside the fuel tank can help keep water from being drawn into the fuel system unless water is all that is left at the bottom of the tank. Over time, moisture in the air inside the fuel tank can condense, causing liquid water to drop to the bottom of the fuel tank (water is heavier than gasoline–about 8 lb per gallon for water and about 6 lb per gallon for gasoline). If alcohol-blended gasoline is used, the alcohol can absorb the water and the alcohol–water combination can be burned inside the engine. However, when water combines with alcohol, a separation layer occurs between the gasoline at the top of the tank and the alcohol–water combination at the bottom. When the fuel level is low, the fuel pump will draw from this concentrated level of alcohol and water. Because alcohol and water do not burn as well as pure gasoline, severe driveability problems can occur such as stalling, rough idle, hard starting, and missing.

FREQUENTLY ASKED QUESTION

What Is "Top-Tier" Gasoline?

Top-tier gasoline is gasoline that has specific standards for quality, including enough detergent to keep all intake valves clean. Four automobile manufacturers, including BMW, General Motors, Honda, and Toyota, developed the standards. Top-tier gasoline exceeds the quality standards developed by the **World Wide Fuel Charter (WWFC)** that was established in 2002 by vehicle and engine manufacturers. The gasoline companies that agreed to make fuel that matches or exceeds the standards as a top-tier fuel include Shell, ChevronTexaco and ConocoPhillips. Ford has specified that BP fuel, sold in many parts of the country, is the recommended fuel to use in Ford vehicles. ● **SEE FIGURE 66–16.**

GENERAL GASOLINE RECOMMENDATIONS

The fuel used by an engine is a major expense in the operation cost of the vehicle. The proper operation of the engine depends on clean fuel of the proper octane rating and vapor pressure for the atmospheric conditions.

To help ensure proper engine operation and keep fuel costs to a minimum, follow these guidelines:

1. Purchase fuel from a busy station to help ensure that it is fresh and less likely to be contaminated with water or moisture.
2. Keep the fuel tank above one-quarter full, especially during seasons in which the temperature rises and falls by more than 20°F between daytime highs and nighttime lows. This helps to reduce condensed moisture in the fuel tank and could prevent gas line freeze-up in cold weather.

TECH TIP

Do Not Overfill the Fuel Tank

Gasoline fuel tanks have an expansion volume area at the top. The volume of this expansion area is equal to 10% to 15% of the volume of the tank. This area is normally not filled with gasoline, but rather is designed to provide a place for the gasoline to expand into, if the vehicle is parked in the hot sun and the gasoline expands. This prevents raw gasoline from escaping from the fuel system. A small restriction is usually present to control the amount of air and vapors that can escape the tank and flow to the charcoal canister.

This volume area could be filled with gasoline if the fuel is slowly pumped into the tank. Since it can hold an extra 10% (2 gallons in a 20-gallon tank), some people deliberately try to fill the tank completely. When this expansion volume is filled, liquid fuel (rather than vapors) can be drawn into the charcoal canister. When the purge valve opens, liquid fuel can be drawn into the engine, causing an excessively rich air-fuel mixture. Not only can this liquid fuel harm vapor recovery parts, but overfilling the gas tank could also cause the vehicle to fail an exhaust emission test, particularly during an enhanced test when the tank could be purged while on the rollers.

NOTE: Gas line freeze-up occurs when the water in the gasoline freezes and forms an ice blockage in the fuel line.

3. Do not purchase fuel with a higher octane rating than is necessary. Most newer engines are equipped with a detonation (knock) sensor that signals the vehicle computer to retard the ignition timing when spark knock occurs. Therefore, an operating difference may not be noticeable to the driver when using a low-octane fuel, except for a decrease in power and fuel economy. In other words, the engine with a knock sensor will tend to operate knock free on regular fuel, even if premium, higher-octane fuel is specified. Using premium fuel may result in more power and greater fuel economy. The increase in fuel economy, however, would have to be substantial to justify the increased cost of high-octane premium fuel. Some drivers find a good compromise by using midgrade (plus) fuel to benefit from the engine power and fuel economy gains without the cost of using premium fuel all the time.
4. Avoid using gasoline with alcohol in warm weather, even though many alcohol blends do not affect engine driveability. If warm-engine stumble, stalling, or rough idle occurs, change brands of gasoline.
5. Do not purchase fuel from a retail outlet when a tanker truck is filling the underground tanks. During the refilling procedure, dirt, rust, and water may be stirred up in the underground tanks. This undesirable material may be pumped into your vehicle's fuel tank.
6. Do not overfill the gas tank. After the nozzle clicks off, add just enough fuel to round up to the next dime. Adding additional gasoline will cause the excess to be drawn into the charcoal canister. This can lead to engine flooding and excessive exhaust emissions.
7. Be careful when filling gasoline containers. Always fill a gas can on the ground to help prevent the possibility of static electricity buildup during the refueling process. ● **SEE FIGURE 66–17.**

FIGURE 66–17 Many gasoline service stations have signs posted warning customers to place plastic fuel containers on the ground while filling. If placed in a trunk or pickup truck bed equipped with a plastic liner, static electricity could build up during fueling and discharge from the container to the metal nozzle, creating a spark and possible explosion. Some service stations have warning signs not to use cell phones while fueling to help avoid the possibility of an accidental spark creating a fire hazard.

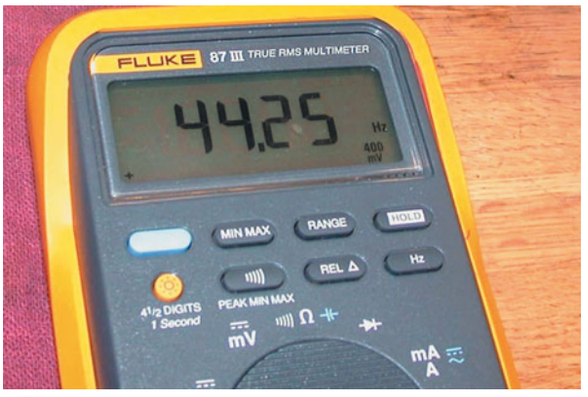
FREQUENTLY ASKED QUESTION

What Are the Pump Nozzle Sizes?

Unleaded gasoline nozzles are smaller than those used for diesel fuel to help prevent fueling errors. However, it is still possible to fuel a diesel vehicle with gasoline. ● **SEE CHART 66–1** for the sizes and colors used for fuel pump nozzles.

Fuel	Nozzle Diameter	Pump Handle Color (Varies—no established standard)
Gasoline	13/16 in. (21 mm)	Black, red, white, green, or blue
E10	13/16 in. (21 mm)	Black, red, white, green, or blue
E85	13/16 in. (21 mm)	Yellow or black
Diesel fuel	15/16 in. (24 mm)	Yellow, green, or black
Biodiesel	15/16 in. (24 mm)	Green
Truckstop diesel	1 1/14 or 1 1/2 in. (32 or 38 mm)	Varies

CHART 66–1



Fuel pump nozzle size is standardized except for use by over-the-road truck stops where high fuel volumes and speedy refills require larger nozzle sizes compared to passenger vehicle filling station nozzles.

1 A fuel composition tester (SPX Kent-Moore J-44175) is the recommended tool, by General Motors, to use to test the alcohol content of gasoline.

2 This battery-powered tester uses light-emitting diodes (LEDs), meter lead terminals, and two small openings for the fuel sample.

3 The first step is to verify the proper operation of the tester by measuring the air frequency by selecting AC hertz on the meter. The air frequency should be between 35 and 48 Hz.

4 After verifying that the tester is capable of correctly reading the air frequency, gasoline is poured into the testing cell of the tool.

5 Record the AC frequency as shown on the meter and subtract 50 from the reading. (e.g., 60.50 − 50.00 = 10.5). This number (10.5) is the percentage of alcohol in the gasoline sample.

6 Adding additional amounts of ethyl alcohol (ethanol) increases the frequency reading.

ETHANOL

ETHANOL TERMINOLOGY

Ethanol is also called **ethyl alcohol** or **grain alcohol,** because it is usually made from grain and is the type of alcohol found in alcoholic drinks such as beer, wine, and distilled spirits like whiskey. Ethanol is composed of two carbon atoms and six hydrogen atoms with one added oxygen atom. **SEE FIGURE 67–1.**

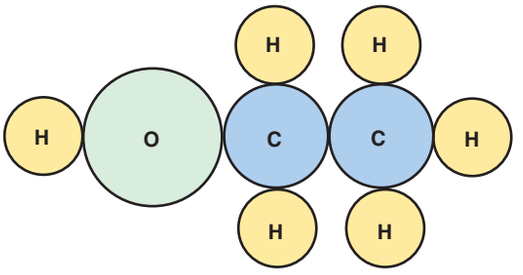

FIGURE 67–1 The ethanol molecule showing two carbon atoms, six hydrogen atoms, and one oxygen atom.

ETHANOL PRODUCTION

Conventional ethanol is derived from grains, such as corn, wheat, or soybeans. Corn, for example, is converted to ethanol in either a dry or wet milling process. In dry milling operations, liquefied cornstarch is produced by heating cornmeal with water and enzymes. A second enzyme converts the liquefied starch to sugars, which are fermented by yeast into ethanol and carbon dioxide. Wet milling operations separate the fiber, germ (oil), and protein from the starch before it is fermented into ethanol.

The majority of the ethanol in the United States is made from:

- Corn
- Grain
- Sorghum
- Wheat
- Barley
- Potatoes

In Brazil, the world's largest ethanol producer, it is made from sugarcane. Ethanol can be made by the dry mill process in which the starch portion of the corn is fermented into sugar and then distilled into alcohol.

The major steps in the dry mill process include:

1. **Milling.** The feedstock passes through a hammer mill that turns it into a fine powder called *meal*.
2. **Liquefaction.** The meal is mixed with water and then passed through cookers where the starch is liquefied. Heat is applied at this stage to enable liquefaction. Cookers use a high-temperature stage of about 250°F to 300°F (120°C to 150°C) to reduce bacteria levels and then a lower temperature of about 200°F (95°C) for a holding period.
3. **Saccharification.** The mash from the cookers is cooled and a secondary enzyme is added to convert the liquefied starch to fermentable sugars (dextrose).
4. **Fermentation.** Yeast is added to the mash to ferment the sugars to ethanol and carbon dioxide.
5. **Distillation.** The fermented mash, now called beer, contains about 10% alcohol plus all the nonfermentable solids from the corn and yeast cells. The mash is pumped to the continuous-flow, distillation system where the alcohol is removed from the solids and the water. The alcohol leaves the top of the final column at about 96% strength, and the residue mash, called *silage*, is transferred from the base of the column to the co-product processing area.

? FREQUENTLY ASKED QUESTION

Does Ethanol Production Harm the Environment?

The production of ethanol is referred to as being carbon neutral because the amount of CO_2 released during production is equal to the amount of CO_2 that would be released if the corn or other products were left to decay.

6. **Dehydration.** The alcohol from the top of the column passes through a dehydration system where the remaining water will be removed. The alcohol product at this stage is called **anhydrous ethanol** (pure, no more than 0.5% water).
7. **Denaturing.** Ethanol that will be used for fuel must be denatured, or made unfit for human consumption, with a small amount of gasoline (2% to 5%), methanol, or denatonium benzoate. This is done at the ethanol plant.

CELLULOSE ETHANOL

TERMINOLOGY

Cellulose ethanol can be produced from a wide variety of cellulose biomass feedstock, including:

- Agricultural plant wastes (corn stalks, cereal straws)
- Plant wastes from industrial processes (sawdust, paper pulp)
- Energy crops grown specifically for fuel production.

These nongrain products are often referred to as **cellulosic biomass.** Cellulosic biomass is composed of cellulose and lignin, with smaller amounts of proteins, lipids (fats, waxes, and oils), and ash. About two-thirds of cellulosic materials are present as cellulose, with lignin making up the bulk of the remaining dry mass.

REFINING CELLULOSE BIOMASS

As with grains, processing cellulose biomass involves extracting fermentable sugars from the feedstock. But the sugars in cellulose are locked in complex carbohydrates called polysaccharides (long chains of simple sugars). Separating these complex structures into fermentable sugars

? FREQUENTLY ASKED QUESTION

What Is Switchgrass?

Switchgrass (*Panicum virgatum*) can be used to make ethanol and is a summer perennial grass that is native to North America. It is a natural component of the tall-grass prairie, which covered most of the Great Plains, but was also found on the prairie soils in the Black Belt of Alabama and Mississippi. Switchgrass is resistant to many pests and plant diseases, and is capable of producing high yields with very low applications of fertilizer. This means that the need for agricultural chemicals to grow switchgrass is relatively low. Switchgrass is also very tolerant of poor soils, flooding, and drought, which are widespread agricultural problems in the Southeast.

There are two main types of switchgrass:

- **Upland types**—usually grow 5 to 6 feet tall
- **Lowland types**—grow up to 12 feet tall and are typically found on heavy soils in bottomland sites

Better energy efficiency is gained because less energy is used to produce ethanol from switchgrass.

is needed to achieve the efficient and economic production of cellulose ethanol.

Two processing options are employed to produce fermentable sugars from cellulose biomass:

- Acid hydrolysis is used to break down the complex carbohydrates into simple sugars.
- Enzymes are employed to convert the cellulose biomass to fermentable sugars. The final step involves microbial fermentation, yielding ethanol and carbon dioxide.

NOTE: Cellulose ethanol production substitutes biomass for fossil fuels. The greenhouse gases produced by the combustion of biomass are offset by the CO_2 absorbed by the biomass as it grows in the field.

E85

WHAT IS E85? Vehicle manufacturers have available vehicles that are capable of operating on gasoline plus ethanol or a combination of gasoline and ethanol called **E85.** E85 is composed of 85% ethanol and 15% gasoline.

Pure ethanol has an octane rating of about 113. E85, which contains 35% oxygen by weight, has an octane rating of about 100 to 105. This compares to a regular unleaded gasoline, which has a rating of 87. ● **SEE FIGURE 67–2.**

NOTE: The octane rating of E85 depends on the exact percent of ethanol used, which can vary from 81% to 85%. It also depends on the octane rating of the gasoline used to make E85.

HEAT ENERGY OF E85 E85 has less heat energy than gasoline.

Gasoline = 114,000 BTUs per gallon

E85 = 87,000 BTUs per gallon

FIGURE 67–2 Some retail stations offer a variety of fuel choices, such as this station in Ohio where E10 and E85 are available.

This means that the fuel economy is reduced by 20% to 30% if E85 is used instead of gasoline.

Example: A Chevrolet Tahoe 5.3-liter V-8 with an automatic transmission has an EPA rating of 15 mpg in the city and 20 mpg on the highway when using gasoline. If this same vehicle was fueled with E85, the EPA fuel economy rating drops to 11 mpg in the city and 15 mpg on the highway.

ALTERNATIVE-FUEL VEHICLES

The 15% gasoline in this blend helps the engine start, especially in cold weather. Vehicles equipped with this capability are commonly referred to as **alternative-fuel vehicles (AFVs), flex fuels,** and **flexible fuel vehicles,** or **FFVs.** Using E85 in a flex-fuel vehicle can result in a power increase of about 5%. For example, an engine rated at 200 hp using gasoline or E10 could produce 210 hp if using E85.

NOTE: E85 may test as containing less than 85% ethanol if tested in cold climates because it is often blended according to outside temperature. A lower percentage of ethanol with a slightly higher percentage of gasoline helps engines start in cold climates.

These vehicles are equipped with an electronic sensor in the fuel supply line that detects the presence and percentage of ethanol. The PCM then adjusts the fuel injector on-time and ignition timing to match the needs of the fuel being used.

E85 contains less heat energy, and therefore will use more fuel, but the benefits include a lower cost of the fuel and the environmental benefit associated with using an oxygenated fuel.

General Motors, Ford, Chrysler, Mazda, and Honda are a few of the manufacturers offering E85 compatible vehicles. E85 vehicles use fuel system parts designed to withstand the additional alcohol content, modified driveability programs that adjust fuel delivery and timing to compensate for the various percentages of ethanol fuel, and a **fuel compensation sensor** that measures both the percentage of ethanol blend and the temperature of the fuel. This sensor is also called a **variable fuel sensor.** ● **SEE FIGURES 67–3 AND 67–4.**

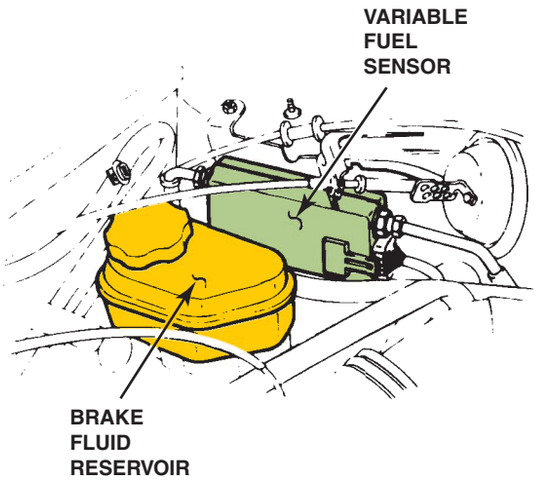

FIGURE 67–3 The location of the variable fuel sensor can vary, depending on the make and model of vehicle, but it is always in the fuel line between the fuel tank and the fuel injectors.

TECH TIP

Purchase a Flex-Fuel Vehicle

If purchasing a new or used vehicle, try to find a flex-fuel vehicle. Even though you may not want to use E85, a flex-fuel vehicle has a more robust fuel system than a conventional fuel system designed for gasoline or E10. The enhanced fuel system components and materials usually include:

- Stainless steel fuel rail
- Graphite commutator bars instead of copper in the fuel pump motor (ethanol can oxidize into acetic acid, which can corrode copper)
- Diamond-like carbon (DLC) corrosion-resistant fuel injectors
- Alcohol-resistant O-rings and hoses

The cost of a flex-fuel vehicle compared with the same vehicle designed to operate on gasoline is a no-cost or a low-cost option.

E85 FUEL SYSTEM REQUIREMENTS

Most E85 vehicles are very similar to non-E85 vehicles. Fuel system components may be redesigned to withstand the effects of higher concentrations of ethanol. In addition, since the stoichiometric point for ethanol is 9:1 instead of 14.7:1 as for gasoline, the air-fuel mixture has to be adjusted for the percentage of ethanol present in the fuel tank. In order to determine this percentage of ethanol in the fuel tank, a compensation sensor is used. The fuel compensation sensor is the only additional piece of hardware required on some E85 vehicles. The fuel compensation sensor provides both the ethanol percentage and the fuel temperature to the PCM. The PCM uses this information to adjust both the ignition timing and the quantity of fuel delivered to the engine. The fuel compensation sensor uses a microprocessor to measure both the ethanol percentage and the fuel temperature. This information is sent to the PCM on the signal circuit. The compensation sensor produces a square wave frequency and pulse width signal. The normal frequency range of the fuel compensation sensor is 50 hertz, which represents 0% ethanol and 150 hertz, which represents 100% ethanol. The pulse width of the signal varies from 1 millisecond to 5 milliseconds. One millisecond would represent a fuel temperature of −40°F (−40°C), and 5 milliseconds would represent a fuel temperature of 257°F (125°C). Since the PCM knows both the fuel temperature and the ethanol percentage of the fuel, it can adjust fuel quantity and ignition timing for optimum performance and emissions.

The benefits of E85 vehicles are less pollution, less CO_2 production, and less dependence on oil. ● **SEE FIGURE 67–5.**

Ethanol-fueled vehicles generally produce the same pollutants as gasoline vehicles; however, they produce less CO and CO_2 emissions. While CO_2 is not considered a pollutant, it is thought to lead to global warming and is called a greenhouse gas.

FREQUENTLY ASKED QUESTION

How Does a Sensorless Flex-Fuel System Work?

Many General Motors flex-fuel vehicles do not use a fuel compensation sensor and instead use the oxygen sensor to detect the presence of the lean mixture and the extra oxygen in the fuel.

The powertrain control module (PCM) then adjusts the injector pulse-width and the ignition timing to optimize engine operation to the use of E85. This type of vehicle is called a **virtual flexible fuel vehicle,** abbreviated **V-FFV.** The virtual flexible fuel vehicle can operate on pure gasoline or blends up to 85% ethanol.

TECH TIP

Avoid Resetting Fuel Compensation

Starting in 2006, General Motors vehicles designed to operate on E85 do not use a fuel compensation sensor, but instead use the oxygen sensor and refueling information to calculate the percentage of ethanol in the fuel. The PCM uses the fuel level sensor to sense that fuel has been added and starts to determine the resulting ethanol content by using the oxygen sensor. However, if a service technician were to reset fuel compensation by clearing long-term fuel trim, the PCM starts the calculation based on base fuel, which is gasoline with less than or equal to 10% ethanol (E10). If the fuel tank has E85, then the fuel compensation cannot be determined unless the tank is drained and refilled with base fuel. Therefore, avoid resetting the fuel compensation setting unless it is known that the fuel tank contains gasoline or E10 only.

FREQUENTLY ASKED QUESTION

How Long Can Oxygenated Fuel Be Stored Before All of the Oxygen Escapes?

The oxygen in oxygenated fuels, such as E10 and E85, is not in a gaseous state like the CO_2 in soft drinks. The oxygen is part of the molecule of ethanol or other oxygenates and does not bubble out of the fuel. Oxygenated fuels, just like any fuel, have a shelf life of about 90 days.

METHANOL

METHANOL TERMINOLOGY

Methanol, also known as *methyl alcohol*, *wood alcohol*, or *methyl hydrate,* is a chemical compound formula that includes one carbon atom and four hydrogen atoms and one oxygen. ● **SEE FIGURE 67–8.**

Methanol is a light, volatile, colorless, tasteless, flammable, poisonous liquid with a very faint odor. It is used as an antifreeze, a solvent, and a fuel. Methanol burns in air, forming CO_2 (carbon dioxide)

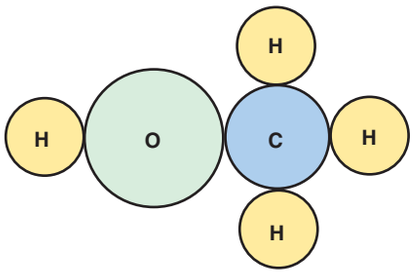

FIGURE 67–8 The molecular structure of methanol showing the one carbon atom, four hydrogen atoms, and one oxygen atom.

FIGURE 67–9 Sign on methanol pump shows that methyl alcohol is a poison and can cause skin irritation and other personal injury. Methanol is used in industry as well as being a fuel.

and H_2O (water). A methanol flame is almost colorless. Because of its poisonous properties, methanol is also used to denature ethanol. Methanol is often called wood alcohol because it was once produced chiefly as a by-product of the destructive distillation of wood. ● **SEE FIGURE 67–9.**

PRODUCTION OF METHANOL The biggest source of methanol in the United States is coal. Using a simple reaction between coal and steam, a gas mixture called **syn-gas** (*synthesis gas*) is formed. The components of this mixture are carbon monoxide and hydrogen, which, through an additional chemical reaction, are converted to methanol.

Natural gas can also be used to create methanol and is reformed or converted to synthesis gas, which is later made into methanol.

Biomass can be converted to synthesis gas by a process called partial oxidation, and later converted to methanol. **Biomass** is organic material, such as:

- Urban wood wastes
- Primary mill residues
- Forest residues
- Agricultural residues
- Dedicated energy crops (e.g., sugarcane and sugar beets) that can be made into fuel

Electricity can be used to convert water into hydrogen, which is then reacted with carbon dioxide to produce methanol.

Methanol is toxic and can cause blindness and death. It can enter the body by ingestion, inhalation, or absorption through the skin. Dangerous doses will build up if a person is regularly exposed to fumes or handles liquid without skin protection. If methanol has been ingested, a doctor should be contacted immediately. The usual fatal dose is 4 fl oz (100 to 125 mL).

FIGURE 67–10 Propane fuel storage tank in the trunk of a Ford taxi.

M85 Some flexible fuel vehicles are designed to operate on 85% methanol and 15% gasoline called **M85.** Methanol is very corrosive and requires that the fuel system components be constructed of stainless steel and other alcohol-resistant rubber and plastic components. The heat content of M85 is about 60% of that of gasoline.

PROPANE

Propane is the most widely used of all of the alternative fuels. Propane is normally a gas but is easily compressed into a liquid and stored in inexpensive containers. When sold as a fuel, it is also known as **liquefied petroleum gas (LPG)** or **LP-gas** because the propane is often mixed with about 10% of other gases such as butane, propylene, butylenes, and mercaptan to give the colorless and odorless propane a smell. Propane is nontoxic, but if inhaled can cause asphyxiation through lack of oxygen. Propane is heavier than air and lays near the floor if released into the atmosphere. Propane is commonly used in forklifts and other equipment used inside warehouses and factories because the exhaust from the engine using propane is not harmful. Propane is a by-product of petroleum refining of natural gas. In order to liquefy the fuel, it is stored in strong tanks at about 300 PSI (2,000 kPa). The heating value of propane is less than that of gasoline; therefore, more is required, which reduces the fuel economy. ● **SEE FIGURE 67–10.**

COMPRESSED NATURAL GAS

CNG VEHICLE DESIGN Another alternative fuel that is often used in fleet vehicles is **compressed natural gas,** or **CNG,** and vehicles using this fuel are often referred to as **natural gas vehicles (NGVs).** Look for the blue CNG label on vehicles designed to operate on compressed natural gas. ● **SEE FIGURE 67–11.**

Natural gas has to be compressed to about 3,000 PSI (20,000 kPa) or more, so that the weight and the cost of the

FIGURE 67–11 The blue sticker on the rear of this vehicle indicates that it is designed to use compressed natural gas.

Honda specifies that three technicians be used to remove or install the tank through the rear door of the vehicle due to the size and weight of the tank.

storage container is a major factor when it comes to preparing a vehicle to run on CNG. The tanks needed for CNG are typically constructed of 0.5-inch-thick (3 mm) aluminum reinforced with fiberglass. ● **SEE FIGURE 67–12.** The octane rating of CNG is about 130 and the cost per gallon is about half of the cost of gasoline. However, the heat value of CNG is also less, and therefore more is required to produce the same power and the miles per gallon is less.

CNG COMPOSITION Compressed natural gas is made up of a blend of:

- Methane
- Propane
- Ethane
- N-butane
- Carbon dioxide
- Nitrogen

Once it is processed, it is at least 93% methane. Natural gas is nontoxic, odorless, and colorless in its natural state. It is odorized during processing, using ethyl mercaptan (“skunk”), to allow for easy leak detection. Natural gas is lighter than air and will rise when released into the air. Since CNG is already a vapor, it does not need heat to vaporize before it will burn, which improves cold start-up and

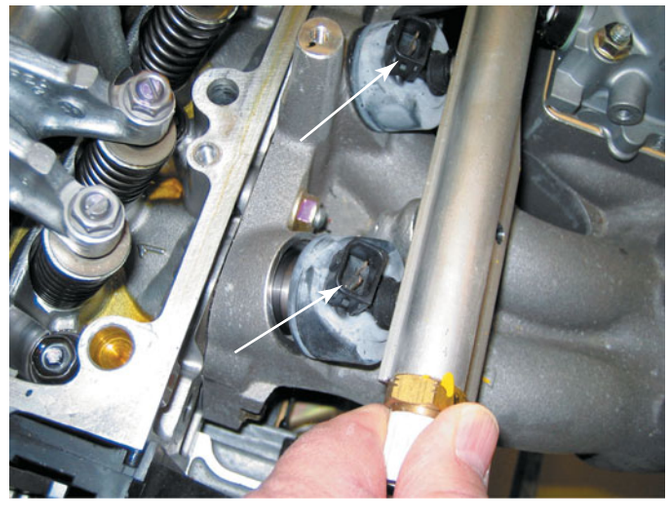

FIGURE 67–13 The fuel injectors used on this Honda Civic GX CNG engine are designed to flow gaseous fuel instead of liquid fuel and cannot be interchanged with any other type of injector.

? FREQUENTLY ASKED QUESTION

What Is the Amount of CNG Equal to in Gasoline?

To achieve the amount of energy of one gallon of gasoline, 122 cubic feet of compressed natural gas (CNG) is needed. While the octane rating of CNG is much higher than gasoline (130 octane), using CNG instead of gasoline in the same engine would result in a reduction of 10% to 20% of power due to the lower heat energy that is released when CNG is burned in the engine.

results in lower emissions during cold operation. However, because it is already in a gaseous state, it does displace some of the air charge in the intake manifold. This leads to about a 10% reduction in engine power as compared to an engine operating on gasoline. Natural gas also burns slower than gasoline; therefore, the ignition timing must be advanced more when the vehicle operates on natural gas. The stoichiometric ratio, the point at which all the air and fuel is used or burned is 16.5:1 compared to 14.7:1 for gasoline. This means that more air is required to burn one pound of natural gas than is required to burn one pound of gasoline. ● **SEE FIGURE 67–13.**

The CNG engine is designed to include:

- Increased compression ratio
- Strong pistons and connecting rods
- Heat-resistant valves
- Fuel injectors designed for gaseous fuel instead of liquid fuel

CNG FUEL SYSTEMS When completely filled, the CNG tank has 3,600 PSI of pressure in the tank. When the ignition is turned on, the alternate fuel electronic control unit activates the high-pressure lock-off, which allows high-pressure gas to pass to the high-pressure regulator. The high-pressure regulator reduces the high-pressure CNG to approximately 170 PSI and sends it to the low-pressure lock-off. The low-pressure lock-off is also controlled by the alternate fuel electronic control unit and is activated at the same time that the high-pressure lock-off is activated. From the low-pressure lock-off, the CNG is directed to the low-pressure regulator. This is a two-stage regulator that first reduces the pressure to approximately 4 to 6 PSI in the first stage and then to 4.5 to 7 inches

FIGURE 67–14 This CNG pump is capable of supplying compressed natural gas at either 3,000 PSI or 3,600 PSI. The price per gallon is higher for the higher pressure.

of water in the second stage. Twenty-eight inches of water is equal to 1 PSI, therefore, the final pressure of the natural gas entering the engine is very low. From here, the low-pressure gas is delivered to the gas mass sensor/mixture control valve. This valve controls the air-fuel mixture. The CNG gas distributor adapter then delivers the gas to the intake stream.

CNG vehicles are designed for fleet use that usually have their own refueling capabilities. One of the drawbacks to using CNG is the time that it takes to refuel a vehicle. The ideal method of refueling is the slow fill method. The slow filling method compresses the natural gas as the tank is being fueled. This method ensures that the tank will receive a full charge of CNG; however, this method can take three to five hours to accomplish. If more than one vehicle needs filling, the facility will need multiple CNG compressors to refuel the vehicles.

There are three commonly used CNG refilling station pressures:

P24—2,400 PSI

P30—3,000 PSI

P36—3,600 PSI

Try to find and use a station with the highest refilling pressure. Filling at lower pressures will result in less compressed natural gas being installed in the storage tank, thereby reducing the driving range. ● **SEE FIGURE 67–14.**

The fast fill method uses CNG that is already compressed. However, as the CNG tank is filled rapidly, the internal temperature of the tank will rise, which causes a rise in tank pressure. Once the temperature drops in the CNG tank, the pressure in the tank also drops, resulting in an incomplete charge in the CNG tank. This refueling method may take only about five minutes; however, it will result in an incomplete charge to the CNG tank, reducing the driving range.

LIQUEFIED NATURAL GAS

Natural gas can be turned into a liquid if cooled to below −260°F (−127°C). The natural gas condenses into a liquid at normal atmospheric pressure and the volume is reduced by about 600 times. This means that the natural gas can be more efficiently transported over long distances where no pipelines are present when liquefied.

Because the temperature of liquefied natural gas (LNG) must be kept low, it is only practical for use in short haul trucks where they can be refueled from a central location.

? FREQUENTLY ASKED QUESTION

What Is a Tri-Fuel Vehicle?

In Brazil, most vehicles are designed to operate on ethanol or gasoline or any combination of the two. In this South American country, ethanol is made from sugarcane, is commonly available, and is lower in price than gasoline. Compressed natural gas (CNG) is also being made available so many vehicle manufacturers in Brazil, such as General Motors and Ford, are equipping vehicles to be capable of using gasoline, ethanol, or CNG. These vehicles are called tri-fuel vehicles.

P-SERIES FUELS

P-series alternative fuel is patented by Princeton University and is a non-petroleum- or natural gas-based fuel suitable for use in flexible fuel vehicles or any vehicle designed to operate on E85 (85% ethanol, 15% gasoline). P-series fuel is recognized by the United States Department of Energy as being an alternative fuel, but is not yet available to the public. P-series fuels are blends of the following:

- Ethanol (ethyl alcohol)
- Methyltetrahydrofuron, abbreviated MTHF
- Natural gas liquids, such as pentanes
- Butane

The ethanol and MTHF are produced from renewable feedstocks, such as corn, waste paper, biomass, agricultural waste, and wood waste (scraps and sawdust). The components used in P-type fuel can be varied to produce regular grade, premium grade, or fuel suitable for cold climates. ● **SEE CHART 67–1** for the percentages of the ingredients based on fuel grade.

● **SEE CHART 67–2** for a comparison of the most frequently used alternative fuels.

SYNTHETIC FUELS

Synthetic fuels can be made from a variety of products, using several different processes. Synthetic fuel must, however, make these alternatives practical only when conventional petroleum products are either very expensive or not available.

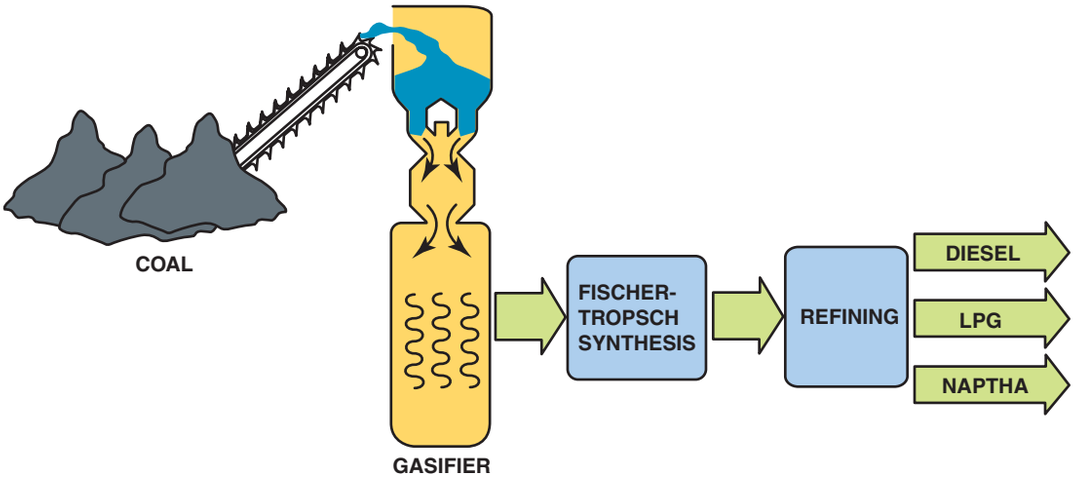

FIGURE 67–15 A Fischer-Tropsch processing plant is able to produce a variety of fuels from coal.

FISCHER-TROPSCH

Synthetic fuels were first developed using the **Fischer-Tropsch** method and have been in use since the 1920s to convert coal, natural gas, and other fossil fuel products into a fuel that is high in quality and clean-burning. The process for producing Fischer-Tropsch fuels was patented by two German scientists, Franz Fischer and Hans Tropsch, during World War I. The Fischer-Tropsch method uses carbon monoxide and hydrogen (the same synthesis gas used to produce hydrogen fuel) to convert coal and other hydrocarbons to liquid fuels in a process similar to hydrogenation, another method for hydrocarbon conversion. The process using natural gas, also called **gas-to-liquid (GTL)** technology, uses a catalyst, usually iron or cobalt, and incorporates steam re-forming to give off the by-products of carbon dioxide, hydrogen, and carbon monoxide. ● **SEE FIGURE 67–15.**

Whereas traditional fuels emit environmentally harmful particulates and chemicals, namely sulfur compounds, Fischer-Tropsch fuels combust with no soot or odors and emit only low levels of toxins. Fischer-Tropsch fuels can also be blended with traditional transportation fuels with little equipment modification, as they use the same engine and equipment technology as traditional fuels.

The fuels contain a very low sulfur and aromatic content and they produce virtually no particulate emissions. Researchers also expect reductions in hydrocarbon and carbon monoxide emissions. Fischer-Tropsch fuels do not differ in fuel performance from gasoline and diesel. At present, Fischer-Tropsch fuels are very expensive to produce on a large scale, although research is under way to lower processing costs. Diesel fuel created using the Fischer-Tropsch diesel (**FTD**) process is often called *GTL diesel*. GTL diesel can also be combined with petroleum diesel to produce a GTL blend. This fuel product is currently being sold in Europe and plans are in place to introduce it in North America.

COAL TO LIQUID (CTL)

Coal is very abundant in the United States and coal can be converted to a liquid fuel through a process called **coal to liquid (CTL).** The huge cost is the main obstacle to these plants. The need to invest $1.4 billion per plant before it can make

product is the reason no one has built a CTL plant yet in the United States. Investors need to be convinced that the cost of oil is going to remain high in order to get them to commit this kind of money.

A large plant might be able to produce 120,000 barrels of liquid fuel a day and would consume about 50,000 tons of coal per day. However, such a plant would create about 6,000 tons of CO_2 per day. These CO_2 emissions, which could contribute to global warming, and the cost involved make CTL a technology that is not likely to expand.

Two procedures can be used to convert coal-to-liquid fuel:

1. **Direct.** In the direct method, coal is broken down to create liquid products. First the coal is reacted with hydrogen (H_2) at high temperatures and pressure with a catalyst. This process creates a synthetic crude, called **syncrude,** which is then refined to produce gasoline or diesel fuel.
2. **Indirect.** In the indirect method, coal is first turned into a gas and the molecules are reassembled to create the desired product. This process involves turning coal into a gas called syn-gas. The syn-gas is then converted into liquid, using the Fischer-Tropsch (FT) process.

Russia has been using CTL by injecting air into the underground coal seams. Ignition is provided and the resulting gases are trapped and converted to liquid gasoline and diesel fuel through the Fischer-Tropsch process. This underground method is called **underground coal gasification (UCG).**

METHANOL TO GASOLINE

Exxon Mobil has developed a process for converting methanol (methyl alcohol) into gasoline in a process called **methanol-to-gasoline (MTG).** The MTG process was discovered by accident when a gasoline additive made from methanol was being created. The process instead created olefins (alkenes), paraffins (alkenes), and aromatic compounds, which in combination are known as gasoline. The process uses a catalyst and is currently being produced in New Zealand.

FUTURE OF SYNTHETIC FUELS

Producing gasoline and diesel fuels by other methods besides refining from crude oil has usually been more expensive. With the increasing cost of crude oil, alternative methods are now becoming economically feasible. Whether or not the diesel fuel or gasoline is created from coal, natural gas, or methanol, or created by refining crude oil, the transportation and service pumps are already in place. Compared to using compressed natural gas or other similar alternative fuels, synthetic fuels represent the lowest cost.

SAFETY PROCEDURES WHEN WORKING WITH ALTERNATIVE FUELS

All fuels are flammable and many are explosive under certain conditions. Whenever working around compressed gases of any kind (CNG, LNG, propane, or LPG), always wear personal protective equipment (PPE), including at least the following items:

1. Safety glasses and/or face shield.
2. Protective gloves.
3. Long-sleeved shirt and pants to help protect bare skin from the freezing effects of gases under pressure in the event that the pressure is lost.
4. If any fuel gets on the skin, the area should be washed immediately.
5. If fuel spills on clothing, change into clean clothing as soon as possible.
6. If fuel spills on a painted surface, flush the surface with water and air dry. If simply wiped off with a dry cloth, the paint surface could be permanently damaged.
7. As with any fuel-burning vehicle, always vent the exhaust to the outside. If methanol fuel is used, the exhaust contains *formaldehyde*, which has a sharp odor and can cause severe burning of the eyes, nose, and throat.

WARNING

Do not smoke or have an open flame in the area when working around or refueling any vehicle.

DIESEL FUEL

FEATURES OF DIESEL FUEL

Diesel fuel must meet an entirely different set of standards than gasoline. Diesel fuel contains 12% more heat energy than the same amount of gasoline. The fuel in a diesel engine is not ignited with a spark, but is ignited by the heat generated by high compression. The pressure of compression (400 to 700 PSI or 2,800 to 4,800 kPa) generates temperatures of 1,200°F to 1,600°F (700°C to 900°C), which speeds the preflame reaction to start the ignition of fuel injected into the cylinder.

DIESEL FUEL REQUIREMENTS

All diesel fuel must have the following characteristics:

- **Cleanliness.** It is imperative that the fuel used in a diesel engine be clean and free from water. Unlike the case with gasoline engines, the fuel is the lubricant and coolant for the diesel injector pump and injectors. Good-quality diesel fuel contains additives such as oxidation inhibitors, detergents, dispersants, rust preventatives, and metal deactivators.
- **Low-temperature fluidity.** Diesel fuel must be able to flow freely at all expected ambient temperatures. One specification for diesel fuel is its "pour point," which is the temperature below which the fuel would stop flowing.
- **Cloud point** is another concern with diesel fuel at lower temperatures. **Cloud point** is the low-temperature point when the waxes present in most diesel fuels tend to form crystals that can clog the fuel filter. Most diesel fuel suppliers distribute fuel with the proper pour point and cloud point for the climate conditions of the area.

CETANE NUMBER

The cetane number for diesel fuel is the opposite of the octane number for gasoline. The **cetane number** is a measure of the ease with which the fuel can be ignited. The cetane rating of the fuel determines, to a great extent, its ability to start the engine at low temperatures and to provide smooth warm-up and even combustion. The cetane rating of diesel fuel should be between 45 and 50. The higher the cetane rating, the more easily the fuel is ignited.

SULFUR CONTENT

The sulfur content of diesel fuel is very important to the life of the engine. Sulfur in the fuel creates sulfuric

(b)

acid during the combustion process, which can damage engine components and cause piston ring wear. Federal regulations are getting extremely tight on sulfur content to less than 15 parts per million (ppm). High-sulfur fuel contributes to acid rain.

DIESEL FUEL COLOR

Diesel fuel intended for use on the streets and highways is clear or green in color. Diesel fuel to be used on farms and off-road use is dyed red. ● **SEE FIGURE 68–1.**

GRADES OF DIESEL FUEL

American Society for Testing Materials (ASTM) also classifies diesel fuel by volatility (boiling range) into the following grades:

GRADE #1 This grade of diesel fuel has the lowest boiling point and the lowest cloud and pour points, as well as a lower BTU content—less heat per pound of fuel. As a result, grade #1 is suitable for use during low-temperature (winter) operation. Grade #1 produces less heat per pound of fuel compared to grade #2 and may be specified for use in diesel engines involved in frequent changes in load and speed, such as those found in city buses and delivery trucks.

? FREQUENTLY ASKED QUESTION

How Can You Tell If Gasoline Has Been Added to the Diesel Fuel by Mistake?

If gasoline has been accidentally added to diesel fuel and is burned in a diesel engine, the result can be very damaging to the engine. The gasoline can ignite faster than diesel fuel, which would tend to increase the temperature of combustion. This high temperature can harm injectors and glow plugs, as well as pistons, head gaskets, and other major diesel engine components. If contaminated fuel is suspected, first smell the fuel at the filler neck. If the fuel smells like gasoline, then the tank should be drained and refilled with diesel fuel. If the smell test does not indicate a gasoline smell (or any rancid smell), then test a sample for proper API gravity.

NOTE: Diesel fuel designed for on-road use should be green in color. Red diesel fuel (high sulfur) should be found only in off-road or farm equipment.

GRADE #2 This grade has a higher boiling point, cloud point, and pour point as compared with grade #1. It is usually specified where constant speed and high loads are encountered, such as in long-haul trucking and automotive diesel applications. Most diesel is Grade #2.

DIESEL FUEL SPECIFIC GRAVITY TESTING

The density of diesel fuel should be tested whenever there is a driveability concern. The density or specific gravity of diesel fuel is measured in units of **API gravity.** API gravity is an arbitrary scale expressing the gravity or density of liquid petroleum products devised jointly by the American Petroleum Institute and the National Bureau of Standards. The measuring scale is calibrated in terms of degrees API. Oil with the least specific gravity has the highest API gravity. The formula for determining API gravity is as follows:

Degrees API gravity = (141.5 ÷ specific gravity at 60°F) − 131.5

The normal API gravity for #1 diesel fuel is 39 to 44 (typically 40). The normal API gravity for #2 diesel fuel is 30 to 39 (typically 35). A hydrometer calibrated in API gravity units should be used to test diesel fuel. ● **SEE FIGURE 68–2.**

● **SEE CHART 68–1** for a comparison among specific gravity, weight density, pounds per gallon, and API gravity of diesel fuel.

DIESEL FUEL HEATERS

Diesel fuel heaters, either coolant or electric, help prevent power loss and stalling in cold weather. The heater is placed in the fuel line between the tank and the primary filter. Some coolant heaters are thermostatically controlled, which allows fuel to bypass the heater once it has reached operating temperature. ● **SEE FIGURE 68–3.**

ULTRA-LOW-SULFUR DIESEL FUEL

Diesel fuel is used in diesel engines and is usually readily available throughout the United States, Canada, and Europe, where many more cars are equipped with diesel engines. Diesel engines manufactured to 2007 or newer standards must use ultra-low-sulfur diesel fuel containing less than 15 ppm of sulfur compared to the older, low-sulfur specification of 500 ppm. The purpose of the lower sulfur amount in diesel fuel is to

reduce emissions of sulfur oxides (SO_x) and particulate matter (PM) from heavy-duty highway engines and vehicles that use diesel fuel. The emission controls used on 2007 and newer diesel engines require the use of **ultra-low-sulfur diesel (ULSD)** for reliable operation.

Ultra-low-sulfur diesel (ULSD) will eventually replace the current highway diesel fuel, low-sulfur diesel, which can have as much as 500 ppm of sulfur. ULSD is required for use in all model year 2007 and newer vehicles equipped with advanced emission control systems. ULSD looks lighter in color and has less smell than other diesel fuel.

BIODIESEL

DEFINITION OF BIODIESEL

Biodiesel is a domestically produced, renewable fuel that can be manufactured from vegetable oils, animal fats, or recycled restaurant greases. Biodiesel is safe, biodegradable, and reduces serious air pollutants such as particulate matter (PM), carbon monoxide, and hydrocarbons. Biodiesel is

defined as mono-alkyl esters of long-chain fatty acids derived from vegetable oils or animal fats which conform to ASTM D6751 specifications for use in diesel engines. Biodiesel refers to the pure fuel before blending with diesel fuel. ● **SEE FIGURE 68–4.**

BIODIESEL BLENDS Biodiesel blends are denoted as "BXX" with "XX" representing the percentage of biodiesel contained in the blend (i.e., **B20** is 20% biodiesel, 80% petroleum diesel). Blends of 20% biodiesel with 80% petroleum diesel (B20) can generally be used in unmodified diesel engines; however, users should consult their OEM and engine warranty statement. Biodiesel can also be used in its pure form (B100), but it may require certain engine modifications to avoid maintenance and performance problems and may not be suitable for wintertime use. Most diesel engine or vehicle manufacturers of diesel vehicles allow the use of B5 (5% biodiesel). For example, Cummins, used in Dodge trucks, allows the use of B20 only if the optional extra fuel filter has been installed. Users should consult their engine warranty statement for more information on fuel blends of greater than 20% biodiesel.

In general, B20 costs 30 to 40 cents more per gallon than conventional diesel. Although biodiesel costs more than regular diesel fuel, often called **petrodiesel,** fleet managers can make the switch to alternative fuels without purchasing new vehicles, acquiring new spare parts inventories, rebuilding refueling stations, or hiring new service technicians.

FEATURES OF BIODIESEL Biodiesel has the following characteristics:

1. Purchasing biodiesel in bulk quantities decreases the cost of fuel.
2. Biodiesel maintains similar horsepower, torque, and fuel economy.
3. Biodiesel has a higher cetane number than conventional diesel, which increases the engine's performance.
4. It is nontoxic, which makes it safe to handle, transport, and store. Maintenance requirements for B20 vehicles and petrodiesel vehicles are the same.
5. Biodiesel acts as a lubricant and this can add to the life of the fuel system components.

NOTE: For additional information on biodiesel and the locations where it can be purchased, visit www.biodiesel.org.

? FREQUENTLY ASKED QUESTION

I Thought Biodiesel Was Vegetable Oil?

Biodiesel is vegetable oil with the glycerin component removed by means of reacting the vegetable oil with a catalyst. The resulting hydrocarbon esters are 16 to 18 carbon atoms in length, almost identical to the petroleum diesel fuel atoms. This allows the use of biodiesel fuel in a diesel engine with no modifications needed. Biodiesel-powered vehicles do not *need* a second fuel tank, whereas vegetable-oil-powered vehicles do. There are three main types of fuel used in diesel engines. These are:

- Petroleum diesel, a fossil hydrocarbon with a carbon chain length of about 16 carbon atoms.
- Biodiesel, a hydrocarbon with a carbon chain length of 16 to 18 carbon atoms.
- Vegetable oil is a triglyceride with a glycerin component joining three hydrocarbon chains of 16 to 18 carbon atoms each, called **straight vegetable oil (SVO).** Other terms used when describing vegetable oil include:
  - **Pure plant oil (PPO)**—a term most often used in Europe to describe SVO
  - **Waste vegetable oil (WVO)**—this oil could include animal or fish oils from cooking
  - **Used cooking oil (UCO)**—a term used when the oil may or may not be pure vegetable oil

Vegetable oil is not liquid enough at common ambient temperatures for use in a diesel engine fuel delivery system designed for the lower-viscosity petroleum diesel fuel. Vegetable oil needs to be heated to obtain a similar viscosity to biodiesel and petroleum diesel. This means that a heat source needs to be provided before the fuel can be used in a diesel engine. This is achieved by starting on petroleum diesel or biodiesel fuel until the engine heat can be used to sufficiently warm a tank containing the vegetable oil. It also requires purging the fuel system of vegetable oil with petroleum diesel or biodiesel fuel prior to stopping the engine to avoid the vegetable oil's thickening and solidifying in the fuel system away from the heated tank. The use of vegetable oil in its natural state does, however, eliminate the need to remove the glycerin component. Many vehicle and diesel engine fuel system suppliers permit the use of biodiesel fuel that is certified as meeting testing standards. None permit the use of vegetable oil in its natural state.

E-DIESEL FUEL

DEFINITION OF E-DIESEL **E-diesel,** also called **diesohol** outside of the United States, is standard No. 2 diesel fuel that contains up to 15% ethanol. While E-diesel can have up to 15% ethanol by volume, typical blend levels are from 8% to 10%.

CETANE RATING OF E-DIESEL The higher the cetane number, the shorter the delay between injection and ignition. Normal diesel fuel has a cetane number of about 50. Adding 15% ethanol lowers the cetane number. To increase the cetane number back

to that of conventional diesel fuel, a cetane-enhancing additive is added to E-diesel. The additive used to increase the cetane rating of E-diesel is ethylhexylnitrate or ditertbutyl peroxide.

E-diesel has better cold-flow properties than conventional diesel. The heat content of E-diesel is about 6% less than conventional diesel, but the particulate matter (PM) emissions are reduced by as much as 40%, 20% less carbon monoxide, and a 5% reduction in oxides of nitrogen (NOX).

Currently, E-diesel is considered to be experimental and can be used legally in off-road applications or in mass-transit buses with EPA approval. For additional information, visit www.e-diesel.org.

IGNITION SYSTEM

PURPOSE AND FUNCTION The ignition system includes components and wiring necessary to create and distribute a high voltage (up to 40,000 volts or more) and send to the spark plug at the correct time. A high-voltage arc occurs across the gap of a spark plug inside the combustion chamber. The spark raises the temperature of the air-fuel mixture and starts the combustion process inside the cylinder.

BACKGROUND All ignition systems apply battery voltage (close to 12 volts) to the positive side of the ignition coil(s) and pulse the negative side to ground on and off.

- **Early ignition systems.** Before the mid-1970s, ignition systems used a mechanically opened set of contact points to make and break the electrical connection to ground. A cam lobe, located in and driven by the distributor, opened the points. There was one lobe for each cylinder. The points used a rubbing block that was lubricated by applying a thin layer of grease on the cam lobe at each service interval. Each time the points opened, a spark was created in the ignition coil. The high-voltage spark then traveled to each spark plug through the distributor cap and rotor and the spark plug wires. The distributor was used twice in the creation of the spark.
  - First, it connected to the camshaft that rotated the distributor cam causing the points to open and close.
  - Second, it used a rotor to direct the high-voltage spark from the coil entering the center of the distributor cap to inserts connected to spark plug wires to each cylinder.

  SEE FIGURE 69–1.
- **Electronic ignition.** Since the mid-1970s, ignition systems have used sensors, such as a pickup coil and reluctor (trigger wheel), to trigger or signal an electronic module that switches the primary ground circuit of the ignition coil. **Distributor ignition (DI)** is the term specified by the Society of Automotive Engineers (SAE) for an ignition system that uses a distributor. **Electronic ignition (EI)** is the term specified by the SAE for an ignition system that does not use a distributor. Types of EI systems include:
  1. **Waste-spark system.** This type of system uses one ignition coil to fire the spark plugs for two cylinders at the same time.
  2. **Coil-on-plug system.** This type of system uses a single ignition coil for each cylinder with the coil placed above or near the spark plug.

IGNITION COIL OPERATION In an ignition coil there are two windings:

- Primary winding
- Secondary winding

All ignition systems use electromagnetic induction to produce a high-voltage spark from the ignition coil. Electromagnetic induction means that a current can be created in a conductor (coil winding) by a moving magnetic field. Current flowing through the primary winding of the coil produces the magnetic field in an ignition coil. An ignition coil is able to increase battery voltage to 40,000 volts or more in the following way.

- Battery voltage is applied to the primary winding.
- A ground is provided to the primary winding by the ignition control module (ICM), igniter, or powertrain control module (PCM).

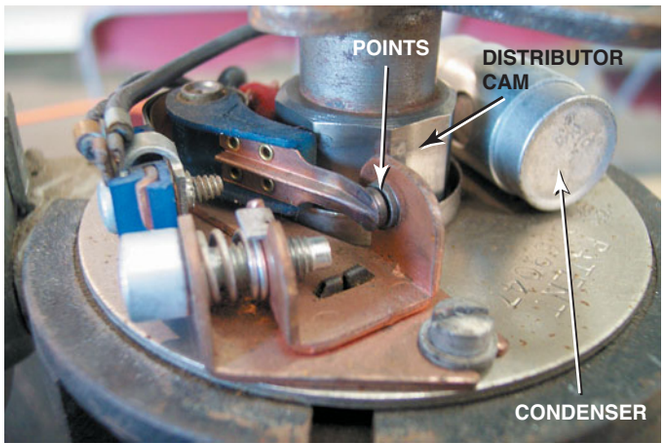

FIGURE 69–1 A point-type distributor from a hot rod being tested on a distributor machine.

- Current (approximately 2 to 6 amperes) flows in the primary coil creating a magnetic field.
- When the ground is opened by the ICM, the primary circuit is turned off and the built-up magnetic field in the secondary winding collapses.
- The movement of the collapsing magnetic field induces a voltage of 250 to 400 volts in the primary winding and 20,000 to 40,000 volts or more in the secondary winding with a current of 0.02 to 0.08 amperes (20 to 80 mA).
- The high voltage created in the secondary winding is high enough to jump the air gap at the spark plug.
- The electrical arc at the spark plug ignites the air-fuel mixture in the combustion chamber of the engine.
- For each spark that occurs, the coil must be charged with a magnetic field and then discharged.

WARNING

The spark from an ignition coil is strong enough to cause physical injury. Always follow the exact service procedure and avoid placing hands near the secondary ignition components when the engine is running.

The ignition components in the coil primary winding are known collectively as the primary ignition circuit.

- When the primary circuit is carrying current, the secondary circuit is off.
- When the primary circuit is turned off, the secondary circuit has high voltage.
- The components necessary to create and distribute the high voltage produced in the secondary windings of the coil are called the secondary ignition circuit. **SEE FIGURE 69–2.**

These circuits include the following components.

- Primary ignition circuit
  1. Battery
  2. Ignition switch
  3. Primary winding of coil
  4. Pickup coil (if distributor ignition)

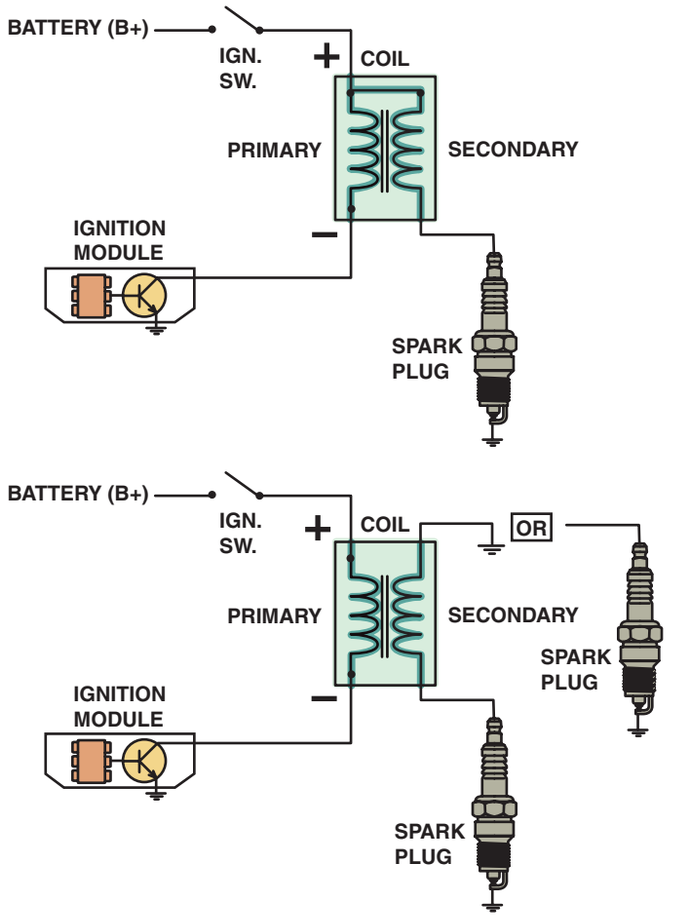

FIGURE 69–2 The primary ignition system is used to trigger and therefore create the secondary (high-voltage) spark from the ignition coil. Some ignition coils are electrically connected, called married (top figure) whereas others use separated primary and secondary windings, called divorced (lower figure).

6. Ignition control module (ICM) or igniter

- Secondary ignition circuit

2. Distributor cap and rotor (if the vehicle is so equipped)

IGNITION COIL CONSTRUCTION Many ignition coils contain two separate but electrically connected windings of copper wire. Other coils are true transformers in which the primary and secondary windings are not electrically connected. ● **SEE FIGURE 69–3.**

The center of an ignition coil contains a core of laminated soft iron (thin strips of soft iron). This core increases the magnetic strength of the coil.

- **Secondary winding.** Surrounding the laminated core are approximately 20,000 turns of fine wire (approximately 42 gauge), which is smaller than a human hair. The winding is called the **secondary** coil winding.
- **Primary winding.** Surrounding the secondary windings are approximately 150 turns of heavy wire (approximately 21 gauge), which is about 0.028 inch in diameter. The winding is called the **primary** coil winding. The secondary winding has about 100 times the number of turns of the primary winding, referred to as the **turns ratio** (approximately 100:1).

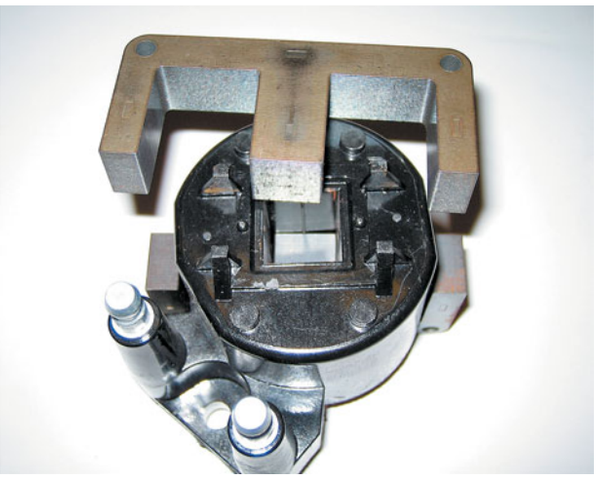

FIGURE 69–3 The steel laminations used in an E coil helps increase the magnetic field strength, which helps the coil produce higher energy output for a more complete combustion in the cylinders.

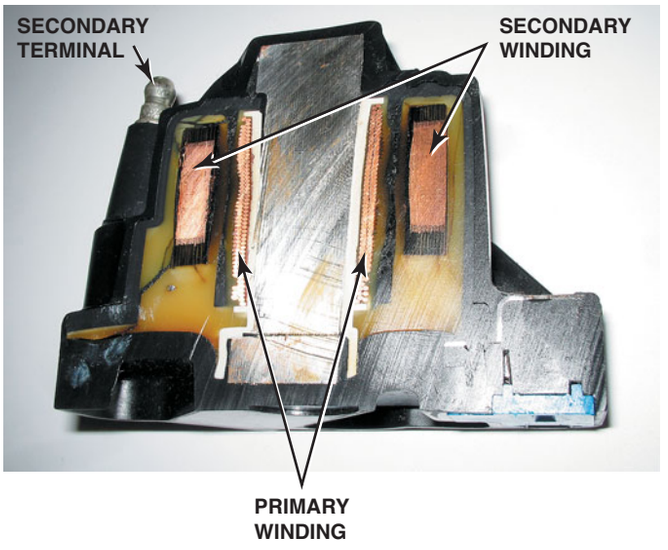

FIGURE 69–4 The primary windings are inside the secondary windings on this General Motors coil.

In older coils, these windings are surrounded with a thin metal shield and insulating paper and placed into a metal container filled with transformer oil to help cool the coil windings. Other coil designs use an air-cooled, epoxy-sealed E coil. The *E coil* is so named because the laminated, soft iron core is E shaped, with the coil wire turns wrapped around the center "finger" of the E and the primary winding wrapped inside the secondary winding. ● **SEE FIGURES 69–4 AND 69–5.**

IGNITION SWITCHING AND TRIGGERING

SWITCHING For any ignition system to function, the primary current must be turned on to charge the coil and off to allow the coil to discharge, creating a high-voltage spark. This turning on and off of the primary circuit is called **switching.** The unit that does the

switching is an electronic switch, such as a power transistor. This power transistor can be located in either of the following locations.

- In the ICM or igniter
- In the PCM (computer)

NOTE: On some coil-on-plug systems, the ICM is part of the ignition coil itself and is serviced as an assembly.

PRIMARY CIRCUIT OPERATION

The device that signals the switching of the coil on and off or just on in most instances is called the **trigger.** A trigger is typically a pickup coil in some distributor-type ignitions and a crankshaft position sensor (CKP) on electronic systems (waste-spark and coil-on-plug systems). To get a spark out of an ignition coil, the primary coil circuit must be turned on and off.

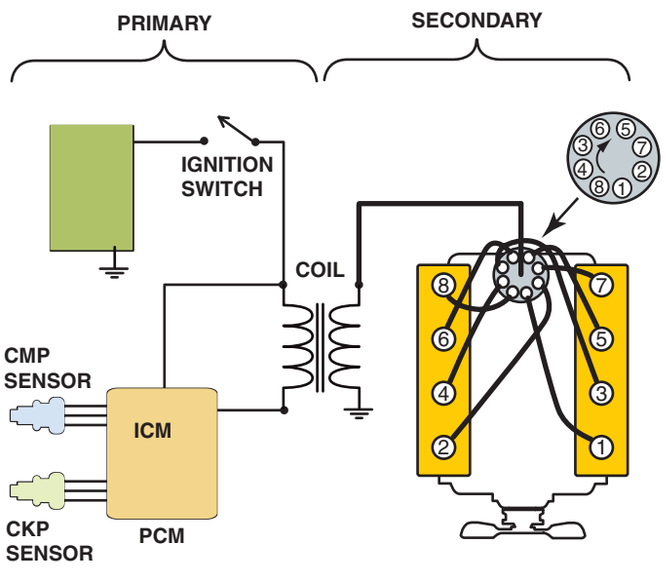

FIGURE 69–5 The primary ignition system is used to trigger and therefore create the secondary (high-voltage) spark from the ignition coil.

The primary circuit current switching is controlled by a **transistor** (electronic switch) inside the ignition module or igniter, and is controlled by one of the following devices.

- **Magnetic sensor.** A simple and common ignition electronic switching device is the magnetic pulse generator system. This type of magnetic sensor is often called a magnetic **pulse generator** or **pickup coil,** and is installed in the distributor housing. The pulse generator consists of a trigger wheel (reluctor) and a pickup coil. The pickup coil consists of an iron core wrapped with fine wire, in a coil at one end and attached to a permanent magnet at the other end. The center of the coil is called the pole piece. The pickup coil signal triggers the transistor inside the module and is also used by the computer for piston position information and engine speed (RPM). The reluctor is shaped so that the magnetic strength changes enough to create a usable varying signal for use by the module to trigger the coil. A magnetic pickup coil produces an analog AC signal. **SEE FIGURE 69–6.**

  Magnetic crankshaft position sensors use the changing strength of the magnetic field surrounding a coil of wire to signal the ICM and PCM. This signal is used by the electronics in the ignition module and computer to determine piston position and engine speed (RPM). This sensor operates similarly to the distributor magnetic pickup coil. The crankshaft position sensor uses the strength of the magnetic field surrounding a coil of wire to signal the ICM. The rotating crankshaft has notches cut into it that trigger the magnetic position sensor, which change the strength of the magnetic field as the notches pass by the position sensor, creating an AC analog signal. **SEE FIGURE 69–7.**

- **Hall-effect switch.** This switch also uses a stationary sensor and rotating trigger wheel (shutter). Unlike the magnetic pulse generator, the Hall-effect switch requires a small input voltage to generate an output or signal voltage. **Hall effect** has the ability to generate a voltage signal in semiconductor material (gallium arsenate crystal) by passing

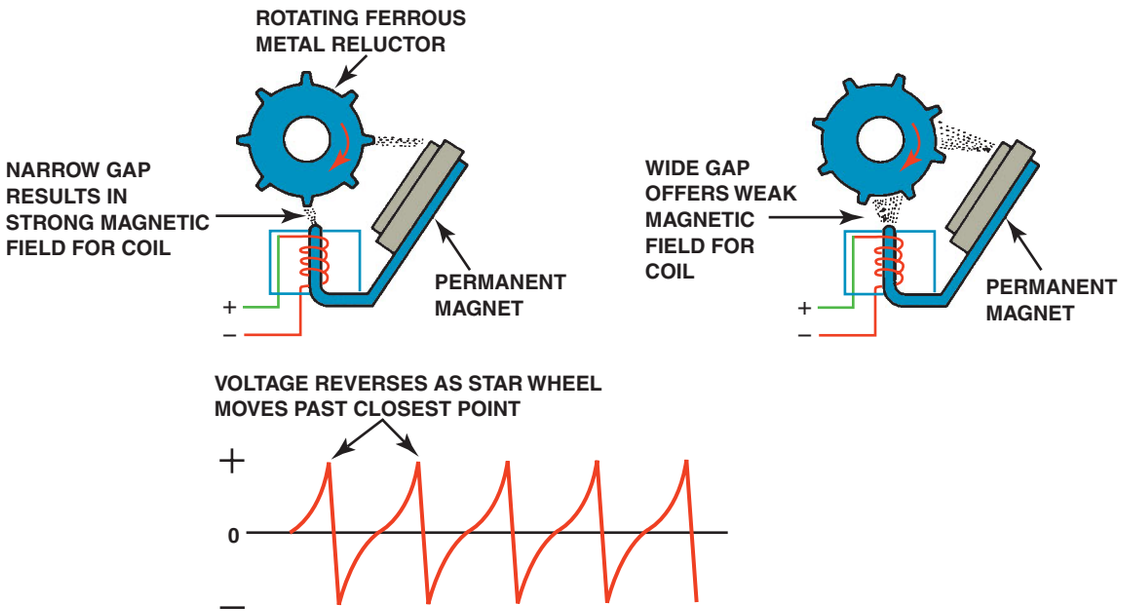

FIGURE 69–6 Operation of a typical pulse generator (pickup coil). At the bottom is a line drawing of a typical scope pattern of the output voltage of a pickup coil. The ICM receives this voltage from the pickup coil and opens the ground circuit to the ignition coil when the voltage starts down from its peak (just as the reluctor teeth start moving away from the pickup coil).

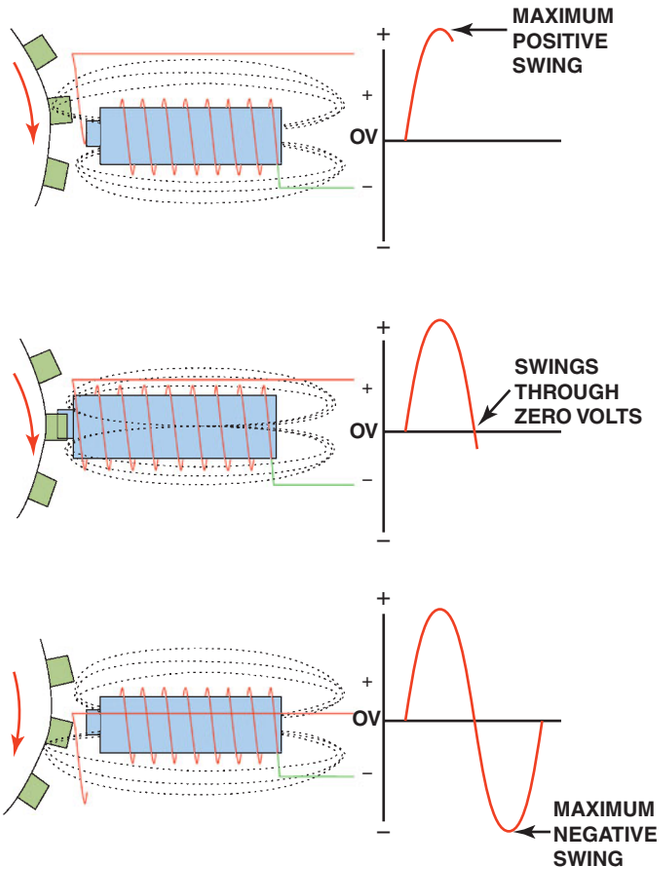

FIGURE 69–7 A magnetic sensor uses a permanent magnet surrounded by a coil of wire. The notches of the crankshaft (or camshaft) create a variable magnetic field strength around the coil. current through it in one direction and applying a magnetic field to it at a right angle to its surface. If the input current is held steady and the magnetic field fluctuates, an output voltage is produced that changes in proportion to field strength. Most Hall-effect switches used in distributors have the following:

1. Hall element or device
2. Permanent magnet
3. Rotating ring of metal blades (shutters) similar to a trigger wheel (Another method uses a stationary sensor with a rotating magnet.) ● **SEE FIGURE 69–8**.

Some blades are designed to hang down, typically found in Bosch and Chrysler systems; others may be on a separate ring on the distributor shaft, typically found in General Motors and Ford Hall-effect distributors.

- When the shutter blade enters the gap between the magnet and the Hall element, it creates a magnetic shunt that changes the field strength through the Hall element.
- This analog signal is sent to a **Schmitt trigger** inside the sensor itself, which converts the analog signal into a digital signal. A digital (on or off) voltage signal is created at a varying frequency to the ignition module or onboard computer. ● **SEE FIGURE 69–9.**
- **Optical sensors.** This type of sensor uses light from an LED and a phototransistor to signal the computer. An interrupter disc between the LED and the phototransistor has slits that allow the light from the LED to trigger the phototransistor on the other side of the disc. Most optical sensors (usually located inside the distributor) use two rows of slits to provide individual cylinder recognition (low-resolution) and precise distributor angle recognition (high-resolution) signals that are used for cylinder misfire detection. ● **SEE FIGURE 69–10.**

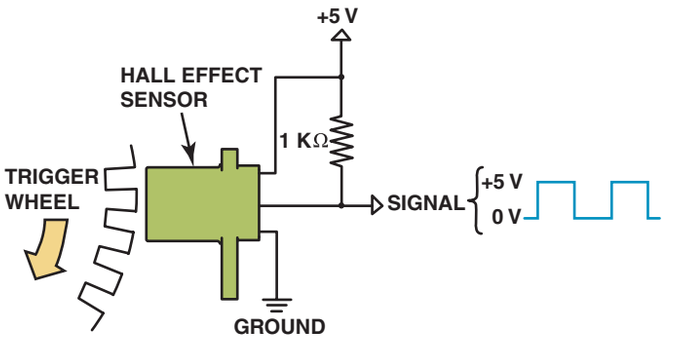

FIGURE 69–8 A Hall-effect sensor produces an on-off voltage signal whether it is used with a blade or a notched wheel.

TECH TIP

The Tachometer Trick

When diagnosing a no-start or intermediate misfiring condition, check the operation of the tachometer. If the tachometer does not indicate engine speed (no-start condition) or drops toward zero (engine missing), then the problem is due to a defect in the *primary* ignition circuit. The tachometer gets its signal from the pulsing of the primary winding of the ignition coil. The following components in the primary circuit could cause the tachometer to not work when the engine is cranking.

- Pickup coil
- Crankshaft position (CKP) sensor
- Ignition control module (ICM) or igniter
- Coil primary wiring

If the vehicle is not equipped with a tachometer, use a scan tool to look at engine RPM. Results:

- No or an unstable engine RPM reading means the problem is in the primary ignition circuit.
- A steady engine RPM reading means the problem is in the secondary ignition circuit or is a fuel-related problem.

DISTRIBUTOR IGNITION

PURPOSE AND FUNCTION The purpose of a distributor is to distribute the high-voltage spark from the secondary terminal of the ignition coil to the spark plugs for each cylinder. A gear or shaft that is part of the distributor is meshed with a gear on the camshaft. The distributor is driven at camshaft speed (one-half of crankshaft speed).

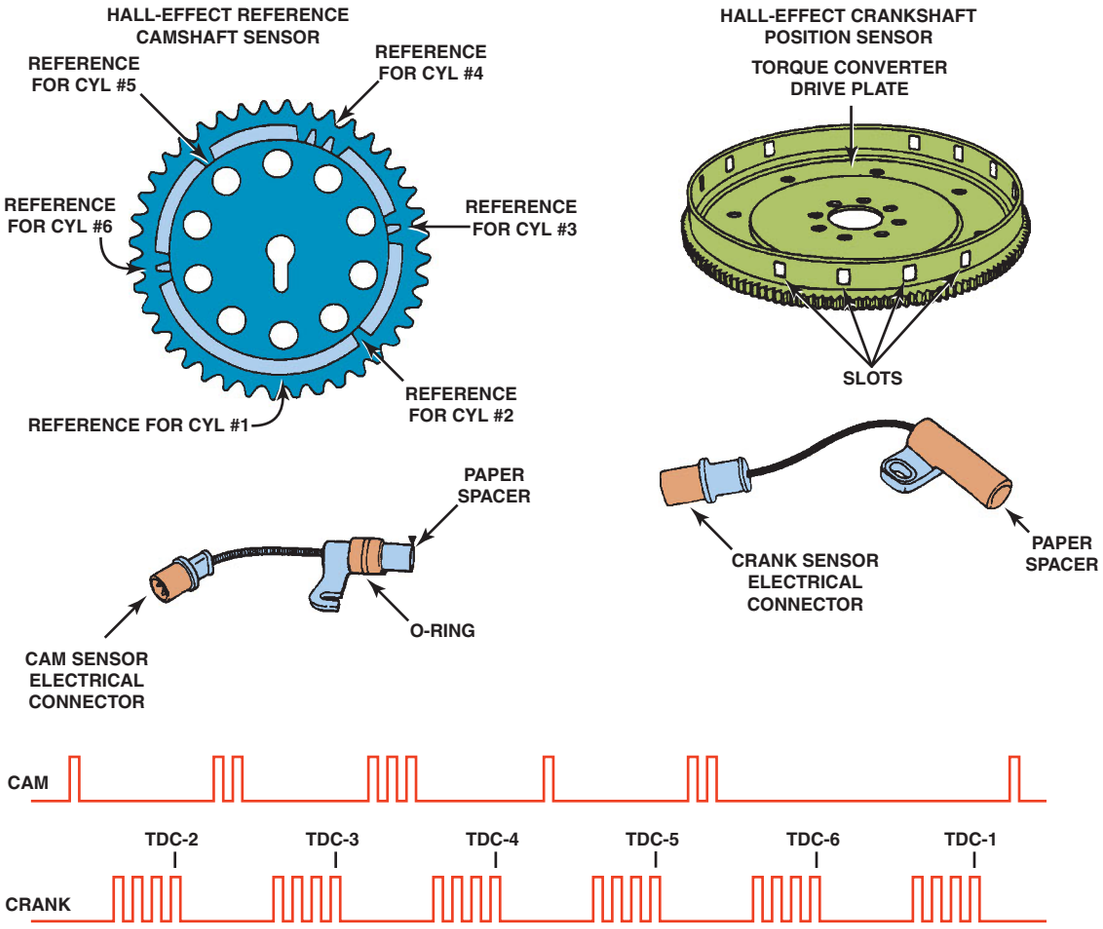

FIGURE 69–9 Some Hall-effect sensors look like magnetic sensors. This Hall-effect camshaft reference sensor and crankshaft position sensor have an electronic circuit built in that creates a 0 to 5 volt signal as shown at the bottom. These Hall-effect sensors have three wires: a power supply (8 volts) from the computer (controller), a signal (0 to 5 volts), and a signal ground.

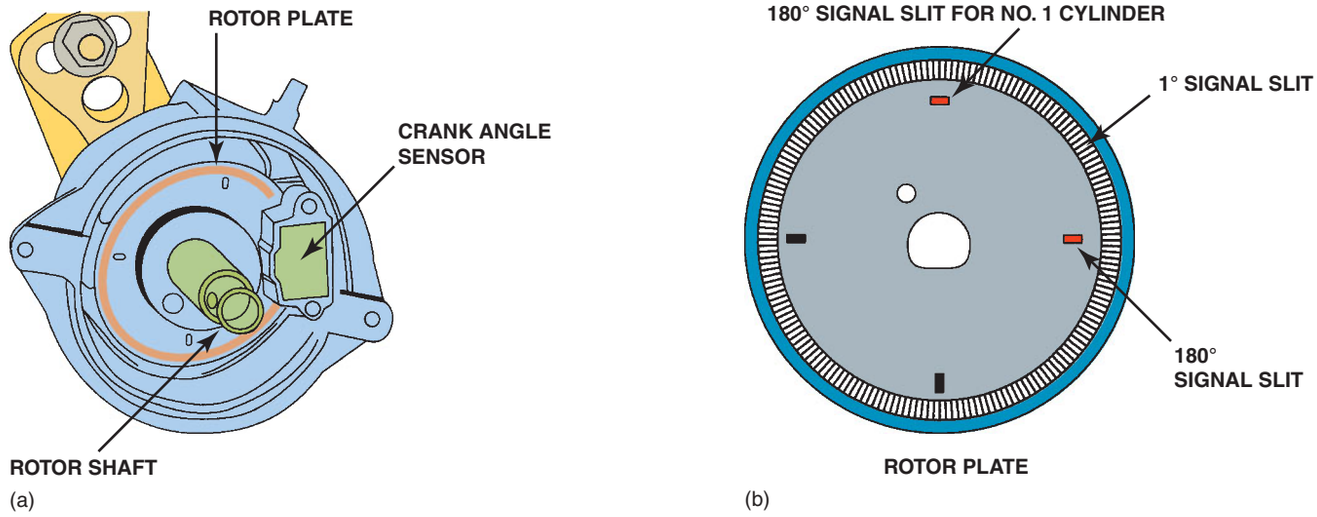

FIGURE 69–10 (a) Typical optical distributor. (b) Cylinder I slit signals the computer the piston position for cylinder I. The 1-degree slits provide accurate engine speed information to the PCM.

Most distributor ignition systems also use a sensor to trigger the ignition control module.

OPERATION OF DISTRIBUTOR IGNITION

The distributor is used twice in most ignition systems that use one.

- The first time is when the **low voltage** triggers the ignition control module (ICM) by the use of the rotating distributor shaft.
- The second time is when the **high voltage** is directed by rotating the rotor to distribute the high-voltage spark to the individual spark plugs.

FIRING ORDER

Firing order means the order that the spark is distributed to the correct spark plug at the right time. The firing order of an engine is determined by crankshaft and camshaft

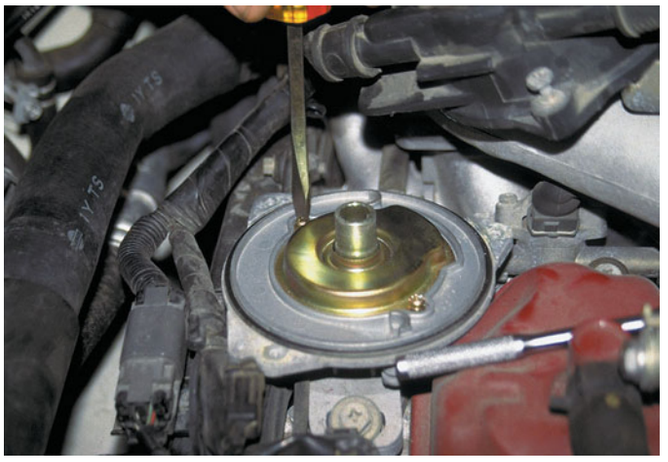

FIGURE 69–11 A light shield being installed before the rotor is attached.

FIGURE 69–12 The firing order is cast or stamped on the intake manifold on most engines that have a distributor ignition.

TECH TIP

Optical Distributors Do Not Like Light

Optical distributors use the light emitted from LEDs to trigger phototransistors. Most optical distributors use a shield between the distributor rotor and the optical interrupter ring. Sparks jump the gap from the rotor tip to the distributor cap inserts. This shield blocks the light from the electrical arcs from interfering with the detection of the light from the LEDs.

If this shield is not replaced during service, the light signals are reduced and the engine may not operate correctly. ● **SEE FIGURE 69–11.**

This can be difficult to detect because nothing looks wrong during a visual inspection. Remember that all optical distributors must be shielded between the rotor and the interrupter ring.

design and the location of the spark plug wires in the distributor cap of an engine equipped with a distributor. The firing order is often cast into the intake manifold for easy reference. ● **SEE FIGURE 69–12.**

Service information also shows the firing order and the direction of the distributor rotor rotation, engine cylinder numbering, and the location of the spark plug wires on the distributor cap.

CAUTION: Ford V-8s use two different firing orders depending on whether the engine is high output (HO) or standard. Using the incorrect firing order can cause the engine to backfire and could cause engine damage or personal injury. General Motors V-6 engines use different firing orders and different locations for cylinder 1 between the 60-degree V-6 and the 90-degree V-6. Using the incorrect firing order or cylinder number location chart could result in poor engine operation or a no-start condition. Firing order is also important for waste-spark-type ignition systems. The spark plug wire can often be installed on the wrong coil pack which can create a no-start condition or poor engine operation.

WASTE-SPARK IGNITION SYSTEMS

PARTS INVOLVED

Waste-spark ignition is another name for the **distributorless ignition system (DIS)** or electronic ignition (EI). Waste-spark ignition was introduced in the mid-1980s and uses the ignition control module (ICM) and/or the powertrain control module (PCM) to fire the ignition coils. A 4-cylinder engine uses two ignition coils and a 6-cylinder engine uses three ignition coils. Each coil is a true transformer because the primary winding and secondary winding are not electrically connected. A waste-spark coil has four terminals:

- Two primary (Bat + and − to ICM)
- Two secondary (each connected to a spark plug)

Each end of the secondary winding is connected to the spark plug of the cylinder exactly opposite the other in the firing order, called a **companion (paired) cylinder.** ● **SEE FIGURE 69–13.**

WASTE-SPARK SYSTEM OPERATION

Both spark plugs fire at the same time (within nanoseconds of each other).

- When one cylinder (for example, cylinder number 6) is on the compression stroke, the other cylinder (number 3) is on the exhaust stroke.
- The spark that occurs on the exhaust stroke is called the waste spark, because it does no useful work and is only used as a ground path for the secondary winding of the ignition coil. The voltage required to jump the spark plug gap on cylinder 3 (the exhaust stroke) is only 2 to 3 kV.
- The cylinder on the compression stroke uses the remaining coil energy.
- One spark plug of each pair always fires straight polarity (from the center electrode to the ground electrode of the spark plug) and the other cylinder always fires reverse polarity (from the ground electrode to the center electrode of the spark plug). Spark plug life is not greatly affected by the reverse polarity. If there is only one defective spark plug wire or spark plug, two cylinders may be affected.

The coil polarity is determined by the direction the coil is wound (left-hand rule for conventional current flow) and cannot be changed.

For example, if a V-6 engine has a firing order of 165432 when one cylinder is on compression, such as cylinder number 1, then the paired cylinder (number 4) is on the exhaust stroke. During the next

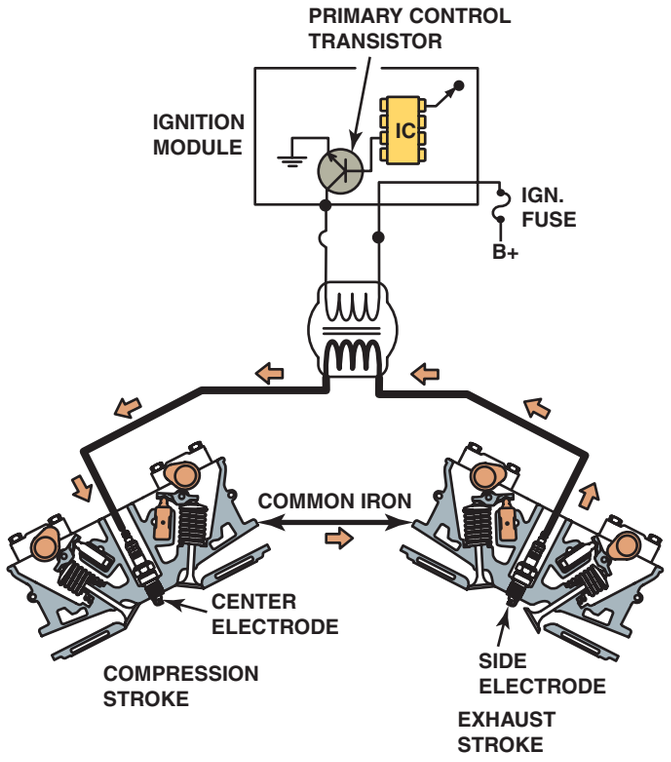

FIGURE 69–13 A waste-spark system fires one cylinder while its piston is on the compression stroke and into paired or companion cylinders while it is on the exhaust stroke. In a typical engine, it requires only about 2 to 3 kV to fire the cylinder on the exhaust stroke. The remaining coil energy is available to fire the spark plug under compression (typically about 8 to 12 kV).

rotation of the crankshaft, cylinder number 4 is on the compression stroke and cylinder number 1 is on the exhaust stroke.

Cylinder 1. Always fires straight polarity (from the center electrode to the ground electrode), one time requiring 10 to 12 kV, and one time requiring 3 to 4 kV.

Cylinder 4. Always fires reverse polarity (from the ground electrode to the center electrode), one time requiring 10 to 12 kV, and one time requiring 3 to 4 kV.

Waste-spark ignitions require a sensor (usually a crankshaft sensor) to trigger the coils at the correct time. ● **SEE FIGURE 69–14.**

The crankshaft sensor cannot be moved to adjust ignition timing, because ignition timing is not adjustable. The slight adjustment of the crankshaft sensor is designed to position the sensor exactly in the middle of the rotating metal disc for maximum clearance.

COMPRESSION-SENSING WASTE-SPARK IGNITION Some waste-spark ignition systems, such as on Saturns and others, use the voltage required to fire the cylinders to determine cylinder position. It requires a higher voltage to fire a spark plug under compression than it does when the spark plug is being fired on the exhaust stroke. The electronics in the coil and the PCM can detect which of the two companion (paired) cylinders that are fired at the same time requires the higher voltage, which indicates the cylinder that is on the compression stroke. For example, a typical 4-cylinder engine equipped with a waste-spark ignition system will fire both cylinders 1 and 4. If cylinder number 4 requires a higher voltage to fire, as determined by the electronics connected to the coil, then the PCM assumes that cylinder number 4 is on the compression stroke. Engines equipped with **compression-sensing ignition** systems do not require the use of a camshaft position sensor to determine specific cylinder numbers. ● **SEE FIGURE 69–15.**

FREQUENTLY ASKED QUESTION

How Can You Determine the Companion Cylinder?

Companion cylinders are two cylinders in the same engine that both reach top dead center at the same time.

- One cylinder is on the compression stroke.
- The other cylinder is on the exhaust stroke.

To determine which two cylinders are companion cylinders in the engine, follow these steps:

STEP 1 Determine the firing order (such as 165432 for a typical V-6 engine).

STEP 2 Write the firing order and then place the second half under the first half.

$$\frac{165}{432}$$

STEP 3 The cylinder numbers above and below each other are companion or paired cylinders.

In this case, 1 and 4, 6 and 3, and 5 and 2 are companion cylinders.

TECH TIP

Odds Fire Straight

Waste-spark ignition systems fire two spark plugs at the same time. Most vehicle manufacturers use a waste-spark system that fires the odd number cylinders (1, 3, and 5) by straight polarity (current flow from the top of the spark plug through the gap and to the ground electrode). The even number cylinders (2, 4, and 6) are fired reverse polarity, meaning that the spark jumps from the side electrode to the center electrode. Some vehicle manufacturers equip their vehicles with platinum plugs, with the expensive platinum alloy only on one electrode as follows:

- On odd number cylinders (1, 3, 5), the platinum is on the center electrode.
- On even number cylinders (2, 4, 6), the platinum is on the ground electrode.

Replacement spark plugs use platinum on both electrodes (double platinum) and, therefore, can be placed in any cylinder location.

COIL-ON-PLUG IGNITION

TERMINOLOGY **Coil-on-plug (COP) ignition** uses one ignition coil for each spark plug. This system is also called *coil-by-plug, coil-near-plug,* or *coil-over-plug* ignition. ● **SEE FIGURES 69–16 AND 69–17.**

ADVANTAGES The coil-on-plug system eliminates the spark plug wires that are often the source of **electromagnetic interference (EMI)** that can cause problems to some computer signals. The vehicle computer controls the timing of the spark. Ignition

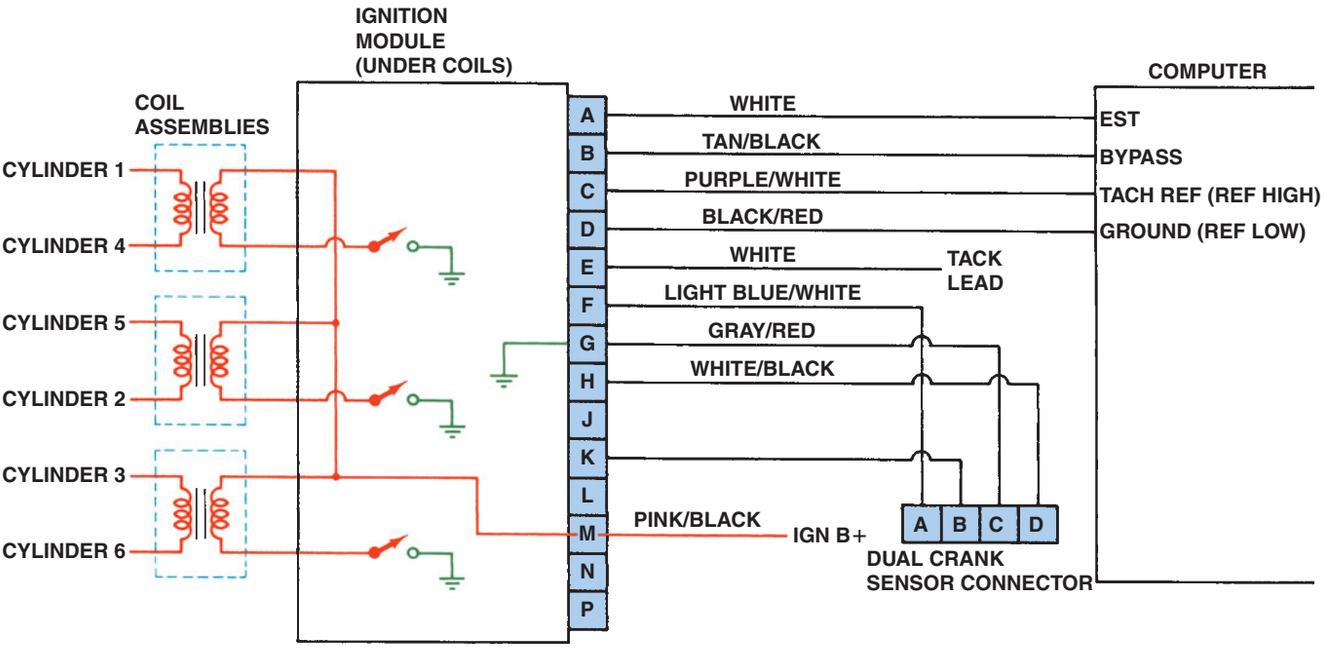

FIGURE 69–14 Typical wiring diagram of a V-6 waste-spark ignition system. The computer (PCM) is in control of the ignition timing based on information from various engine sensors including engine speed (RPM), MAP and engine coolant temperature (ECT). The timing signal is sent to the module through the electronic spark timing (EST) wire in this example.

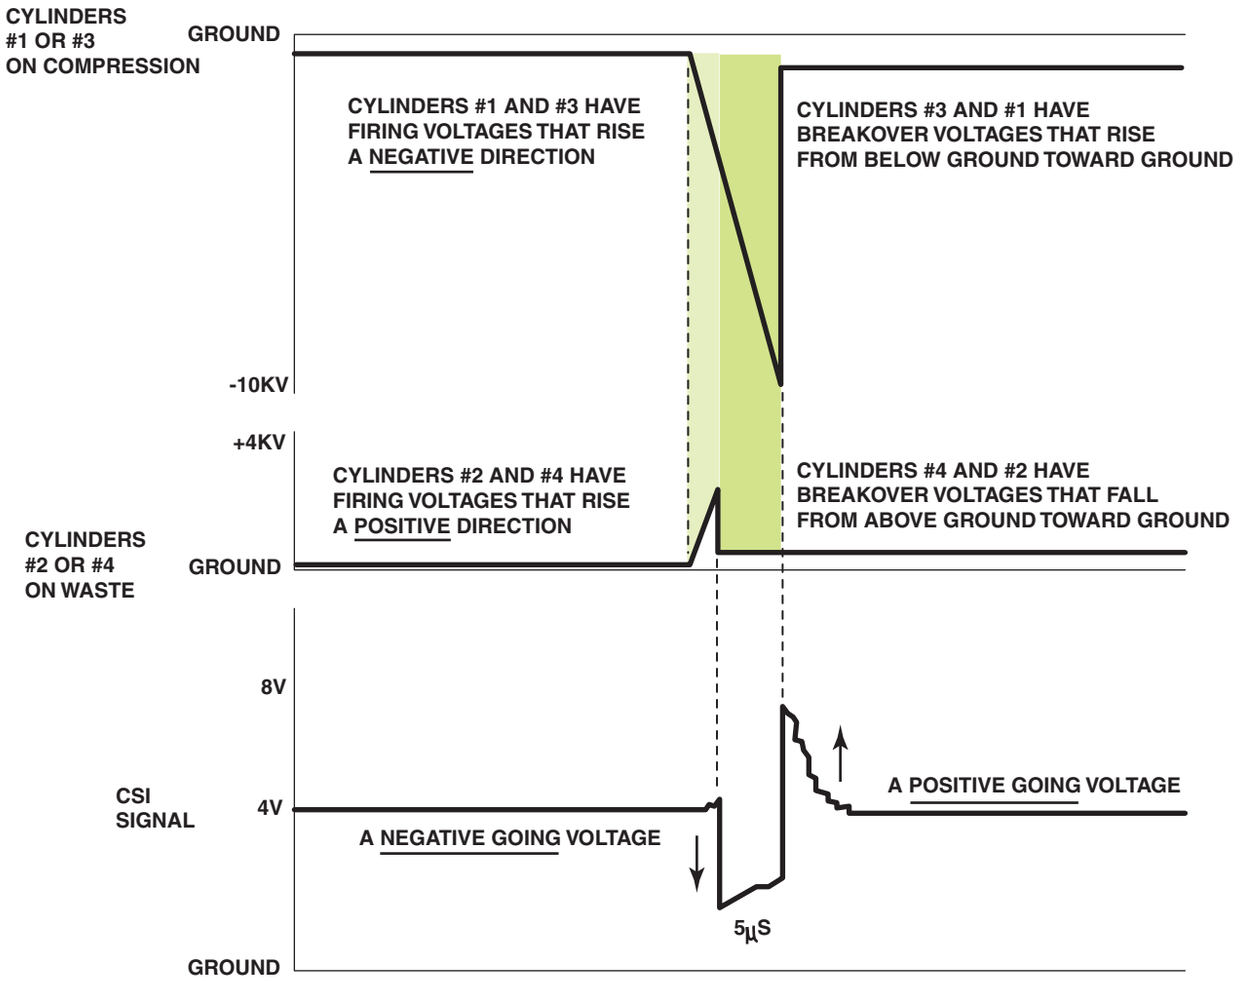

FIGURE 69–15 The slight (5 microsecond) difference in the firing of the companion cylinders is enough time to allow the PCM to determine which cylinder is firing on the compression stroke. The compression sensing ignition (CSI) signal is then processed by the PCM which then determines which cylinder is on the compression stroke.

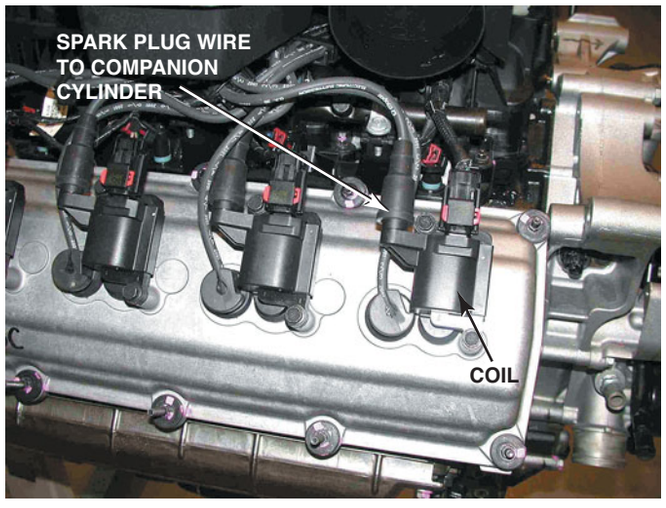

FIGURE 69–18 A Chrysler Hemi V-8 that has two spark plugs per cylinder. The coil on top of one spark plug fires that plug and, through a spark plug wire, fires a plug in the companion cylinder.

SAFETY TIP

Never Disconnect a Spark Plug Wire When the Engine Is Running!

Ignition systems produce a high-voltage pulse necessary to ignite a lean air-fuel mixture. If you disconnect a spark plug wire when the engine is running, this high-voltage spark could cause personal injury or damage to the ignition coil and/or ignition module.

timing also can be changed (retarded or advanced) on a cylinder-by-cylinder basis for maximum performance and to respond to knock sensor signals.

TYPES OF COP SYSTEMS

There are two basic types of coil-on-plug ignition.

- **Two primary wires.** This design uses the vehicle computer to control the firing of the ignition coil. The two wires include ignition voltage feed and the pulse ground wire, which is controlled by the PCM. The ignition control module (ICM) is located in the PCM, which handles all ignition timing and coil on-time control.
- **Three primary wires.** This design includes an ignition module at each coil. The three wires include:
  - Ignition voltage
  - Ground
  - Pulse from the PCM to the built-in ignition module

Vehicles use a variety of coil-on-plug-type ignition systems, such as the following:

- Many General Motors V-8 engines use a coil-near-plug system with individual coils and modules for each individual cylinder placed on the valve covers. Short secondary ignition spark plug wires are used to connect the output terminal of the ignition coil to the spark plug, which explains why this system is called a *coil-near-plug* system.
- A combination of coil-on-plug and waste-spark systems fires a spark plug attached to the coil and uses a spark plug wire attached to the other secondary terminal of the coil to fire another spark plug of the companion cylinder. This type of system is used in some Chrysler Hemi V-8 and Toyota V-6 engines. ● **SEE FIGURE 69–18.**

Most new engines use coil-over-plug-type ignition systems. Each coil is controlled by the PCM, which can vary the ignition timing separately for each cylinder based on signals the PCM receives from the knock sensor(s). For example, if the knock sensor detects that a spark knock has occurred after firing cylinder 3, then the PCM will continue to monitor cylinder 3 and retard timing on just this one cylinder if necessary to prevent engine damaging detonation.

ION-SENSING IGNITION

In an **ion-sensing ignition** system, the spark plug itself becomes a sensor. An ion-sensing ignition uses

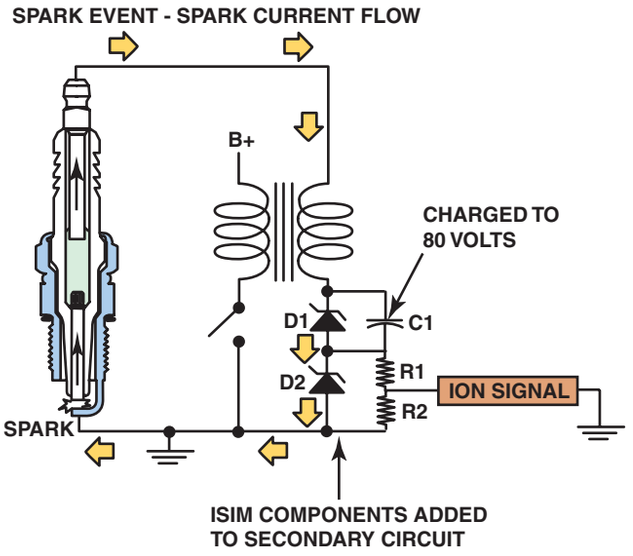

FIGURE 69–19 A DC voltage is applied across the spark plug gap after the plug fires and the circuit can determine if the correct air-fuel ratio was present in the cylinder and if knock occurred. The applied voltage for ion sensing does not jump the spark plug gap but rather determines the conductivity of the ionized gases left over from the combustion process.

a coil-on-plug design where the **ignition control module (ICM)** applies a DC voltage across the spark plug gap *after* the ignition event to sense the ionized gases (called plasma) inside the cylinder. Ion-sensing ignition is used in the General Motors EcoTec 4-cylinder engines. ● **SEE FIGURE 69–19.**

The secondary coil discharge voltage (10 to 15 kV) is electrically isolated from the ion-sensing circuit. The combustion flame is ionized and will conduct some electricity, which can be accurately measured at the spark plug gap. The purpose of this circuit includes:

- Misfire detection (required by OBD-II regulations)
- Knock detection (eliminates the need for a knock sensor)
- Ignition timing control (to achieve the best spark timing for maximum power with lowest exhaust emissions)
- Exhaust gas recirculation (EGR) control
- Air-fuel ratio control on an individual cylinder basis

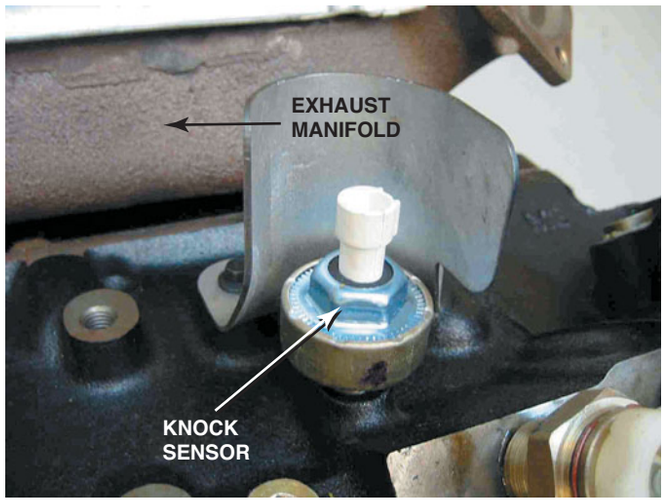

FIGURE 69–20 A typical knock sensor on the side of the block. Some are located in the "V" of a V-type engine and are not noticeable until the intake manifold has been removed.

Ion-sensing ignition systems still function the same as conventional coil-on-plug designs, but the engine does not need to be equipped with a camshaft position sensor for misfire detection or a knock sensor, because both of these faults are achieved using the electronics inside the ignition control circuits.

KNOCK SENSORS

PURPOSE AND FUNCTION

Knock sensors (KS) are used to detect abnormal combustion, often called **ping, spark knock,** or **detonation.** Whenever abnormal combustion occurs, a rapid pressure increase occurs in the cylinder, creating a vibration in the engine block. It is this vibration that is detected by the knock sensor. The signal from the knock sensor is used by the PCM to retard the ignition timing until the knock is eliminated, thereby reducing the damaging effects of the abnormal combustion on pistons and other engine parts.

Inside the knock sensor is a piezoelectric element which is a type of crystal that produces a voltage when pressure or a vibration is applied to the unit. The knock sensor is tuned to the engine knock frequency, in a range from 5 to 10 kHz depending on the engine design. The voltage signal from the knock sensor is sent to the PCM, which then retards the ignition timing until the knocking stops. ● **SEE FIGURE 69–20.**

DIAGNOSING THE KNOCK SENSOR

If a knock sensor diagnostic trouble code (DTC) is present, follow the specified testing procedure in the service information. A scan tool can be used to check the operation of the knock sensor, using the following procedure.

STEP 1 Start the engine and connect a scan tool to monitor ignition timing and/or knock sensor activity.

STEP 2 Create a simulated engine knocking sound by tapping on the engine block or cylinder head with a soft faced mallet or small ball peen hammer.

STEP 3 Observe the scan tool display. The vibration from the tapping should have been interpreted by the knock sensor as a knock, resulting in a knock sensor signal and a reduction in the spark advance.

A knock sensor also can be tested using a digital storage oscilloscope. ● **SEE FIGURE 69–21.**

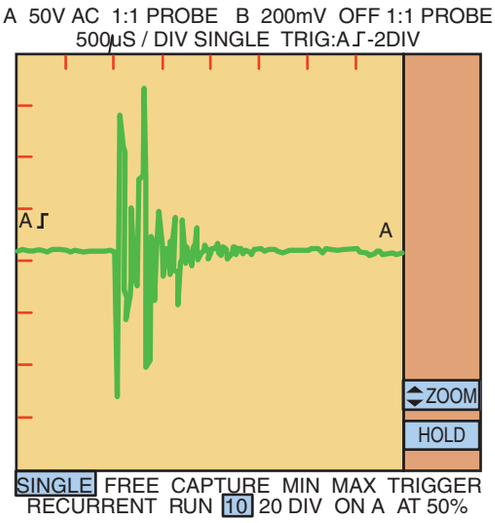

FIGURE 69–21 A typical waveform from a knock sensor during a spark knock event. This signal is sent to the computer which in turn retards the ignition timing. This timing retard is accomplished by an output command from the computer to either a spark advance control unit or directly to the ignition module.

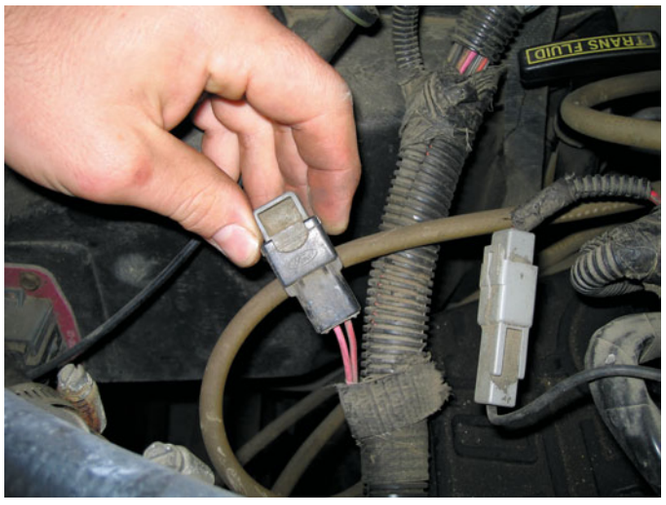

FIGURE 69–22 A SPOUT connector on a Ford that is equipped with a distributor ignition. This connector has to be disconnected to separate the PCM in order to set base ignition timing.

REAL WORLD FIX

The Low Power Toyota

A technician talked about the driver of a Toyota who complained about poor performance and low fuel economy. The technician checked everything, and even replaced all secondary ignition components. Then the technician connected a scan tool and noticed that the knock sensor was commanding the timing to be retarded. Careful visual inspection revealed a "chunk" missing from the serpentine belt, causing a "noise" similar to a spark knock. Apparently the knock sensor was "hearing" the accessory drive belt noise and kept retarding the ignition timing. After replacing the accessory drive belt, a test drive confirmed that normal engine power was restored.

Other items that can fool the knock sensor to retard the ignition timing include:

- Loose valve lifter adjustment
- Engine knocks
- Loose accessory brackets such as the air-conditioning compressor, power steering pumps, or alternator.

NOTE: Some engine computers are programmed to ignore knock sensor signals when the engine is at idle speed, to avoid having the noise from a loose accessory drive belt or other accessory interpreted as engine knock. Always follow the vehicle manufacturer's recommended testing procedure.

REPLACING A KNOCK SENSOR

If replacing a knock sensor, be sure to purchase the exact replacement needed, because they often look the same, but the frequency range can vary according to engine design and location on the engine. Many engines also use two knock sensors, so check service information for exact details and locations of the sensors for the engine being serviced. Always tighten the knock sensor using a torque wrench and tighten to the specified torque to avoid causing damage to the piezoelectric element inside the sensor.

TERMINOLOGY

Ignition control (IC) is the OBD-II terminology for the output signal from the PCM to the ignition system that controls engine timing. Previously, each manufacturer used a different term to describe this signal. For instance, Ford referred to this signal as **spark output (SPOUT)** and General Motors referred to this signal as **electronic spark timing (EST).** This signal is now referred to as the ignition control (IC) signal. The ignition control signal is usually a digital output that is sent to the ignition system as a timing signal. If the ignition system is equipped with an ignition module, then this signal is used by the ignition module to vary the timing as engine speed and load change. If the PCM directly controls the coils, such as most coil-on-plug ignition systems, then this IC signal directly controls the coil primary and there is a separate IC signal for each ignition coil. The IC signal controls the time that the coil fires and it can also either advance or retard the ignition timing. On many systems, this signal controls the duration of the primary current flow in the coil, referred to as the **dwell.** ● **SEE FIGURE 69–22.**

BYPASS IGNITION CONTROL SYSTEM

With **bypass ignition** control, the engine starts using the ignition module for timing control and then switches to the PCM for timing control after the engine starts. A bypass ignition is commonly used on General Motors engines equipped with distributor ignition (DI), as well as those equipped with waste-spark ignition.

The bypass circuit includes four wires.

- The *tach reference (purple/white)* wire comes from the ignition control (IC) module and is used by the PCM as engine speed information.
- The *ground (black/white)* wire is used to ensure that both the PCM and the ignition control module share the same ground.

- The *bypass (tan/black)* wire is used to conduct a 5 volt DC signal from the PCM to the ignition control module to switch the timing control from the module to the PCM.

  NOTE: It is this bypass wire that is disconnected before the ignition timing can be set on many General Motors engines equipped with a distributor ignition.

- The *EST (ignition control) (white)* wire is the ignition timing control signal from the PCM to the ignition control module.

UP-INTEGRATED IGNITION CONTROL Most coil-on-plug and many waste-spark-type ignition systems use the PCM for ignition timing control. This type of ignition control is called **up-integrated ignition** because all timing functions are interpreted in the PCM, rather than being split between the ignition control module and the PCM. The ignition module, if even used, contains only the power transistor for coil switching. The signal as to when the coil fires is determined and controlled from the PCM.

Unlike a bypass ignition control circuit, it is not possible to separate the PCM from the ignition coil control to help isolate a fault.

CHECKING FOR SPARK

SPARK TESTER In the event of a no-start condition, the first step should be to check for secondary voltage out of the ignition coil or to the spark plugs. If the engine is equipped with a separate ignition coil, remove the coil wire from the center of the distributor cap, install a **spark tester,** and crank the engine. See the Tech Tip, "Always Use a Spark Tester." A good coil and ignition system should produce a blue spark at the spark tester. ● **SEE FIGURES 70–1 AND 70–2.**

If the ignition system being tested does not have a separate ignition coil, disconnect any spark plug wire from a spark plug and, while cranking the engine, test for spark available at the spark plug wire, again using a spark tester.

NOTE: An intermittent spark should be considered a no-spark condition.

Typical causes of a no-spark (intermittent spark) condition include the following:

1. Weak ignition coil
2. Low or no voltage to the primary (positive) side of the coil
3. High resistances or open coil wire, or spark plug wire
4. Negative side of the coil not being pulsed by the ignition module
5. Defective pickup coil or crankshaft position sensor
6. Defective ignition control module (ICM)
7. Defective main relay (can be labeled main, EFI, ASD [Chrysler products], or EEC [Ford vehicles] relay)

The triggering sensor has to work to create a spark from the ignition coil(s). If a no-spark condition occurs, then check for triggering by using a scan tool and check for engine RPM while cranking the engine.

FIGURE 70–1 A spark tester looks like a regular spark plug with an alligator clip attached to the shell. This tester has a specified gap that requires at least 25,000 volts (25 kV) to fire.

FIGURE 70–2 A close-up showing the recessed center electrode on a spark tester. It is recessed 3/8 in. into the shell and the spark must then jump another 3/8 in. to the shell for a total gap of 3/4 in.

- If the engine speed (RPM) shows zero or almost zero while cranking, the most likely cause is a defective triggering sensor or sensor circuit fault.
- If the engine speed (RPM) is shown on the scan tool while cranking the engine, then the triggering sensor is working (in most cases).

Check service information for the exact procedure to follow for testing triggering sensors.

IGNITION COIL TESTING

IGNITION COIL TESTING USING AN OHMMETER

If an ignition coil is suspected of being defective, a simple ohmmeter check can be performed to test the resistance of the primary and secondary winding inside the coil. For accurate resistance measurements, the wiring to the coil should be removed before testing. To test the primary coil winding resistance, take the following steps. ● **SEE FIGURE 70–3.**

STEP 1 Set the meter to read low ohms.

STEP 2 Measure the resistance between the positive terminal and the negative terminal of the ignition coil. Most coils will give a reading between 0.5 and 3 ohms. Check the manufacturer's specifications for the exact resistance values.

To test the secondary coil winding resistance, follow these steps.

STEP 1 Set the meter to read kilohms (kΩ).

STEP 2 Measure the resistance either between the primary terminal and the secondary coil tower or between the secondary towers. The normal resistance of most coils ranges between 6,000 and 30,000 ohms.

Check service information for the exact procedures and specifications.

CURRENT RAMPING IGNITION COILS

Testing an ignition coil for resistance does not always find a coil problem that occurs under actual heat and loads. However, by using a digital storage oscilloscope and a low-current probe, the ignition system can be checked for module current limits and the charging rise time.

Ignition coil operation begins with the ignition control module (ICM) completing the primary circuit through the ignition coil winding. The module allows primary current to ramp upward (primary charging time) to a preset limit. Once ramped to the preset limit, the coil remains on for a set period of time (primary saturation), known as the *dwell* period. Coil current is then turned off (open circuit) allowing the magnetic field built up through the dwell cycle to collapse inward, cutting across many turns of secondary coil windings, inducing a higher output voltage to fire the coil. The ignition systems used today must provide voltages of at least 25,000 volts and maintain spark duration of over 2 ms to assure good ignition over extended service intervals.

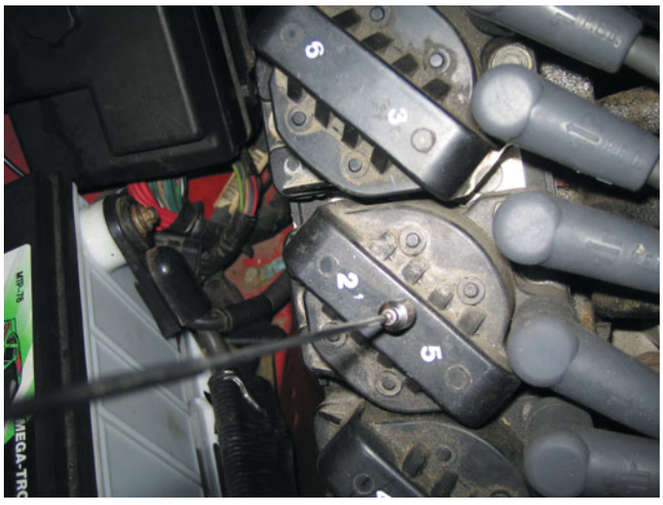

FIGURE 70–4 If the coil is working, the end of the magnetic pickup tool will move with the changes in the magnetic field around the coil with the engine running.

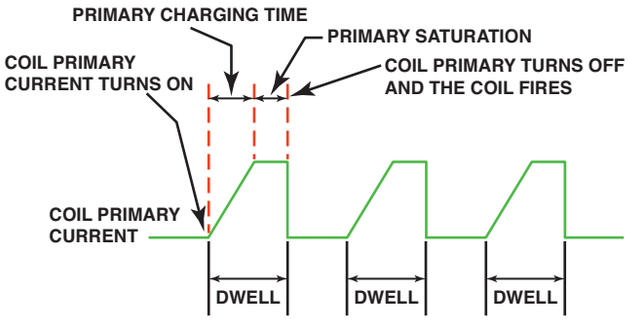

FIGURE 70–5 A waveform showing the primary current flow through the primary windings of an ignition coil.

TECH TIP

Always Use a Spark Tester

A spark tester looks like a spark plug except it has a recessed center electrode and no side electrode. The tester commonly has an alligator clip attached to the shell so that it can be clamped on a good ground connection on the engine. A good ignition system should be able to cause a spark to jump this wide gap at atmospheric pressure. Without a spark tester, a technician might assume that the ignition system is okay, because it can spark across a normal, grounded spark plug. The voltage required to fire a standard spark plug when it is out of the engine and not under pressure is about 3,000 volts or less. An electronic ignition spark tester requires a minimum of 25,000 volts to jump the 3/4 in. gap. Therefore, never assume that the ignition system is okay because it fires a spark plug—always use a spark tester. *Remember that an intermittent spark across a spark tester should be interpreted as a no-spark condition.*

TECH TIP

The Magnetic Pickup Tool Test

All ignition coils are pulsed on and off by the ignition control module or PCM. When the coil charges and discharges, the magnetic field around the coil changes. This pulsing of the coil can be observed by holding the magnetic end of a pickup tool near an operating ignition coil. The magnet at the end of the pickup tool will move as the magnetic field around the coil changes. ● **SEE FIGURE 70–4.**

Using the digital storage oscilloscope and a current probe, a quick check can be made of the overall primary condition of the two most important parameters of the ignition circuit, the **module current limits** and the **charging rise time** of the circuit. Actual circuit operation of the primary current control is a precise element in total ignition function and output. ● **SEE FIGURE 70–5.**

CURRENT RAMP TEST PROCEDURE

To perform a current ramp test of the ignition coil(s), take the following steps.

STEP 1 Every ignition system has a power feed circuit to the ignition coil(s). To perform current probe testing on the system, first locate the feed wire and make it current probe accessible. ● **SEE FIGURE 70–6.**

This will serve as a common point on all ignition systems and include both the DI and EI units.

STEP 2 Set up the scope to read approximately 100 mV per division and 2 ms per division. This may be adjusted to suit the waveform, but will give an initial reference point. ● **SEE CHART 70–1.**

A good current ramp waveform is shown in ● **FIGURE 70–7.**

Examples of some faults that a current waveform can detect are shown in ● **FIGURE 70–8.**

IGNITION SENSOR TESTING

MAGNETIC SENSOR TESTING

Magnetic sensors are found in pickup coils, located under the distributor cap on many distributor ignition (DI) equipped engines and in crankshaft position (CKP) sensors. If defective, they can cause a no-spark condition. Magnetic sensors must generate an AC voltage pulse to the ignition control module (ICM) so that the module can pulse the ignition coil.

A pickup coil or magnetic sensor contains a coil of wire, and the resistance of this coil should be within the range specified by the manufacturer.

Common tests for pickup coils and magnetic crankshaft position (CKP) sensors include:

- **Resistance.** The resistance is usually between 150 and 1,500 ohms (check service information for exact specifications). ● **SEE FIGURE 70–9.**
- **Short to ground.** Ensure that the coil windings are insulated from ground by checking for continuity using an ohmmeter. With one ohmmeter lead attached to ground, touch the other lead of the ohmmeter to either of the two pickup coil terminals. The ohmmeter should read OL (over limit or infinity) with the ohmmeter set on the highest ohms scale. If the ohmmeter shows a reading of any resistance or even zero, then the pickup coil is shorted to ground and should be

GOOD COIL PATTERN

replaced. If the pickup coil resistance is not within the specified range or if it has continuity to ground, then replace the pickup coil assembly.

- **AC voltage output.** The pickup coil also can be tested for proper voltage output. During cranking, most pickup coils should produce a minimum of 0.25 volt AC.

AN OPEN COIL PRIMARY WINDING WILL BE IDENTIFIED BY A MISSING PULSE IN THE CURRENT PATTERN.

- **Scope testing.** A pickup coil can also be checked on a scope. The waveform created is an analog (continuously variable) and is produced by the strengthening and weakening of the magnetic field as the points of the timer core rotate past the points of the pole pieces. ● **SEE FIGURE 70–10.**

The changing magnetic field is sent to the ICM where it turns off the current through the primary winding of the ignition coil. ● **SEE FIGURE 70–11.**

REAL WORLD FIX

The Weird Running Chevrolet Truck

An older Chevrolet pickup truck equipped with a V-8 engine was towed into a shop because it would not start. A quick check of the ignition system showed that the pickup coil had a broken wire below it and the ignition control module. The distributor was removed from the engine and the distributor shaft was removed, cleaned, and a replacement pickup coil was installed. The engine started but ran rough and hesitated when the accelerator pedal was depressed.

After an hour of troubleshooting, a careful inspection of the new pickup coil showed that the time core had six instead of eight points, meaning that the new pickup coil was meant for a V-6 instead of a V-8 engine. Replacing the pickup coil again solved the problem.

REAL WORLD FIX

The Hard-to-Start Chevrolet HHR

The owner of a 2008 Chevrolet HHR complained that the engine was hard to start and required a long period of cranking. Once the engine started, it ran great all day. A P0336 crankshaft position (CKP) sensor fault code was stored. ● **SEE FIGURE 70–12.**

The CKP sensor had been replaced several times before and the sensor output was scope tested yet everything appeared to be normal. Then one time when the engine started, the technician noticed that while it was running the engine speed (RPM) displayed on the Tech 2 scan tool was zero. ● **SEE FIGURE 70–13.**

After replacing the crankshaft position sensor again and checking the wiring, the technician looked at the reluctor wheel using a boroscope. Some blades of the reluctor wheel were bent. The cause was likely when the first sensor failed and possibly damaged the reluctor. As a result of the testing, the local Chevrolet dealer replaced the crankshaft under warranty. ● **SEE FIGURE 70–14.**

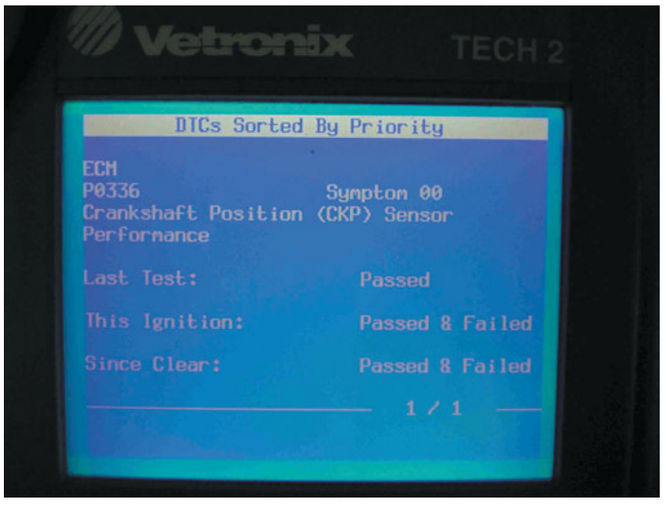

FIGURE 70–12 A diagnostic trouble code P0336 was displayed on a Tech 2 scan tool as the only code.

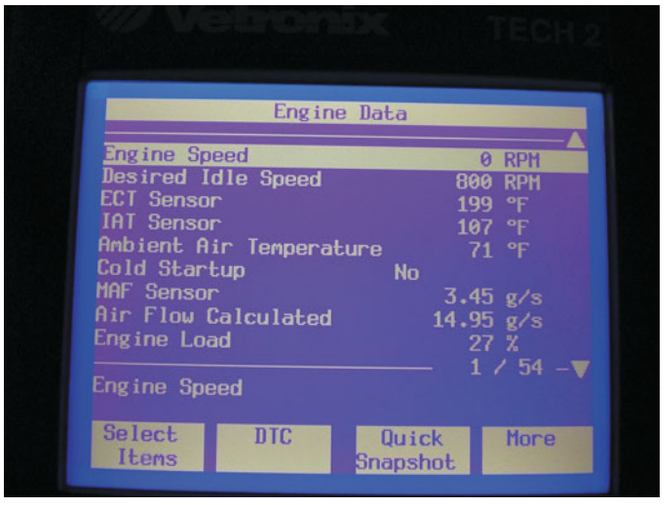

FIGURE 70–13 The engine started and was running, but the Tech 2 displayed zero RPM.

HALL-EFFECT SENSOR TESTING

A Hall effect sensor uses a semiconductor chip to produce an on and off signal when exposed to a magnetic field. Using a digital voltmeter, check for the following:

- Power and ground to the sensor
- Changing voltage (pulsed on and off or digital DC voltage) when the engine is being cranked (The usual voltage range is 0 to 5 volts, or 0 to 8 volts depending on the sensors and the application.)

Another test is to use an oscilloscope and observe the waveform. ● **SEE FIGURE 70–15.**

OPTICAL SENSOR TESTING

Optical sensors will not operate if dirty or covered in oil. Perform a thorough visual inspection and look for an oil leak that could cause dirty oil to get on the LED or phototransistor. Also be sure that the light shield is securely fastened and that the seal is lightproof. An optical sensor also can be checked using an oscilloscope. ● **SEE FIGURE 70–16.**

Because of the speed of the engine and the number of slits in the optical sensor disk, a scope is one of the only tools that can capture useful information. For example, a Nissan has 360 slits and if it is running at 2,000 RPM, a signal is generated 720,000 times per minute or 12,000 times per second.

SPARK PLUG WIRE INSPECTION

VISUAL INSPECTION

Spark plug wires should be visually inspected for cuts or defective insulation. Faulty spark plug wire insulation can cause hard starting or no starting in rainy or damp weather conditions. When removing a spark plug wire, be sure to rotate the boot of the wire at the plug before pulling it off the spark plug. This

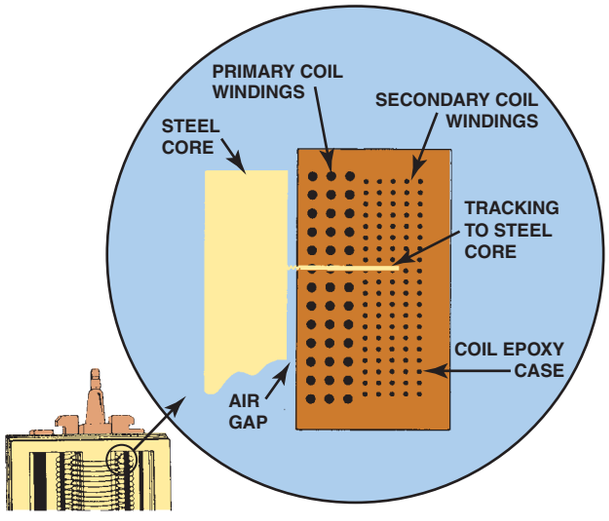

FIGURE 70–17 A track inside an ignition coil is not a short, but a low-resistance path or hole that has been burned through from the secondary wiring to the steel core.

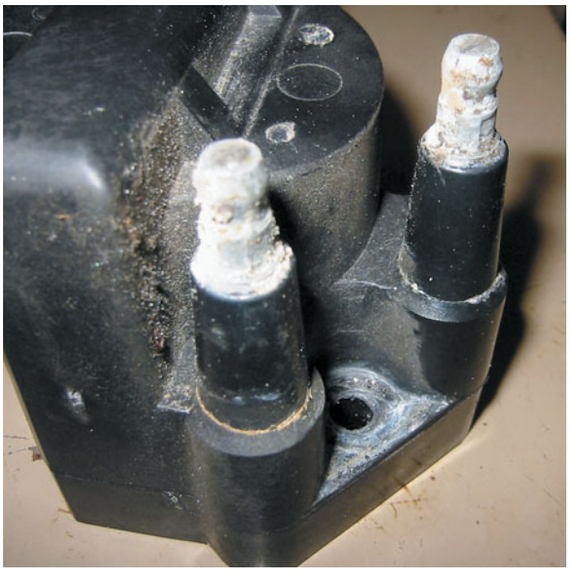

FIGURE 70–18 Corroded terminals on a waste-spark coil can cause misfire diagnostic trouble codes to be set.

TECH TIP

Bad Wire? Replace the Coil!

When performing engine testing (such as a compression test), always ground the coil wire or disable the primary ignition circuit by removing the ignition fuse. If the spark cannot spark to ground, the coil energy can (and usually does) arc inside the coil itself, creating a low-resistance path to the primary windings or the steel laminations of the coil. ● **SEE FIGURE 70–17.**

This low-resistance path is called a *track* and could cause an engine miss under load even though all of the remaining component parts of the ignition system are functioning correctly. Often these tracks do not show up on any coil test, including most scopes. Because the track is a lower resistance path to ground than normal, it requires that the ignition system be put under a load for it to be detected; and even then, the problem such as an engine misfire may be intermittent.

TECH TIP

Spark Plug Wire Pliers Are a Good Investment

Spark plug wires are often difficult to remove. Using good-quality spark plug wire pliers, as shown in ● **FIGURE 70–18,** saves time and reduces the chance of harming the wire during removal.

will help prevent damaging the wire as many wires are stuck to the spark plug and are often difficult to remove.

Make a thorough visual inspection of the following items.

- Check all spark plug wires for proper routing. All plug wires should be in the factory wiring separators and be clear of any metallic object that could damage the insulation and cause a short-to-ground fault.
- Check that all spark plug wires are securely attached to the spark plugs and to the distributor cap or ignition coil(s).

FIGURE 70–19 This spark plug boot on an overhead camshaft engine has been arcing to the valve cover causing a misfire to occur.

FIGURE 70–20 Measuring the resistance of a spark plug wire with a multimeter set to the ohms position. The reading of 16.03 kΩ (16.03 ohms) is okay because the wire is about 2 ft long. Maximum allowable resistance for a spark plug wire this long would be 20 kΩ (20,000 ohms).

FIGURE 70–21 Spark plug wire boot pliers are a handy addition to any tool box.

- Check that all spark plug wires are clean and free from excessive dirt or oil. Check that all protective covers normally covering the coil and/or distributor cap are in place and not damaged.
- Carefully check the cap and distributor rotor for faults or coil secondary terminal on waste spark coils. ● **SEE FIGURE 70–19.**

Visually check the wires and boots for damage. ● **SEE FIGURE 70–20.**

OHMMETER TESTING Check all spark plug wires with an ohmmeter for proper resistance. Good spark plug wires should measure less than 10,000 ohms per foot of length. ● **SEE FIGURE 70–21.**

FIGURE 70–22 A water spray bottle is an excellent diagnostic tool to help find an intermittent engine misfire caused by a break in a secondary ignition circuit component.

TECH TIP

Use a Water Spray Bottle to Check for Bad Spark Plug Wires

For intermittent problems, use a spray bottle to apply a water mist to the spark plugs, distributor cap, and spark plug wires. ● **SEE FIGURE 70–22.** With the engine running, the water may cause an arc through any weak insulating materials and cause the engine to miss or stall.

NOTE: Adding a little salt or liquid soap to the water makes the water more conductive and also makes it easier to find those hard-to-diagnose intermittent ignition faults.

SPARK PLUGS

SPARK PLUG CONSTRUCTION Spark plugs are manufactured from ceramic insulators inside a steel shell. The threads of the shell are rolled and a seat is formed to create a gas-tight seal with the cylinder head. ● **SEE FIGURE 70–23.**

Physical differences in spark plugs include the following:

- **Reach.** The reach is the length of the threaded part of the plug.
- **Heat range.** The heat range of the spark plug refers to how rapidly the heat created at the tip is transferred to the cylinder head. A plug with a long ceramic insulator path will run hotter at the tip than a spark plug that has a shorter path because the heat must travel farther. ● **SEE FIGURE 70–24.**
- **Type of seat.** Some spark plugs use a gasket and others rely on a tapered seat to seal.

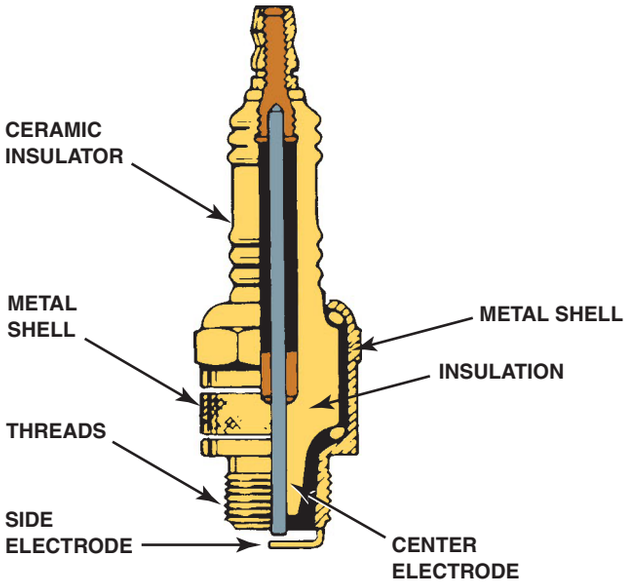

FIGURE 70–23 Parts of a spark plug.

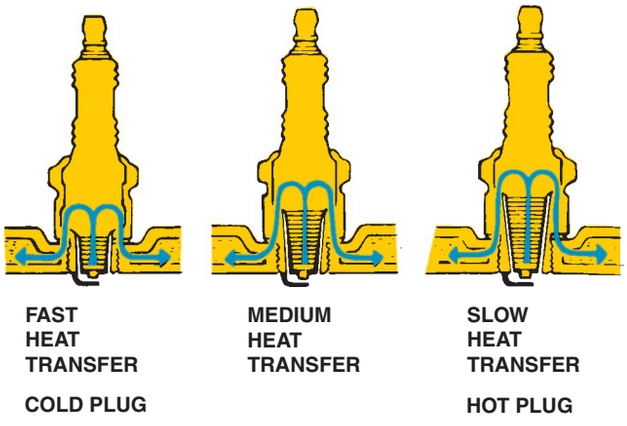

FIGURE 70–24 The heat range of a spark plug is determined by the distance the heat flows from the tip to the cylinder head.

RESISTOR SPARK PLUGS

Most spark plugs include a resistor in the center electrode, to reduce electromagnetic noise or radiation from the ignition system. The closer the resistor is to the actual spark or arc, the more effective it becomes. The value of the resistor is usually between 2,500 and 7,500 ohms.

PLATINUM SPARK PLUGS

Platinum spark plugs have a small amount of the precious metal platinum included onto the end of the center electrode, as well as on the ground or side electrode. Platinum is a gray-white metal that does not react with oxygen and, therefore, will not erode away as can occur with conventional nickel alloy spark plug electrodes. Platinum is also used as a catalyst in catalytic converters where it is able to start a chemical reaction without itself being consumed.

IRIDIUM SPARK PLUGS

Iridium is a white precious metal and is the most corrosion-resistant metal known. Most **iridium spark plugs** use a small amount of iridium welded onto the tip of a small center electrode 0.0015 to 0.002 in. (0.4 to 0.6 mm) in diameter. The small diameter reduces the voltage required to jump the gap between the center and the side electrode, thereby reducing possible misfires. The ground or side electrode is usually tipped with platinum to help reduce electrode gap wear.

Spark plugs should be inspected when an engine performance problem occurs and should be replaced at specified intervals to ensure proper ignition system performance.

FIGURE 70–25 When removing spark plugs, it is wise to arrange them so that they can be compared and any problem can be identified with a particular cylinder.

FIGURE 70–26 A spark plug thread chaser is a low-cost tool that hopefully will not be used often, but is necessary in order to clean the threads before installing new spark plugs.

- Nonplatinum spark plugs have a service life of over 20,000 miles (32,000 km).
- Platinum-tipped original equipment spark plugs have a typical service life of 60,000 to 100,000 miles (100,000 to 160,000 km) or longer.

Used *Platinum-tipped spark plugs should not be regapped!* Using a gapping tool can break the platinum after it has been used in an engine. Check service information regarding the recommended type of spark plugs and the specified service procedures.

SPARK PLUG SERVICE

When replacing spark plugs, perform the following steps.

STEP 1 **Check service information.** Check for the exact spark plug to use and the specified instructions and/or technical service bulletins that affect the part number of plug to be used or a revised replacement procedure.

STEP 2 **Allow the engine to cool before removing spark plugs.** This step is especially critical on engines with aluminum cylinder heads.

STEP 3 **Use compressed air or a brush to remove dirt from around the spark plug before removal.** This step helps prevent dirt from getting into the cylinder of an engine while removing a spark plug.

STEP 4 **Check the spark plug gap and correct as needed.** Be careful not to damage the tip on the center electrode if adjusting a platinum or iridium type of spark plug.

STEP 5 **Install the spark plugs.** Be sure the threads are clean by using a thread chaser. Then install the spark plug by hand, then using the proper spark plug socket and a torque wrench, tighten the plugs to factory specifications.

● **SEE FIGURES 70–25 AND 70–26.**

FIGURE 70–27 A normally worn spark plug that uses a tapered platinum-tipped center electrode.

FIGURE 70–28 Spark plug removed from an engine after a 500-mile race. Note the clipped side (ground) electrode. The electrode design and narrow (0.025 in.) gap are used to ensure that a spark occurs during extremely high engine speed operation.

Spark plugs are the windows to the inside of the combustion chamber. A thorough visual inspection of the spark plugs often can lead to the root cause of an engine performance problem. Two indications on spark plugs and their possible root causes in engine performance include the following:

1. **Carbon fouling.** If the spark plug(s) has *dry black carbon* (soot), the usual causes include:
   - Excessive idling
   - Defective thermostat
   - Overly rich air-fuel mixture due to a fuel system fault
   - Weak ignition system output
2. **Oil fouling.** If the spark plug has *wet, oily* deposits with little electrode wear, oil may be getting into the combustion chamber from the following:

FIGURE 70–29 Typical worn spark plug. Notice the rounded center electrode. The deposits indicate a possible coolant usage problem.

FIGURE 70–30 New spark plug that was fouled by an overly rich air-fuel mixture. The engine from which this spark plug came had a defective (stuck partially open) injector on this one cylinder only.

   - Worn or broken piston rings
   - Worn valve guides
   - Defective or missing valve stem seals

When removing spark plugs, place them in order so that they can be inspected to check for engine problems that might affect one or more cylinders. All spark plugs should be in the same condition, and the color of the center insulator should be light tan or gray. If all the spark plugs are black or dark, the engine should be checked for conditions that could cause an overly rich air-fuel mixture or possible oil burning. If only one or a few spark plugs are black, check those cylinders for proper firing (possible defective spark plug wire) or an engine condition affecting only those particular cylinders. ● **SEE FIGURES 70–27 THROUGH 70–30.**

If all spark plugs are white, check for possible overadvanced ignition timing or a vacuum leak causing a lean air-fuel mixture. If only one or a few spark plugs are white, check for a vacuum leak or injector fault affecting the air-fuel mixture only to those particular cylinders.

CHART 70–2

TECH TIP

Two-Finger Trick

To help prevent overtightening a spark plug when a torque wrench is not available, simply use two fingers on the ratchet handle. Even the strongest service technician cannot overtighten a spark plug by using two fingers.

NOTE: The PCM "senses" rich or lean air-fuel ratios by means of input from the oxygen sensor(s). If one cylinder is lean, the PCM may make all other cylinders richer to compensate.

Inspect all spark plugs for wear by first checking the condition of the center electrode. As a spark plug wears, the center electrode becomes rounded. If the center electrode is rounded, higher ignition system voltage is required to fire the spark plug.

When installing spark plugs, always use the correct tightening torque to ensure proper heat transfer from the spark plug shell to the cylinder head. ● **SEE CHART 70–2.**

NOTE: General Motors does not recommend the use of antiseize compound on the threads of spark plugs being installed in an aluminum cylinder head, because the spark plug will be overtightened. This excessive tightening torque places the threaded portion of the spark plug too far into the combustion chamber where carbon can accumulate and result in the spark plugs being difficult to remove. If antiseize compound is used on spark plug threads, reduce the tightening torque by 40%. Always follow the vehicle manufacturer's recommendations.

IGNITION TIMING

PURPOSE **Ignition timing** refers to when the spark plug fires in relation to piston position. The time when the spark occurs depends on engine speed, and therefore, it must be advanced (spark plugs fire sooner) as the engine rotates faster. The ignition process in the cylinder takes a certain amount of time, usually 30 ms (30/1,000 of a second) and remains constant regardless of engine speed. Therefore, to maintain the most efficient combustion, the ignition sequence has to occur sooner as the engine speed increases. For maximum efficiency from the expanding gases inside the combustion chamber, the burning of the air-fuel mixture should end by about 10 degrees after top dead center (ATDC). If the burning of the mixture is still occurring after that point, the expanding gases do not exert much force on the piston because the gases are "chasing" the piston as it moves downward.

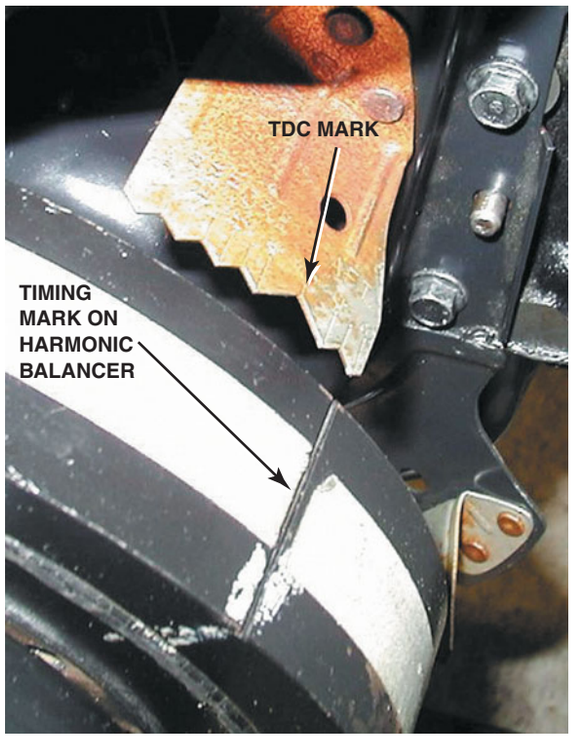

FIGURE 70–31 Ignition timing marks are found on the harmonic balancers on engines equipped with distributors that can be adjusted for timing.

Therefore, to achieve the goal of having the air-fuel mixture be completely burned by the time the piston reaches 10° after top dead center (ATDC), the spark must be advanced (occur sooner) as the engine speed increases. This timing advance is determined and controlled by the PCM on most vehicles. ● **SEE FIGURE 70–31.**

If the engine is equipped with a distributor, it *may* or *may not* be possible to adjust the base or the initial timing. Check service information for details regarding the vehicle being serviced.

The initial timing is usually set to fire the spark plug between zero degrees (top dead center, or TDC) or slightly before TDC (BTDC). Initial (base) ignition timing changes as mechanical wear occurs on the following:

- Timing chain
- Distributor gear
- Camshaft drive gear

● **SEE FIGURE 70–32.**

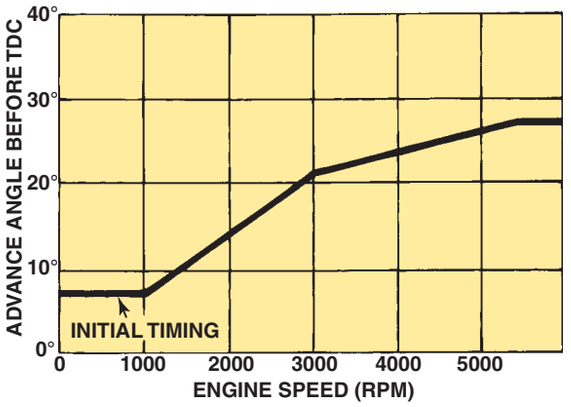

FIGURE 70–32 The initial (base) timing is where the spark plug fires at idle speed. The PCM then advances the timing based primarily on engine speed.

TECH TIP

Two Marks Are the Key to Success

When a distributor is removed from an engine, always mark where the rotor is pointing to ensure that the distributor is reinstalled in the correct position. Because of the helical cut on the distributor drive gear, the rotor rotates as the distributor is being removed from the engine. To help reinstall a distributor without problems, simply make another mark where the rotor is pointing just as the distributor is lifted out of the engine. Then to reinstall, line up the rotor to the second mark and lower the distributor into the engine. The rotor should then line up with the original mark as a double check.

CHECKING IGNITION TIMING To be assured of the proper ignition timing, follow the exact timing procedure indicated on the underhood vehicle emission control information (VECI) decal. If the decal is missing, check with service information for the timing procedure.

NOTE: The ignition timing for waste-spark and coil-on-plug ignition systems cannot be adjusted.

FIRING ORDER

Firing order is the order that the spark is distributed to the correct spark plug at the right time. The firing order of an engine is determined by crankshaft and camshaft design. The ignition firing order is determined by the location of the spark plug wires in the distributor cap of an engine equipped with a distributor and how the spark plug wires are installed on the waste-spark coils. The firing order is often cast into the intake manifold for easy reference. ● **SEE FIGURE 70–33.**

NOTE: Most service manuals also show the firing order and the direction of the distributor rotor rotation, how the cylinders are numbered, and the location of the spark plug wires on the distributor cap.

Firing order is also important for waste-spark-type ignition systems. The spark plug wire can often be installed on the wrong coil pack, creating a no-start condition or poor engine operation.

FIGURE 70–33 The firing order is cast or stamped on the intake manifold of most engines that have a distributor ignition.

FIGURE 70–34 Always take the time to install spark plug wires back into the original holding brackets (wiring combs).

TECH TIP

Route the Wires Right!

High voltage is present through spark plug wires when the engine is running. Surrounding the spark plugs is a magnetic field that can affect other circuits or components of the vehicle. For example, if a spark plug wire is routed too closely to the signal wire from a mass airflow (MAF) sensor, the induced signal from the ignition wire could create a false MAF signal to the PCM. The PCM, not knowing the signal was false, would act on the MAF signal and command the appropriate amount of fuel based on the false MAF signal.

To prevent any problems associated with high-voltage spark plug wires, be sure to route them the same as the original plug wires, using all factory holding brackets and wiring combs. ● **SEE FIGURE 70–34.**

Most factory service manuals show the correct routing if the factory method is unknown.

DISTRIBUTOR INDEXING

A few engines using a distributor also use it to house a camshaft position (CMP) sensor. One purpose of this sensor is to properly initiate the fuel-injection sequence. Some of these engines use a positive distributor position notch or clamp that allows the distributor to be placed in only one position, while others use a method of indexing to verify the distributor position. ● **SEE FIGURE 70–35.**

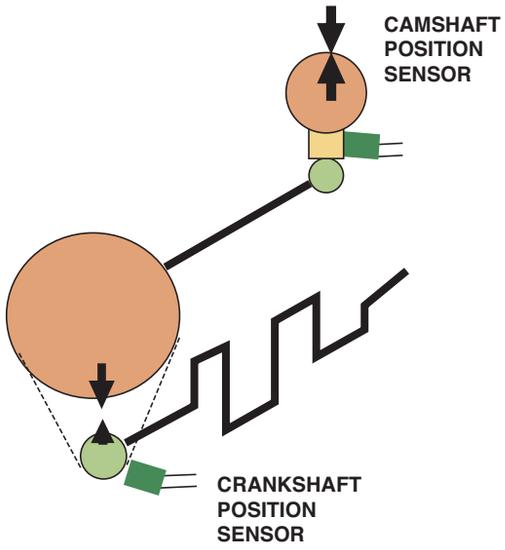

FIGURE 70–35 The relationship between the crankshaft position (CKP) sensor and the camshaft position (CMP) sensor is affected by wear in the timing gear and/or chain.

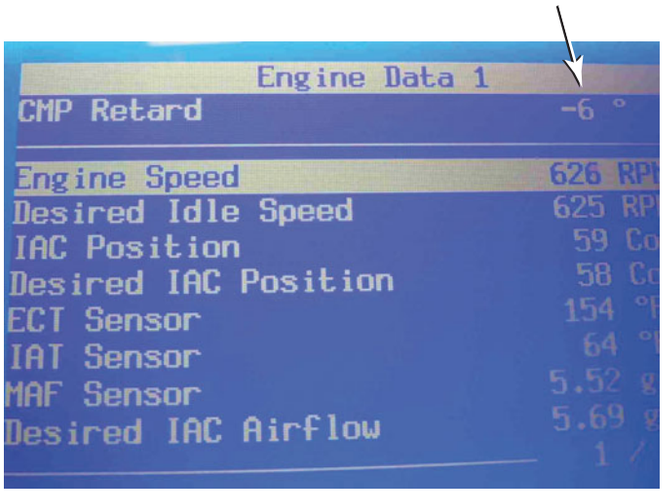

FIGURE 70–36 A scan tool displays excessive cam retard on a Chevrolet pickup truck V-6. The cam retard value should be ± 2 degrees.

If a distributor is not indexed correctly, the following symptoms may occur.

- Surging (especially at idle speed)
- Light bucking
- Intermittent engine misfiring

This will most likely occur when the vehicle is at operating temperature, and under a light load at approximately 2,000 RPM. A misindexed distributor may cause these conditions.

NOTE: This is not the same as setting the ignition timing. Indexing the distributor does not affect the ignition timing.

Always use the factory procedure as stated in service information. Some of the methods may require a scan tool, while others require the use of a voltmeter to verify position. Jeep, late model Chrysler V-6 and V-8 engines, and some GM trucks require indexing. ● **SEE FIGURES 70–36 AND 70–37.**

FIGURE 70–37 A worn distributor drive gear can be the cause of an out-of-specification camshaft position (CMP) signal.

NO-START DIAGNOSIS

A no-start condition (with normal engine cranking speed) can be the result of either no spark or no fuel delivery.

The PCM uses the ignition primary pulses as a signal to inject fuel in a fuel-injection system. If there is no pulse, then there is no squirt of fuel. To determine exactly what is wrong, follow these steps.

STEP 1 Test the output signal from the crankshaft sensor. Most engines with waste-spark or COP ignitions use a crankshaft position (CKP) sensor. These sensors are either the Hall-effect or the magnetic type. The sensors must be able to produce a variable (either analog or digital) signal. A voltmeter set to read DC volts for a Hall-effect sensor or set to read AC volts for a magnetic sensor should read a voltage across the sensor leads when the engine is being cranked. If there is no changing voltage output, replace the sensor.

STEP 2 If the sensor tests okay in step 1, check for a changing voltage signal at the ignition module.

NOTE: Step 2 checks the wiring between the crankshaft position (CKP) sensor and the ignition control module.

STEP 3 If the ignition control module is receiving a changing signal from the crankshaft position sensor, it must be capable of switching the power to the ignition coils on and off. Remove a coil or coil package, and with the ignition switched to on (run), check for voltage at the positive terminal of the coil(s).

NOTE: Several manufacturers program the current to the coils to be turned off within several seconds of the ignition being switched to on if no pulse is received by the PCM. This circuit design helps prevent ignition coil damage in the event of a failure in the control circuit or driver error, by keeping the ignition switch on (run) without operating the starter (start position). Some Chrysler brand engines do not supply power to the positive (+) side of the coil through the automatic shutdown (ASD) relay until a crank pulse is received by the PCM.

CAUTION: Most ignition systems can produce 40,000 volts or more, with energy levels high enough to cause personal injury. Do not disconnect a spark plug wire while the engine is running, because it may damage the ignition system or create a shock hazard.

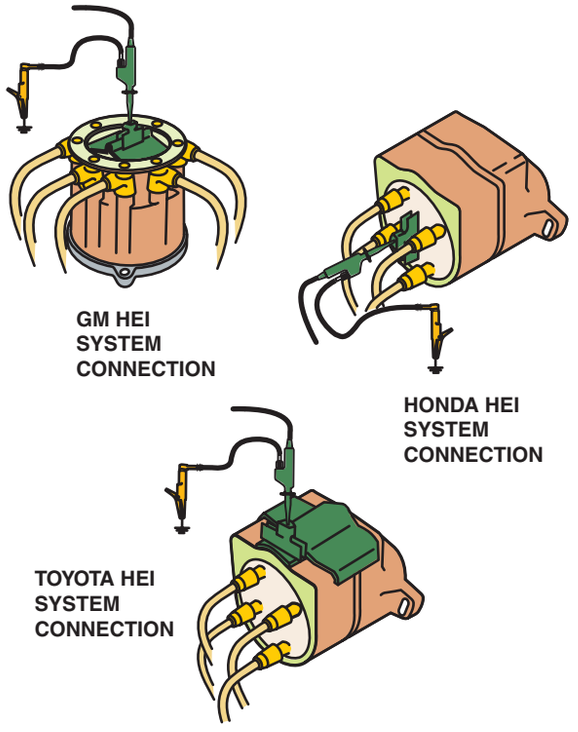

FIGURE 70–39 Clip-on adapters are used with an ignition system that uses an integral ignition coil.

IGNITION SCOPE TESTING

TERMINOLOGY All ignition systems must charge and discharge an ignition coil. With the engine off, ignition scopes will display a horizontal line. With the engine running, this horizontal (zero) line is changed to a pattern that will have sections both above and below the zero line. Sections of this pattern that are above the zero line indicate that the ignition coil is discharging. Sections of the scope pattern below the zero line indicate charging of the ignition coil. The height of the scope pattern indicates voltage. The length (from left to right) of the scope pattern indicates time. ● **SEE FIGURES 70–38 AND 70–39** for typical scope hookups.

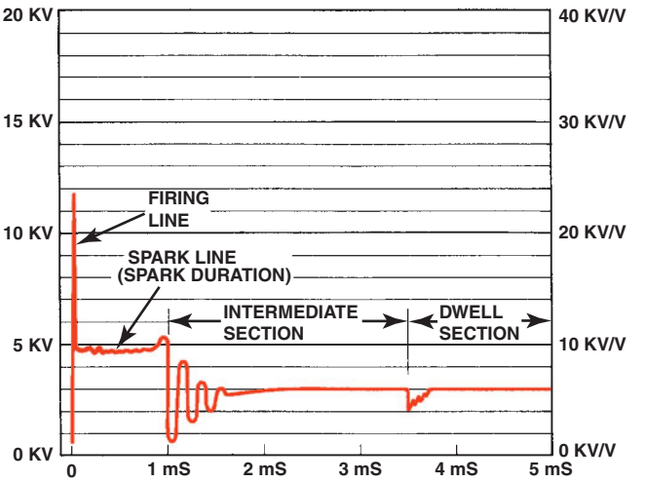

FIGURE 70–40 Typical secondary ignition oscilloscope pattern.

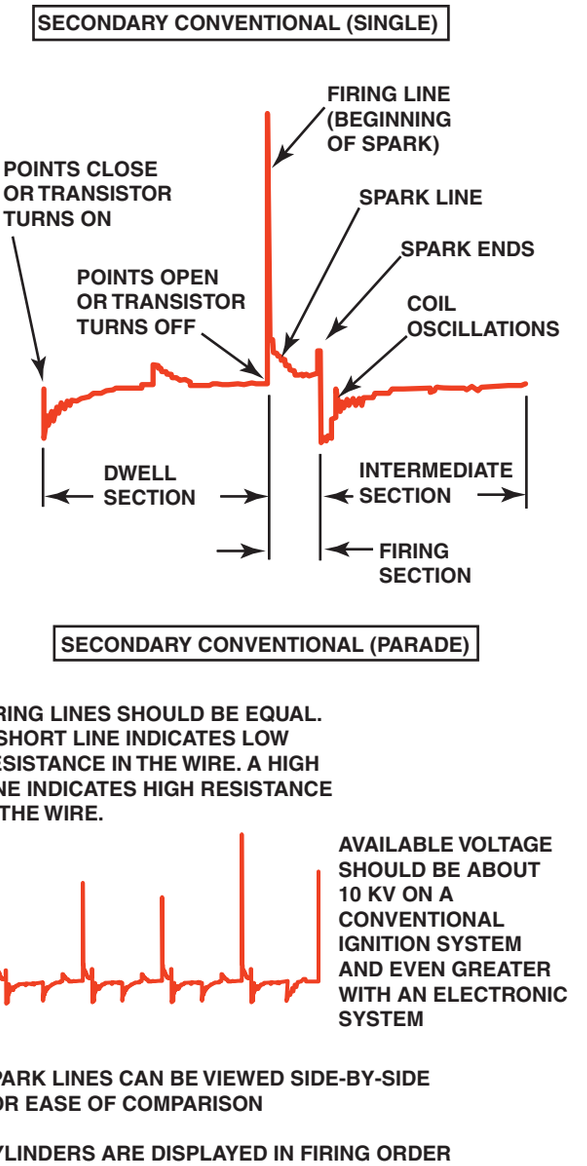

FIGURE 70–41 A single cylinder is shown at the top and a 4-cylinder engine at the bottom.

FIRING LINE The leftmost vertical (upward) line is called the **firing line.** The height of the firing line should be between 5,000 and 15,000 volts (5 and 15 kV) with not more than a 3 kV difference between the highest and the lowest cylinder's firing line. ● **SEE FIGURES 70–40 AND 70–41.**

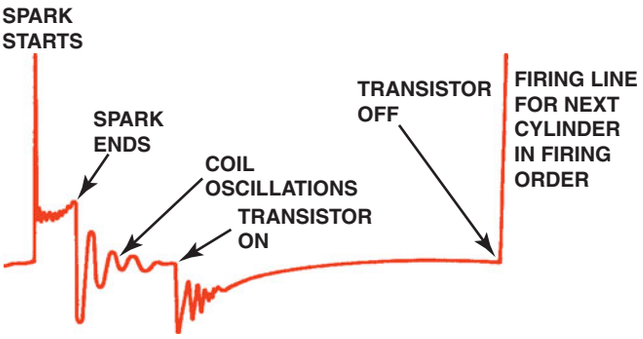

FIGURE 70–42 Drawing shows what is occurring electrically at each part of the scope pattern.

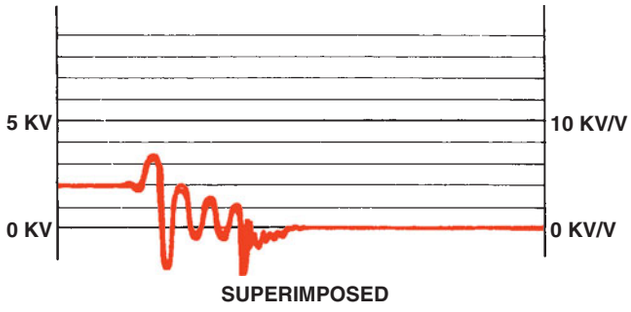

FIGURE 70–43 Typical secondary ignition pattern. Note the lack of firing lines on the superimposed pattern.

The height of the firing line indicates the *voltage* required to fire the spark plug. It requires a high voltage to make the air inside the cylinder electrically conductive (to ionize the air). One or more of the following conditions may cause higher-than-normal height firing lines.

1. Spark plug gapped too wide
2. Lean fuel mixture
3. Defective spark plug wire (excessive resistance or electrically open)

If the firing lines are higher than normal for *all* cylinders, then possible causes include one or more of the following:

1. Worn distributor cap and/or rotor (if the vehicle is so equipped)
2. Excessive wearing of all spark plugs
3. Defective coil wire (the high voltage could still jump across the open section of the wire to fire the spark plugs)

SPARK LINE

The **spark line** is a short horizontal line connected to the firing line. The height of the spark line represents the voltage required to maintain the spark across the spark plug after the spark has started. The height of the spark line should be one-fourth of the height of the firing line (between 1.5 and 2.5 kV). The length (from left to right) of the line represents the length of time for which the spark lasts (duration). The spark duration should be between 0.8 and 2.2 milliseconds (usually between 1.0 and 2.0 ms). The spark stops at the end (right side) of the spark line, as shown in ● **FIGURE 70–42.**

INTERMEDIATE OSCILLATIONS

After the spark has stopped, some energy remains in the coil. This remaining energy dissipates in the coil windings and the entire secondary circuit. The oscillations are also called the "ringing" of the coil as it is pulsed.

The secondary pattern amplifies any voltage variation occurring in the primary circuit because of the turns ratio between the primary and secondary windings of the ignition coil. A correctly operating ignition system should display five or more "bumps" (oscillations) (three or more for a GM HEI system).

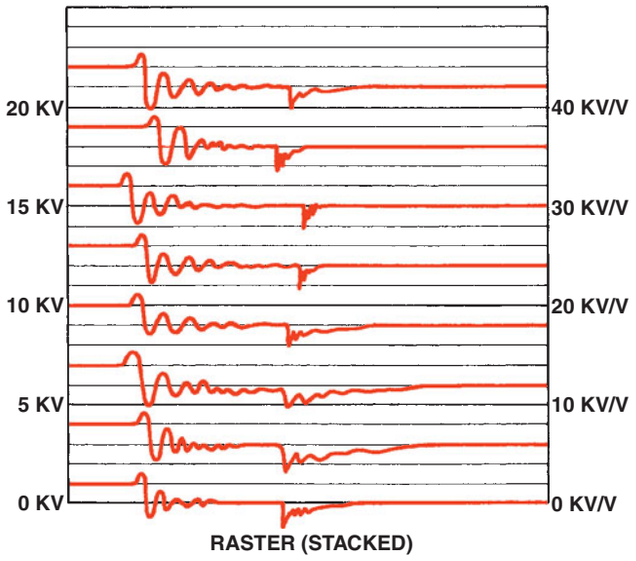

FIGURE 70–44 Raster is the best scope position to view the spark lines of all the cylinders to check for differences. Most scopes display cylinder 1 at the bottom. The other cylinders are positioned by firing order above cylinder 1.

TRANSISTOR-ON POINT

After the intermediate oscillations, the coil is empty (not charged), as indicated by the scope pattern being on the zero line for a short period. When the transistor turns on in an electronic ignition system, the coil is being charged. Note that the charging of the coil occurs slowly (coil-charging oscillations) because of the inductive reactance of the coil.

DWELL SECTION

Dwell is the amount of time that the current is charging the coil from the transistor-on point to the transistor-off point. The end of the dwell section marks the beginning of the next firing line. This point is called "transistor off," and indicates that the primary current of the coil is stopped, resulting in a high-voltage spark out of the coil.

PATTERN SELECTION

The entire pattern is not seen on a scope. Ignition oscilloscopes use three positions to view certain sections of the basic pattern more closely. These three positions are as follows:

1. **Superimposed.** This superimposed position is used to look at differences in patterns between cylinders in all areas except the firing line. There are no firing lines illustrated in superimposed positions. ● **SEE FIGURE 70–43.**
2. **Raster (*stacked*).** Cylinder 1 appears at the bottom of the screen and all other cylinder patterns are displayed upward in the engine's firing order. Use the raster (stacked) position to look at the spark line length and transistor-on point. The raster pattern shows all areas of the scope pattern except the firing lines. ● **SEE FIGURE 70–44.**
3. **Display *(parade).*** Display (parade) is the only position in which firing lines are visible and the cylinders are displayed on the screen from left to right in the engine's firing order. This selection is used to compare the height of firing lines among all cylinders. ● **SEE FIGURE 70–45.**

READING THE SCOPE ON DISPLAY (PARADE)

Start the engine and operate at approximately 1,000 RPM to ensure a smooth and accurate scope pattern. Firing lines are visible only on the display (parade) position. The firing lines should all be 5 to 15 kV in height and be within 3 kV of each other. If one or more cylinders have high firing lines, this could indicate a defective (open) spark

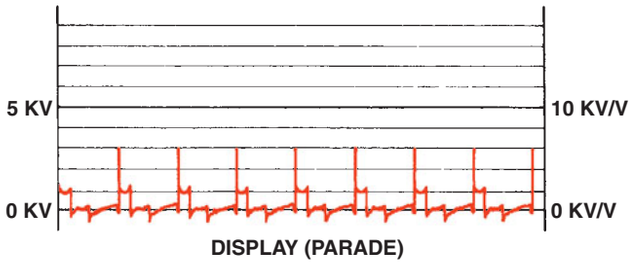

FIGURE 70–45 Display is the only position to view the firing lines of all cylinders. Cylinder 1 is displayed on the left (except for its firing line, which is shown on the right). The cylinders are displayed from left to right by firing order.

REAL WORLD FIX

A Technician's Toughie

A vehicle ran poorly, yet its scope patterns were "perfect." Remembering that the scope indicates only that a spark has occurred (not necessarily inside the engine), the technician grounded one spark plug wire at a time using a vacuum hose and a test light. Every time a plug wire was grounded, the engine ran worse, until the last cylinder was checked. When the last spark plug wire was grounded, the engine ran the same. The technician checked the spark plug wire with an ohmmeter; it tested within specifications (less than 10,000 ohms per foot of length). The technician also removed and inspected the spark plug. The spark plug looked normal. The spark plug was reinstalled and the engine tested again. The test had the same results as before—the engine seemed to be running on seven cylinders, yet the scope pattern was perfect.

The technician then replaced the spark plug for the affected cylinder. The engine ran correctly. Very close examination of the spark plug showed a thin crack between the wire terminal and the shell of the plug. Why didn't the cracked plug show on the scope? The scope simply indicated that a spark had occurred. The scope cannot distinguish between a spark inside and outside the engine. In this case, the voltage required to travel through the spark plug crack to ground was about the same voltage required to jump the spark plug electrodes inside the engine. The spark that occurred across the cracked spark plug, however, may have been visible at night with the engine running.

plug wire, a spark plug gapped too far, or a lean fuel mixture affecting only those cylinders.

A lean mixture (not enough fuel) requires a higher voltage to ignite because there are fewer droplets of fuel in the cylinder for the spark to use as "stepping stones" for the voltage to jump across. Therefore, a lean mixture is less conductive than a rich mixture.

READING THE SPARK LINES

Spark lines can easily be seen on either superimposed or raster (stacked) position. On the raster position, each individual spark line can be viewed.

The spark lines should be level and one-fourth as high as the firing lines (1.5 to 2.5 kV, but usually less than 2 kV). The spark line voltage is called the **burn kV.** The *length* of the spark line is the critical factor for determining proper operation of the engine because it represents the spark duration time. There is only a limited amount of energy in an ignition coil. If most of the energy is used to ionize the air

NORMAL SPARK LINE LENGTH (AT 700 TO 1200 RPM)

NUMBER OF CYLINDERS	MILLISECONDS	PERCENTAGE (%) OF DWELL SCALE	DEGREES
4	1–2	3–6	3–5
6	1–2	4–9	2–5
8	1–2	6–13	3–6

CHART 70–3

Converting between units is sometimes needed depending on the type of scope used.

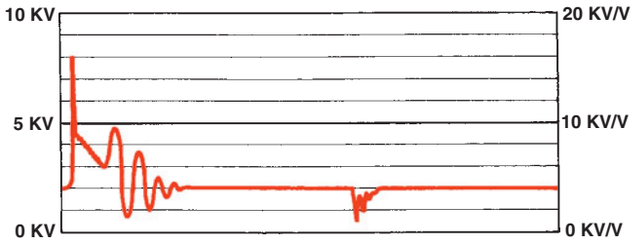

FIGURE 70–46 A downward-sloping spark line usually indicates high secondary ignition system resistance or an excessively rich air-fuel mixture.

gaps of the rotor and the spark plug, there may not be enough energy remaining to create a spark duration long enough to completely burn the air-fuel mixture. Many scopes are equipped with a **millisecond (ms) sweep.** This means that the scope will sweep only that portion of the pattern that can be shown during a 5 ms or 25 ms setting.

Following are guidelines for spark line length.

- 0.8 ms: too short
- 1.5 ms: average
- 2.2 ms: too long

If the spark line is too short, possible causes include the following:

1. Spark plug(s) gapped too widely
2. Rotor tip to distributor cap insert distance gapped too widely (worn cap or rotor)
3. High-resistance spark plug wire
4. Air-fuel mixture too lean (vacuum leak, broken valve spring, etc.)

If the spark line is too long, possible causes include the following:

1. Fouled spark plug(s)
2. Spark plug(s) gapped too closely
3. Shorted spark plug or spark plug wire

Many scopes do not have a millisecond scale. Some scopes are labeled in degrees and/or percentage (%) of dwell. ● **CHART 70–3** can be used to determine acceptable spark line length.

SPARK LINE SLOPE

Downward-sloping spark lines indicate that the voltage required to maintain the spark duration is decreasing during the firing of the spark plug. Although it is normal for the spark line to angle downward slightly, a steep slope indicates that the spark energy is finding ground through spark plug deposits (the plug is fouled) or other ignition problems. ● **SEE FIGURE 70–46.**

An upward-sloping spark line usually indicates a mechanical engine problem. A defective piston ring or valve would tend to seal better in the increasing pressures of combustion. As the spark plug fires, the effective increase in pressures increases the voltage required to maintain the spark, and the height of the spark line rises during the duration of the spark. ● **SEE FIGURE 70–47.**

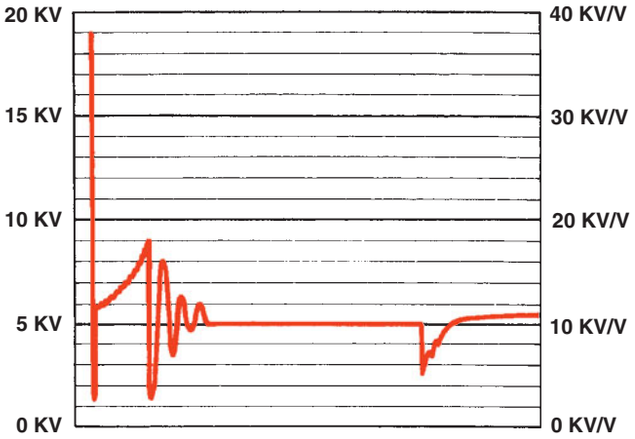

FIGURE 70–47 An upward-sloping spark line usually indicates a mechanical engine problem or a lean air-fuel mixture.

An upward-sloping spark line can also indicate a lean air-fuel mixture. Typical causes include:

1. Clogged injector(s)
2. Vacuum leak
3. Sticking intake valve

● **SEE FIGURE 70–48** for an example showing the relationship between the firing line and the spark line.

READING THE INTERMEDIATE SECTION

The intermediate section should have three or more oscillations (bumps) for a correctly operating ignition system. Because approximately 250 volts are in the primary ignition circuit when the spark stops flowing across the spark plugs, this voltage is reduced by about 75 volts per oscillation. Additional resistances in the primary circuit would decrease the number of oscillations. If there are fewer than three oscillations, possible problems include the following:

1. Shorted ignition coil
2. Loose or high-resistance primary connections on the ignition coil or primary ignition wiring

DWELL AND CURRENT-LIMITING HUMP

Ignition systems use a dwell period to charge the coil. Dwell is the time that current is charging the coil, and changes with increasing RPM in many electronic ignition systems. This change in dwell with RPM should be considered normal.

Many EI systems also produce a "hump" in the dwell section, which reflects a current-limiting circuit in the control module. These current-limiting humps may have slightly different shapes depending on the exact module used. For example, the humps produced by various GM HEI modules differ slightly.

DWELL VARIATION (DISTRIBUTOR IGNITION)

A worn distributor gear, worn camshaft gear, or other distributor problem may cause engine performance problems, because the signal created in the distributor will be affected by the inaccurate distributor operation. However, many electronic ignitions vary the length of the dwell period electronically in the module to maintain acceptable current flow levels through the ignition coil and ignition control module (ICM).

Different EI systems use one of three different designs. The dwell length characteristic and the types of EI systems that use each design are as follows:

1. Dwell time remains *constant* as the engine speed is increased.
2. Dwell time *decreases* as the engine speed is increased.
3. Dwell time *increases* as the engine speed is increased.

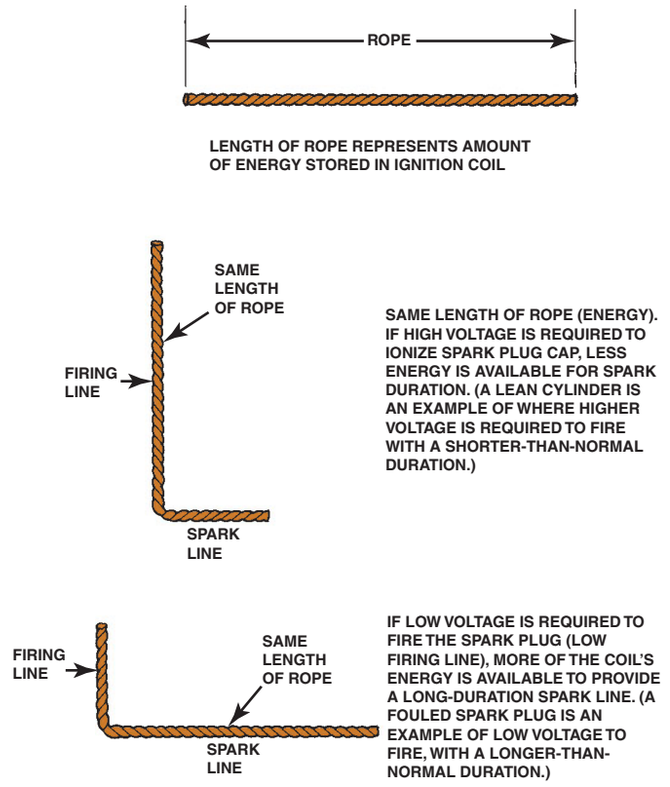

FIGURE 70–48 The relationship between the height of the firing line and length of the spark line can be illustrated using a rope. Because energy cannot be destroyed, the stored energy in an ignition coil must dissipate totally, regardless of engine operating conditions.

NOTE: Waste-spark and coil-on-plug ignition systems also vary dwell time electronically within the PCM or ignition module.

ACCELERATION CHECK

With the scope selector set on the display (parade) position, rapidly accelerate the engine (gear selector in park or neutral with the parking brake on). The results should be interpreted as follows:

1. All firing lines should rise evenly (not to exceed 75% of maximum coil output) for properly operating spark plugs.
2. If the firing lines on one or more cylinders fail to rise, this indicates fouled spark plugs.

ROTOR GAP VOLTAGE (DI SYSTEMS)

The rotor gap voltage test measures the voltage required to jump the gap (0.03 to 0.05 in., or 0.8 to 1.3 mm) between the rotor and the inserts (segments) of the distributor cap. Select the display (parade) scope pattern and remove a spark plug wire (at the spark plug end), then using a jumper connected to a good ground, insert the jumper into the spark plug boot making sure it contacts the plug wire terminal. Start the engine and observe the height of the firing line for the cylinder being tested. Because the spark plug wire is connected directly to ground, the firing line height on the scope will indicate the voltage required to jump the air gap between the rotor and the distributor cap insert. The normal rotor gap voltage is 3 to 7 kV, and the voltage should not exceed 8 kV. If the rotor gap voltage indicated is near or above 8 kV, inspect and replace the distributor cap and/or rotor as required.

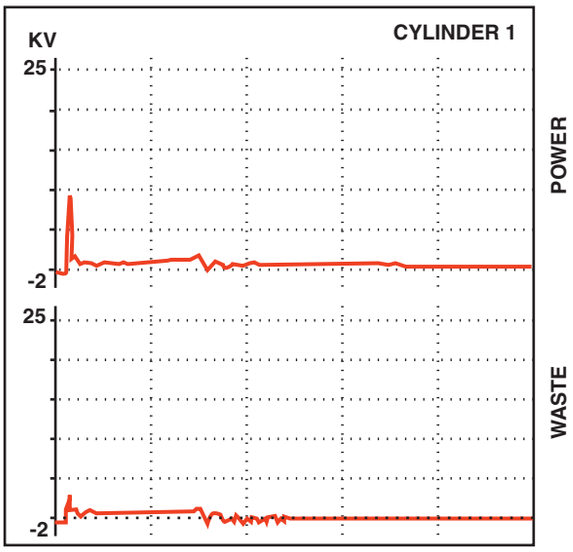

FIGURE 70–49 A dual trace scope pattern showing both the power and the waste spark from the same coil (cylinders 1 and 6). Note that the firing line is higher on the cylinder that is under compression (power); otherwise, both patterns are almost identical.

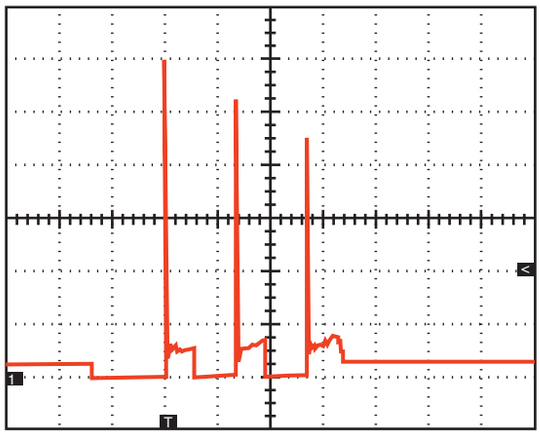

FIGURE 70–50 A secondary waveform of a Ford 4.6 liter V-8, showing three sparks occurring at idle speed.

The spark plugs are fired three times when the engine is at idle speed to improve idle quality and to reduce exhaust emissions. Above certain engine speeds, the ignition system switches to a single-fire event. ● **SEE FIGURE 70–50.**

SCOPE-TESTING A WASTE-SPARK SYSTEM

A handheld digital storage oscilloscope can be used to check the pattern of individual cylinders. Some larger scopes can be connected to all spark plug wires and therefore are able to display both power and waste-spark waveforms. ● **SEE FIGURE 70–49.**

Because the waste spark does not require as high a voltage level as the cylinder on the power stroke, the waste-spark firing line will be normally lower. The high and low firing lines will alternately change from high to low as the "paired" cylinders change from the compression to the exhaust strokes.

SCOPE-TESTING A COP SYSTEM

On a coil-on-plug (COP) type of ignition system, the individual coils can be shown on a scope and using the proper cables and adapters, the waveform for all of the cylinders can be viewed at the same time. Always follow the scope equipment manufacturer's instructions. Many Ford COP systems use a triple-strike secondary spark event.

COMPUTER FUNDAMENTALS

PURPOSE AND FUNCTION Modern automotive control systems consist of a network of electronic sensors, actuators, and computer modules designed to regulate the powertrain and vehicle support systems. The onboard automotive computer has many names. It may be called an **electronic control unit (ECU), electronic control module (ECM), electronic control assembly (ECA),** or a **controller,** depending on the manufacturer and the computer application. The **Society of Automotive Engineers (SAE)** bulletin J1930 standardizes the name as a **powertrain control module (PCM).** The PCM coordinates engine and transmission operation, processes data, maintains

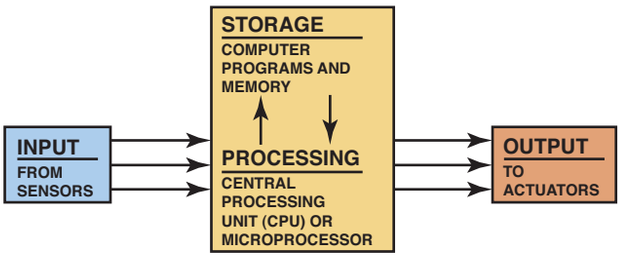

FIGURE 71–1 All computer systems perform four basic functions: input, processing, storage, and output.

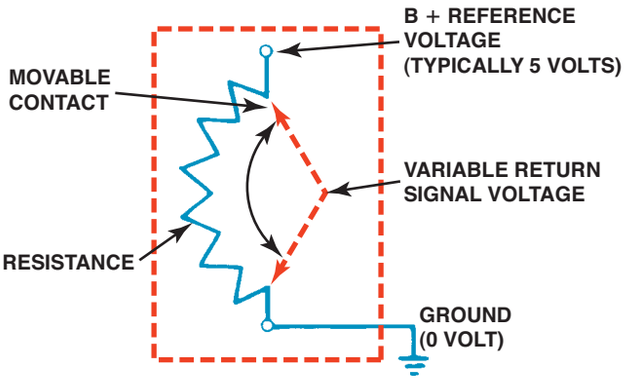

FIGURE 71–2 A potentiometer uses a movable contact to vary resistance and send an analog voltage right to the PCM.

communications, and makes the control decisions needed to keep the vehicle operating. Not only is it capable of operating the engine and transmission, but it is also able to perform the following:

- Undergo self-tests (40% of the computing power is devoted to diagnosis)
- Set and store diagnostic trouble codes (DTCs)
- Communicate with the technician using a scan tool

VOLTAGE SIGNALS Automotive computers use voltage to send and receive information. Voltage is electrical pressure and does not flow through circuits, but voltage can be used as a signal. A computer converts input information or data into voltage signal combinations that represent number combinations. A computer processes the input voltage signals it receives by computing what they represent, and then delivering the data in computed or processed form.

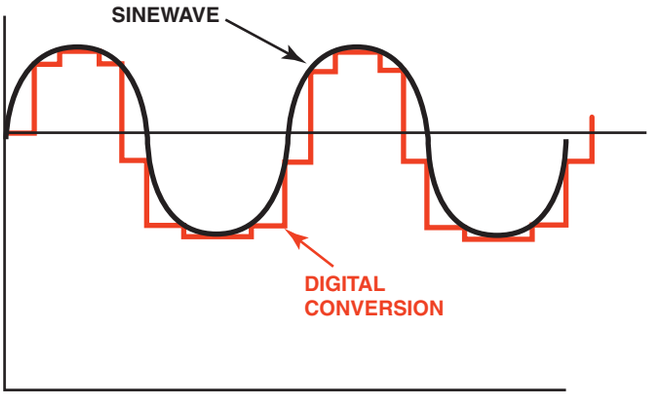

FIGURE 71–3 An AD converter changes analog (variable) voltage signals into digital signals that the PCM can process.

COMPUTER FUNCTIONS

BASIC FUNCTIONS The operation of every computer can be divided into four basic functions. ● **SEE FIGURE 71–1.**

- **Input.** Receives voltage signals from sensors
- **Processing.** Performs mathematical calculations
- **Storage.** Includes short-term and long-term memory
- **Output.** Controls an output device by either turning it on or off

INPUT FUNCTIONS First, the computer receives a voltage signal (input) from an input device. **Input** is a signal from a device that can be as simple as a button or a switch on an instrument panel, or a sensor on an automotive engine. ● **SEE FIGURE 71–2** for a typical type of automotive sensor.

Vehicles use various mechanical, electrical, and magnetic sensors to measure factors such as vehicle speed, throttle position, engine RPM, air pressure, oxygen content of exhaust gas, airflow, engine coolant temperature, and status of electrical circuits (on-off). Each sensor transmits its information in the form of voltage signals. The computer receives these voltage signals, but before it can use them, the signals must undergo a process called **input conditioning.** This process includes amplifying voltage signals that are too small for the computer circuitry to handle. Input conditioners generally are located inside the computer, but a few sensors have their own input conditioning circuitry.

A digital computer changes the analog input signals (voltage) to digital bits (*bi*nary digit*s*) of information through an **analog-to-digital (AD) converter** circuit. The binary digital number is used by the computer in its calculations or logic networks. ● **SEE FIGURE 71–3.**

PROCESSING The term *processing* is used to describe how input voltage signals received by a computer are handled through a series of electronic logic circuits maintained in its programmed instructions. These logic circuits change the input voltage signals, or data, into output voltage signals or commands.

STORAGE Storage is the place where the program instructions for a computer are stored in electronic memory. Some programs may require that certain input data be stored for later reference or future processing. In others, output commands may be delayed or stored before they are transmitted to devices elsewhere in the system.

Computers have two types of memory.

1. Permanent memory is called **read-only memory (ROM)** because the computer can only read the contents; it cannot change the data stored in it. This data is retained even when power to the computer is shut off. Part of the ROM is built into the computer, and the rest is located in an integrated circuit (IC) chip called a **programmable read-only memory (PROM)** or calibration assembly. Many chips are erasable, meaning that the program can be changed. These chips are called erasable programmable read-only memory, or EPROM. Since the early 1990s, most programmable memory has been electronically erasable, meaning that the program in the chip can be reprogrammed by using a scan tool and the proper software. This computer reprogramming is usually called *reflashing*. These chips are electrically erasable programmable read-only memory, abbreviated **EEPROM** or **E²PROM.**

   All vehicles equipped with onboard diagnosis second generation, called OBD-II, are equipped with EEPROMs.

2. Temporary memory is called **random-access memory (RAM),** because the computer can write or store new data into it as directed by the computer program, as well as read the data already in it. Automotive computers use two types of RAM memory.
   - Volatile RAM memory is lost whenever the ignition is turned off. However, a type of volatile RAM called **keep-alive memory (KAM)** can be wired directly to battery power. This prevents its data from being erased when the ignition is turned off. One example of RAM and KAM is the loss of station settings in a programmable radio when the battery is disconnected. Because all the settings are stored in RAM, they have to be reset when the battery is reconnected. System trouble codes are commonly stored in RAM and can be erased by disconnecting the battery.
   - **Nonvolatile RAM** memory can retain its information even when the battery is disconnected. One use for this type of RAM is the storage of odometer information in an electronic speedometer. The memory chip retains the mileage accumulated by the vehicle. When speedometer replacement is necessary, the odometer chip is removed and installed in the new speedometer unit. KAM is used primarily in conjunction with adaptive strategies.

OUTPUT FUNCTIONS

After the computer has processed the input signals, it sends voltage signals or commands to other devices in the system, such as system actuators. An **actuator** is an electrical or mechanical output device that converts electrical energy into a mechanical action, such as:

- Adjusting engine idle speed
- Operating fuel injectors
- Ignition timing control
- Altering suspension height

COMPUTER COMMUNICATION

A typical vehicle can have many computers, also called modules or controllers. Computers also can communicate with, and control, each other through their output and input functions. This means that the output signal from one computer system can be the input signal for another computer system through a data network. See Chapter 14 for details on network communications.

DIGITAL COMPUTERS

PARTS OF A COMPUTER

The software consists of the programs and logic functions stored in the computer's circuitry. The hardware is the mechanical and electronic parts of a computer.

- **Central processing unit.** The microprocessor is the **central processing unit (CPU)** of a computer. Because it performs the essential mathematical operations and logic decisions that make up its processing function, the CPU can be considered the brain of a computer. Some computers use more than one microprocessor, called a coprocessor. The digital computer can process thousands of digital signals per second because its circuits are able to switch voltage signals on and off in billionths of a second. It is called a **digital computer** because it processes zeros and ones (digits) and needs to have any variable input signals, called analog inputs, converted to digital form before it can function. ● **SEE FIGURE 71–4.**

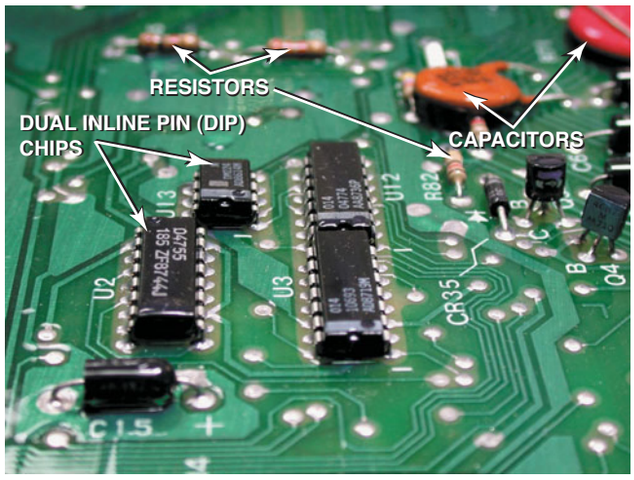

FIGURE 71–4 Many electronic components are used to construct a typical vehicle computer including chips, resistors, and capacitors.

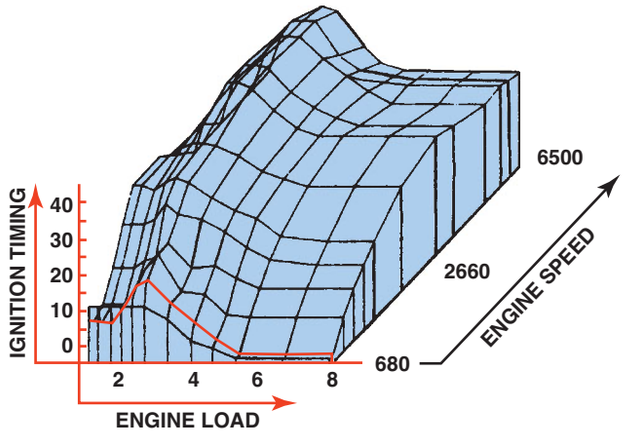

FIGURE 71–5 Typical engine map developed from testing and used by the vehicle computer to provide the optimum ignition timing for all engine speeds and load combinations.

- **Computer memory.** Other integrated circuit (IC) devices store the computer operating program, system sensor input data, and system actuator output data—information that is necessary for CPU operation.
- **Computer programs.** By operating a vehicle on a dynamometer and manually adjusting the variable factors such as speed, load, and spark timing, it is possible to determine the optimum output settings for the best driveability, economy, and emission control. This is called engine mapping. ● **SEE FIGURE 71–5.**

Engine mapping creates a three-dimensional performance graph that applies to a given vehicle and powertrain combination. Each combination is mapped in this manner to produce a PROM or EEPROM calibration. This allows an automaker to use one basic computer for all models.

Many older-vehicle computers used a single PROM that plugged into the computer.

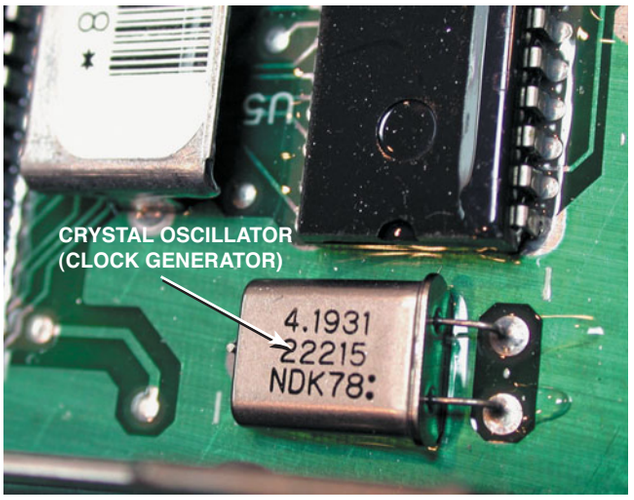

FIGURE 71–6 The clock generator produces a series of pulses that are used by the microprocessor and other components to stay in step with each other at a steady rate.

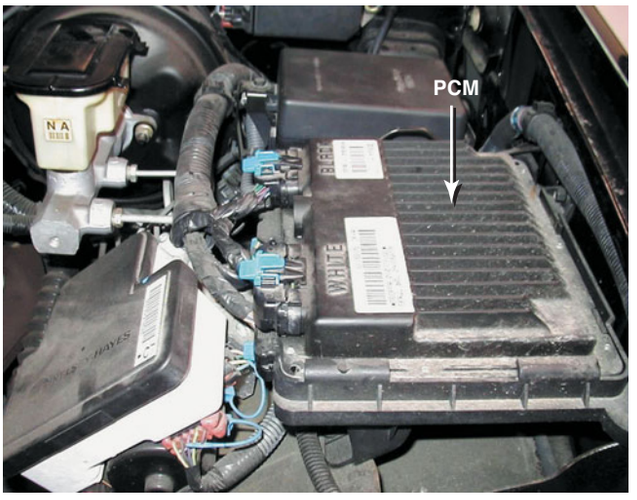

FIGURE 71–7 This powertrain control module (PCM) is located under the hood on this Chevrolet pickup truck.

NOTE: If the computer needs to be replaced, the PROM or calibration module must be removed from the defective unit and installed in the replacement computer. Since the mid-1990s, PCMs do not have removable calibration PROMs, and must be programmed or *flashed* using a scan tool before being put into service.

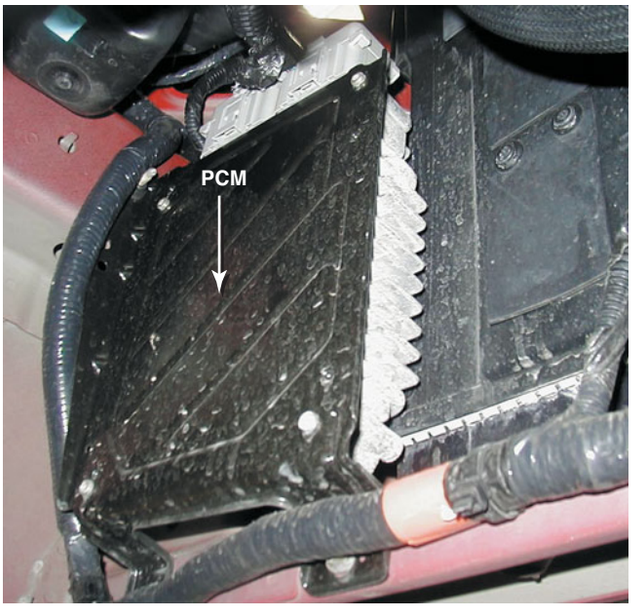

FIGURE 71–8 This PCM on a Chrysler vehicle can only be seen by hoisting the vehicle, because it is located next to the radiator and in the airflow to help keep it cool.

CLOCK RATES AND TIMING

The microprocessor receives sensor input voltage signals, processes them by using information from other memory units, and then sends voltage signals to the appropriate actuators. The microprocessor communicates by transmitting long strings of 0s and 1s in a language called binary code; but the microprocessor must have some way of knowing when one signal ends and another begins. That is the job of a crystal oscillator called a **clock generator.** ● **SEE FIGURE 71–6.**

The computer's crystal oscillator generates a steady stream of one-bit-long voltage pulses. Both the microprocessor and the memories monitor the clock pulses while they are communicating. Because they know how long each voltage pulse should be, they can distinguish between a 01 and a 0011. To complete the process, the input and output circuits also watch the clock pulses.

COMPUTER SPEEDS

Not all computers operate at the same speed; some are faster than others. The speed at which a computer operates is specified by the cycle time, or clock speed, required to perform certain measurements. Cycle time or clock speed is measured in megahertz (4.7 MHz, 8 MHz, 15 MHz, 18 MHz, and 32 Hz, which is the clock speed of most vehicle computers today).

BAUD RATE

The computer transmits bits of a serial datastream at precise intervals. The computer's speed is called the **baud rate,** or bits per second. The term *baud* was named after J. M. Emile Baudot (1845–1903), a French telegraph operator who developed a five-bit-per-character code of telegraph. Just as mph helps in estimating the length of time required to travel a certain distance, the baud rate is useful in estimating how long a given computer will need to transmit a specified amount of data to another computer.

Automotive computers have evolved from a baud rate of 160 used in the early 1980s to a baud rate as high as 500,000 for some networks. The speed of data transmission is an important factor both in system operation and in system troubleshooting.

CONTROL MODULE LOCATIONS

The computer hardware is all mounted on one or more circuit boards and installed in a metal case to help shield it from electromagnetic interference (EMI). The wiring harnesses that link the computer to sensors and actuators connect to multipin connectors or edge connectors on the circuit boards.

Onboard computers range from single-function units that control a single operation to multifunction units that manage all of the separate (but linked) electronic systems in the vehicle. They vary in size from a small module to a notebook-size box. Most other engine computers are installed in the passenger compartment either under the instrument panel or in a side kick panel where they can be shielded from physical damage caused by temperature extremes, dirt, and vibration, or interference by the high currents and voltages of various underhood systems. ● **SEE FIGURES 71–7 AND 71–8.**

FREQUENTLY ASKED QUESTION

What Is a Binary System?

In a digital computer the signals are simple high-low, yes-no, on-off signals. The digital signal voltage is limited to two voltage levels: high voltage and low voltage. Since there is no stepped range of voltage or current in between, a digital binary signal is a "square wave." The signal is called "digital" because the on and off signals are processed by the computer as the digits or numbers 0 and 1. The number system containing only these two digits is called the **binary system.** Any number or letter from any number system or language alphabet can be translated into a combination of binary 0s and 1s for the digital computer. A digital computer changes the analog input signals (voltage) to digital bits (*bi*nary digi*ts*) of information through an analog-to-digital (AD) converter circuit. The binary digital number is used by the computer in its calculations or logic networks. Output signals usually are digital signals that turn system actuators on and off.

COMPUTER INPUT SENSORS

The vehicle computer uses signals (voltage levels) from the following sensors.

- **Engine speed (revolutions per minute, or RPM) sensor.** This signal comes from the primary ignition signal in the ignition control module (ICM) or directly from the crankshaft position (CKP) sensor.
- **Switches or buttons for accessory operation.** Many accessories use control buttons that signal the body computer to turn on or off an accessory such as the windshield wiper or heated seats.
- **Manifold absolute pressure (MAP) sensor.** This sensor detects engine load by using a signal from a sensor that measures the vacuum in the intake manifold.
- **Mass airflow (MAF) sensor.** This sensor measures the mass (weight and density) of the air flowing through the sensor and entering the engine.
- **Engine coolant temperature (ECT) sensor.** This sensor measures the temperature of the engine coolant. This is a sensor used for engine controls and for automatic air-conditioning control operation.
- **Oxygen sensor (O2S).** This sensor measures the oxygen in the exhaust stream. There are as many as four oxygen sensors in some vehicles.
- **Throttle position (TP) sensor.** This sensor measures the throttle opening and is used by the computer for engine control and the shift points of the automotive transmission/transaxle.
- **Vehicle speed (VS) sensor.** This sensor measures the vehicle speed using a sensor located at the output of the transmission/transaxle or by monitoring sensors at the wheel speed sensors. This sensor is used by the speedometer, cruise control, and airbag systems.

COMPUTER OUTPUTS

OUTPUT CONTROLS After the computer has processed the input signals, it sends voltage signals or commands to other devices in the system, as follows:

- **Operate actuators.** An actuator is an electrical or mechanical device that converts electrical energy into heat, light, or motion to control engine idle speed, suspension height, ignition timing, and other output devices.
- **Network communication.** Computers also can communicate with another computer system through a network.

A vehicle computer can do only two things.

1. Turn a device on.
2. Turn a device off.

Typical output devices include the following:

- **Fuel injectors.** The computer can vary the amount of time in milliseconds the injectors are held open, thereby controlling the amount of fuel supplied to the engine.
- **Blower motor control.** Many blower motors are controlled by the body computer by pulsing the current on and off to maintain the desired speed.
- **Transmission shifting.** The computer provides a ground to the shift solenoids and torque converter clutch (TCC) solenoid. The operation of the automatic transmission/transaxle is optimized based on vehicle sensor information.
- **Idle speed control.** The computer can control the idle air control (IAC) or electronic throttle control (ETC) to maintain engine idle speed and to provide an increased idle speed as needed.
- **Evaporative emission control solenoids.** The computer can control the flow of gasoline fumes from the charcoal canister to the engine and seal off the system to perform a fuel system leak detection test as part of the OBD-II system requirements.

Most outputs work electrically in one of three ways:

1. Digital
2. Pulse-width modulated
3. Switched

Digital control is mostly used for computer communications and involves voltage signals that are transmitted and received in packets.

Pulse-width control allows a device, such as a blower motor, to be operated at variable speed by changing the amount of time electrical power is supplied to the device.

A switched output is an output that is either on or off. In many circuits, the PCM uses a relay to switch a device on or off, because the relay is a low-current device that can switch to a higher current device. Most computer circuits cannot handle high amounts of current. By using a relay circuit, the PCM provides the output control to the relay, which in turn provides the output control to the device.

The relay coil, which the PCM controls, typically draws less than 0.5 ampere. The device that the relay controls may draw 30 amperes or more. The PCM switches are actually transistors, and are often called **output drivers.** ● **SEE FIGURE 71–9.**

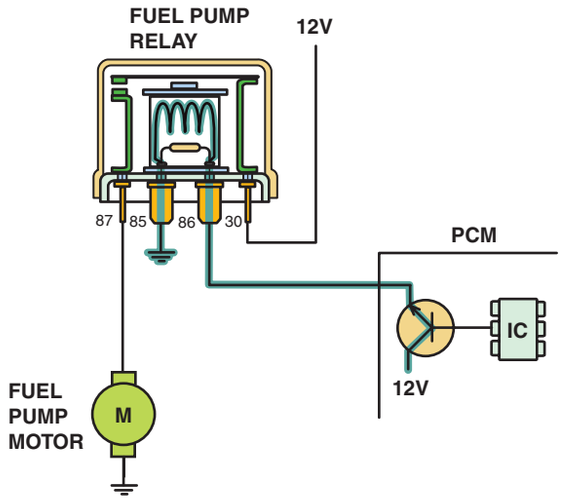

FIGURE 71–9 A typical output driver. In this case, the PCM applies voltage to the fuel pump relay coil to energize the fuel pump.

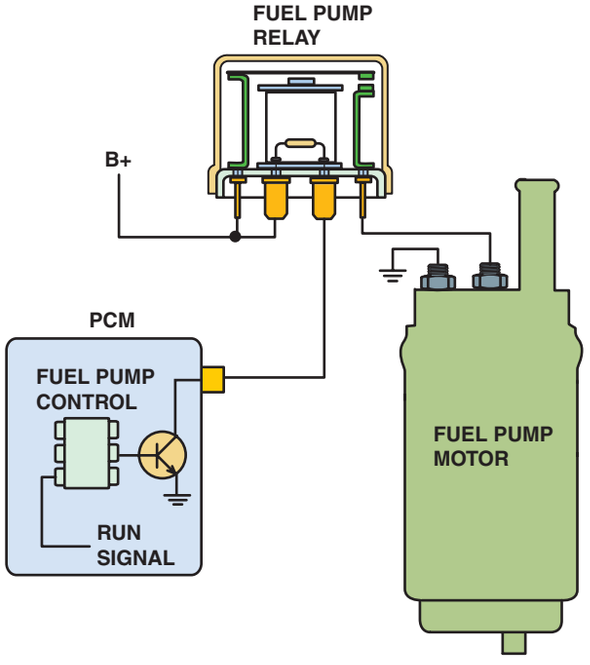

FIGURE 71–10 A typical low-side driver (LSD) which uses a control module to control the ground side of the relay coil.

OUTPUT DRIVERS

There are two basic types of output drivers.

1. **Low-side drivers.** The low-side drivers (LSDs) are transistors inside the computer that complete the ground path of relay coil. Ignition (key-on) voltage and battery voltage are supplied to the relay. The ground side of the relay coil is connected to the transistor inside the computer. In the example of a fuel pump relay, when the transistor turns "on," it will complete the ground for the relay coil, and the relay will then complete the power circuit between the battery power and the fuel pump. A relatively low current flows through the relay coil and transistor that is inside the computer. This causes the relay to switch and provides the fuel pump with battery voltage. The majority of switched outputs have typically been low-side drivers. ● **SEE FIGURE 71–10.**

   Low-side drivers can often perform a diagnostic circuit check by monitoring the voltage from the relay to check that the control circuit for the relay is complete. A low-side driver, however, cannot detect a short-to-ground.

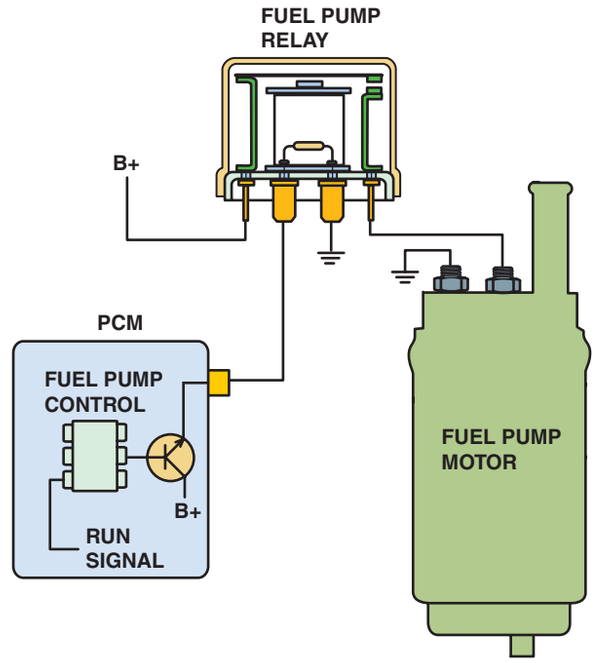

FIGURE 71–11 A typical module-controlled high-side driver (HSD) where the module itself supplies the electrical power to the device. The logic circuit inside the module can detect circuit faults including continuity of the circuit and if there is a short-to-ground in the circuit being controlled.

2. **High-side drivers.** The high-side drivers (HSDs) control the power side of the circuit. In these applications when the transistor is switched on, voltage is applied to the device. A ground has been provided to the device so when the high-side driver switches, the device will be energized. In some applications, high-side drivers are used instead of low-side drivers to provide better circuit protection. General Motors vehicles have used a high-side driver to control the fuel pump relay instead of a low-side driver. In the event of an accident, should the circuit to the fuel pump relay become grounded, a high-side driver would cause a short circuit, which would cause the fuel pump relay to de-energize. High-side drivers inside modules can detect electrical faults such as a lack of continuity when the circuit is not energized. ● **SEE FIGURE 71–11.**

PULSE-WIDTH MODULATION

Pulse-width modulation (PWM) is a method of controlling an output using a digital signal. Instead of just turning devices on or off, the computer can control the amount of on-time. For example, a solenoid could be a PWM device. If, for example, a vacuum solenoid is controlled by a switched driver, switching either on or off would mean that either full vacuum would flow through the solenoid or no vacuum would flow through the solenoid. However, to control the amount of vacuum that flows through the solenoid, pulse-width modulation could be used. A PWM signal is a digital signal, usually 0 volt and 12 volts, which is cycling at a fixed frequency. Varying the length of time that the signal is on provides a signal that can vary the on- and off-time of an output. The ratio of on-time relative to the period of the cycle is referred to as **duty cycle.** ● **SEE FIGURE 71–12.**

Depending on the frequency of the signal, which is usually fixed, this signal would turn the device on and off a fixed number of times per second. When, for example, the voltage is high (12 volts) 90% of the time and low (0 volt) the other 10% of the time, the signal has a 90% duty cycle. In other words, if this signal were applied to

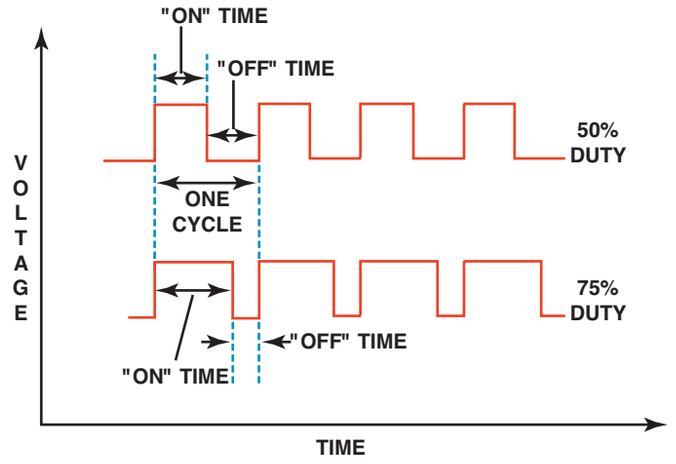

FIGURE 71–12 Both the top and bottom pattern have the same frequency. However, the amount of on-time varies. Duty cycle is the percentage of the time during a cycle that the signal is turned on.

the vacuum solenoid, the solenoid would be on 90% of the time. This would allow more vacuum to flow through the solenoid. The computer has the ability to vary this on- and off-time or pulse-width modulation at any rate between 0% and 100%. A good example of pulse-width modulation is the cooling fan speed control. The speed of the cooling fan is controlled by varying the amount of on-time that the battery voltage is applied to the cooling fan motor.

- 100% duty cycle: fan runs at full speed
- 75% duty cycle: fan runs at 3/4 speed
- 50% duty cycle: fan runs at 1/2 speed
- 25% duty cycle: fan runs at 1/4 speed

The use of PWM, therefore, results in precise control of an output device to achieve the amount of cooling needed and conserve electrical energy compared to simply timing the cooling fan on high when needed. PWM may be used to control vacuum through a solenoid, the amount of purge of the evaporative purge solenoid, the speed of a fuel pump motor, control of a linear motor, or even the intensity of a light bulb.

TEMPERATURE SENSORS

OBJECTIVES: **After studying Chapter 72, the reader will be able to:** • Prepare for ASE Engine Performance (A8) certification test content area "E" (Computerized Engine Controls Diagnosis and Repair). • Explain the purpose and function of the ECT and IAT temperature sensors. • Describe how to test temperature sensors. • Discuss how automatic transmission fluid temperature sensor values can affect transmission operation.

KEY TERMS: Cylinder head temperature (CHT) 826 • Engine coolant temperature (ECT) 819 • Engine fuel temperature (EFT) 826 • Negative temperature coefficient (NTC) 819 • Throttle-body temperature (TBT) 824 • Transmission fluid temperature (TFT) 825

ENGINE COOLANT TEMPERATURE SENSORS

PURPOSE AND FUNCTION Computer-equipped vehicles use an **engine coolant temperature (ECT)** sensor. When the engine is cold, the fuel mixture must be richer to prevent stalling and engine stumble. When the engine is warm, the fuel mixture can be leaner to provide maximum fuel economy with the lowest possible exhaust emissions. Because the computer controls spark timing and fuel mixture, it will need to know the engine temperature. An engine coolant temperature (ECT) sensor installed into the engine coolant passage will provide the computer with this information. ● **SEE FIGURE 72–1.** This will be the most important (high-authority) sensor while the engine is cold. The ignition timing can also be tailored to engine (coolant) temperature. A hot engine cannot have the spark timing as far advanced as can a cold engine. The ECT sensor is also used as an important input for the following:

- Idle air control (IAC) position
- Oxygen sensor closed-loop status
- Canister purge on/off times
- Idle speed

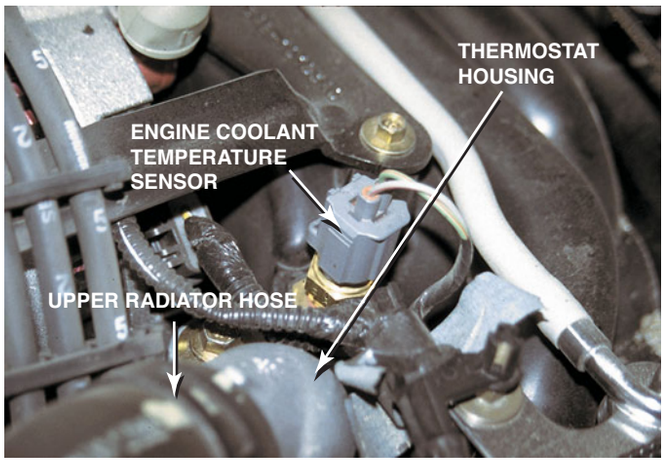

FIGURE 72–1 A typical engine coolant temperature (ECT) sensor. ECT sensors are located near the thermostat housing on most engines.

ECT SENSOR CONSTRUCTION Engine coolant temperature sensors are constructed of a semiconductor material that decreases in resistance as the temperature of the sensor increases. Coolant sensors have very high resistance when the coolant is cold and low resistance when the coolant is hot. This is referred to as having a **negative temperature coefficient (NTC),** which is opposite to the situation with most other electrical components. ● **SEE FIGURE 72–2.** Therefore, if the coolant sensor has a poor connection (high resistance) at the wiring connector, the computer will supply a richer-than-normal fuel mixture based on the resistance of the coolant sensor. Poor fuel economy and a possible-rich code can be caused by a defective sensor or high resistance in the sensor wiring. If the sensor was shorted or defective and had too low a resistance, a leaner-than-normal fuel mixture would be supplied to the engine. A too-lean fuel mixture can cause driveability problems and a possible-lean computer code.

STEPPED ECT CIRCUITS Some vehicle manufacturers use a step-up resistor to effectively broaden the range of the ECT sensor. Chrysler and General Motors vehicles use the same sensor as a non-stepped ECT circuit, but instead apply the sensor voltage through two different resistors.

- When the temperature is cold, usually below 120°F (50°C), the ECT sensor voltage is applied through a high-value resistor inside the PCM.
- When the temperature is warm, usually above 120°F (50°C), the ECT sensor voltage is applied through a much lower resistance value inside the PCM. ● **SEE FIGURE 72–3.**

The purpose of this extra circuit is to give the PCM a more accurate reading of the engine coolant temperature compared to the same sensor with only one circuit. ● **SEE FIGURE 72–4.**

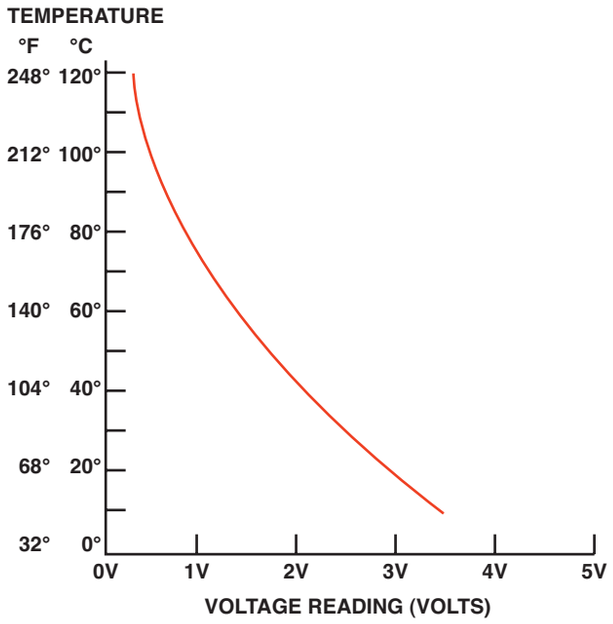

FIGURE 72–2 A typical ECT sensor temperature versus voltage curve.

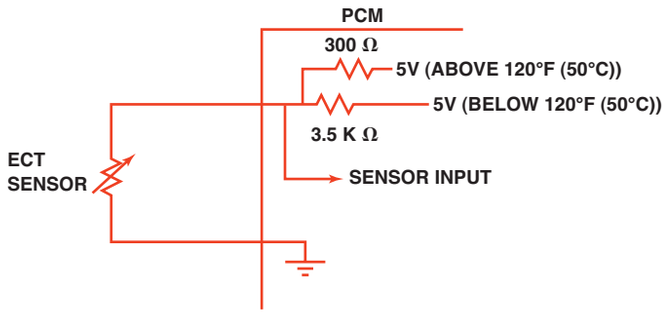

FIGURE 72–3 A typical two-step ECT circuit showing that when the coolant temperature is low, the PCM applies a 5-volt reference voltage to the ECT sensor through a higher resistance compared to when the temperature is higher.

TESTING THE ENGINE COOLANT TEMPERATURE SENSOR

TESTING THE ENGINE COOLANT TEMPERATURE BY VISUAL INSPECTION

The correct functioning of the engine coolant temperature (ECT) sensor depends on the following items that should be checked or inspected:

- **Properly filled cooling system.** Check that the radiator reservoir bottle is full and that the radiator itself is filled to the top.

  CAUTION: Be sure that the radiator is cool before removing the radiator cap to avoid being scalded by hot coolant.

  The ECT sensor must be submerged in coolant to be able to indicate the proper coolant temperature.
- **Proper pressure maintained by the radiator cap.** If the radiator cap is defective and cannot allow the cooling system to become pressurized, air pockets could develop. These air pockets could cause the engine to operate at a hotter-than-normal temperature and prevent proper temperature measurement, especially if the air pockets occur around the sensor.
- **Proper antifreeze–water mixture.** Most vehicle manufacturers recommend a 50/50 mixture of antifreeze and water as the best compromise between freezing protection and heat transfer ability.
- **Proper operation of the cooling fan.** If the cooling fan does not operate correctly, the engine may overheat.

TESTING THE ECT USING A MULTIMETER

Both the resistance (in ohms) and the voltage drop across the sensor can be measured and compared with specifications. ● **SEE FIGURE 72–5.** See the following charts showing examples of typical engine coolant temperature sensor specifications. Some vehicles use the PCM to attach another resistor in the ECT circuit to provide a more accurate measure of the engine temperature. ● **SEE FIGURE 72–6.**

If resistance values match the approximate coolant temperature and there is still a coolant sensor trouble code, the problem is generally in the wiring between the sensor and the computer. Always consult the manufacturers' recommended procedures for checking this wiring. If the resistance values do not match, the sensor may need to be replaced.

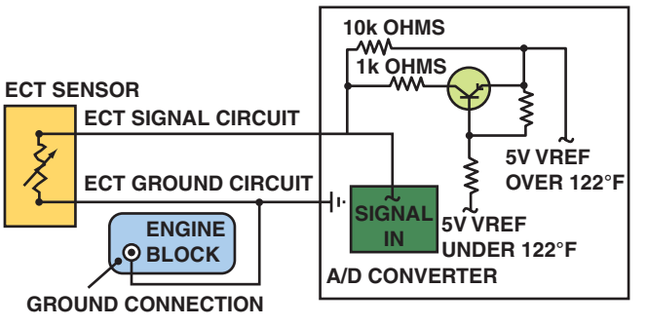

FIGURE 72–6 When the voltage drop reaches approximately 1.20 volts, the PCM turns on a transistor. The transistor connects a 1-kΩ resistor in parallel with the 10-kΩ resistor. Total circuit resistance now drops to around 909 ohms. This function allows the PCM to have full binary control at cold temperatures up to approximately 122°F, and a second full binary control at temperatures greater than 122°F.

Normal operating temperature varies with vehicle make and model. Some vehicles are equipped with a thermostat with an opening temperature of 180°F (82°C), whereas other vehicles use a thermostat that is 195°F (90°C) or higher. Before replacing the ECT sensor, be sure that the engine is operating at the temperature specified by the manufacturer. Most manufacturers recommend checking the ECT sensor after the cooling fan has cycled twice, indicating a fully warmed engine. To test for voltage at the ECT sensor, select DC volts on a digital meter and carefully back probe the sensor wire and read the voltage. ● **SEE FIGURE 72–7.**

TESTING THE ECT SENSOR USING A SCAN TOOL

Follow the scan tool manufacturer's instructions and connect a scan tool to the data link connector (DLC) of the vehicle. Comparing the temperature of the engine coolant as displayed on a scan tool with the actual temperature of the engine is an excellent method to test an engine coolant temperature sensor.

1. Record the scan tool temperature of the coolant (ECT).
2. Measure the actual temperature of the coolant using an infrared pyrometer or contact-type temperature probe.

NOTE: Often the coolant temperature gauge in the dash of the vehicle can be used to compare with the scan tool temperature. Although not necessarily accurate, it may help to diagnose a faulty sensor, especially if the temperature shown on the scan tool varies greatly from the temperature indicated on the dash gauge.

The maximum difference between the two readings should be 10°F (5°C). If the actual temperature varies by more than 10°F from the temperature indicated on the scan tool, check the ECT sensor wiring and connector for damage or corrosion. If the connector and wiring are okay, check the sensor with a DVOM for resistance and compare to the actual engine temperature chart. If that checks out okay, check the computer.

NOTE: Some manufacturers use two coolant sensors, one for the dash gauge and another one for the computer.

INTAKE AIR TEMPERATURE SENSOR

PURPOSE AND FUNCTION

The intake air temperature (IAT) sensor is a negative temperature coefficient (NTC) thermistor that decreases in resistance as the temperature of the sensor increases. The IAT sensor can be located in one of the following locations:

- In the air cleaner housing
- In the air duct between the air filter and the throttle body, as shown in ● **FIGURE 72–8**
- Built into the mass air flow (MAF) or airflow sensor
- Screwed into the intake manifold where it senses the temperature of the air entering the cylinders

NOTE: An IAT installed in the intake manifold is the most likely to suffer damage due to an engine backfire, which can often destroy the sensor.

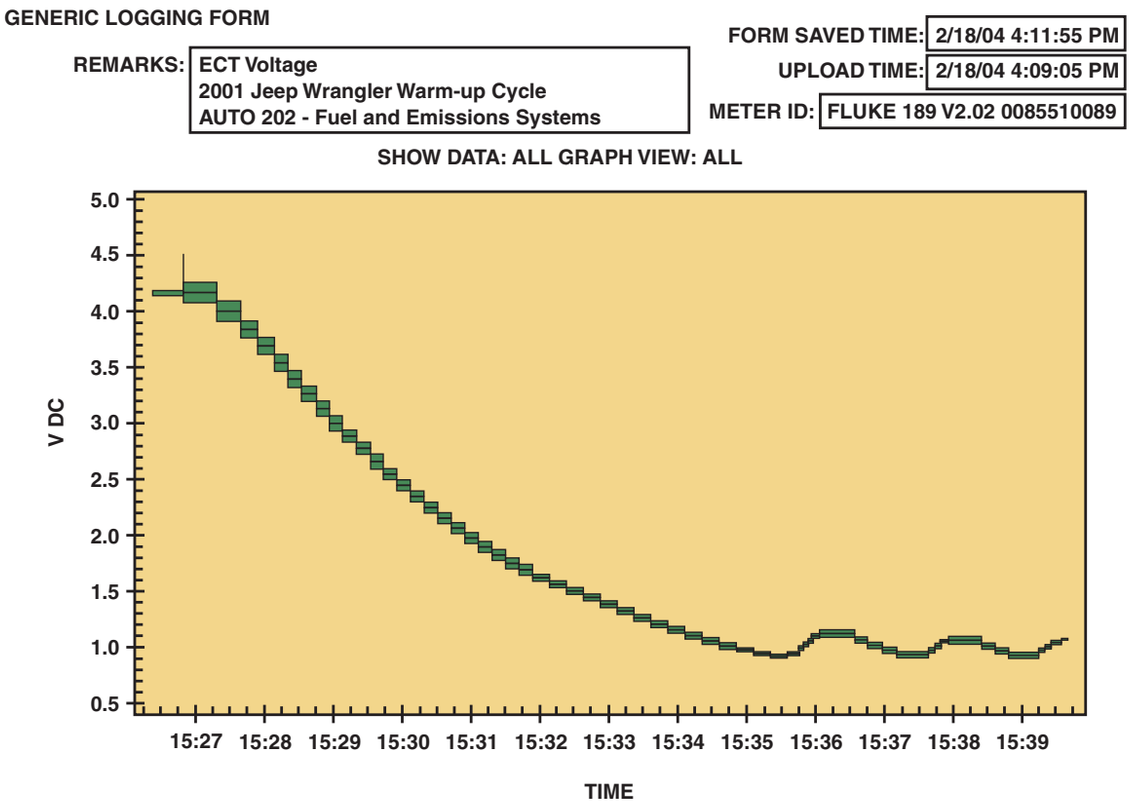

FIGURE 72–7 An ECT sensor being tested using a digital meter set to DC volts and record mode to capture the data shown. A chart showing the voltage decrease of the ECT sensor as the temperature increases from a cold start. The bumps at the bottom of the waveform represent temperature decreases when the thermostat opens and is controlling coolant temperature.

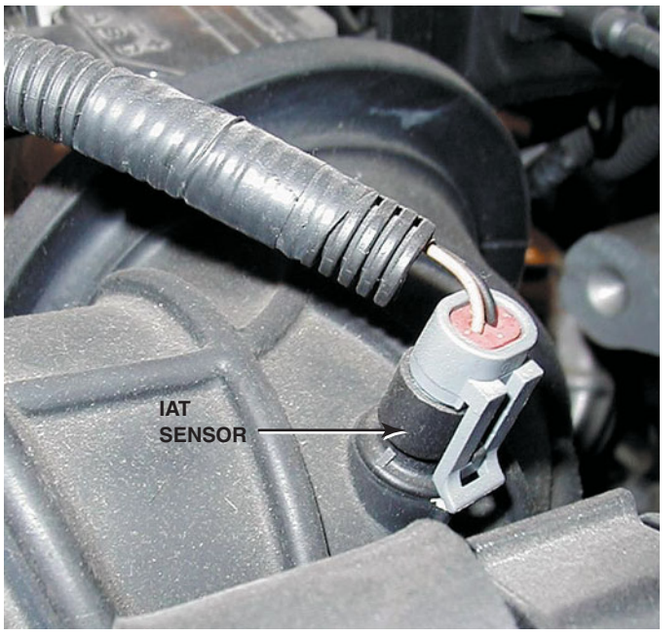

FIGURE 72–8 The IAT sensor on this General Motors 3800 V-6 engine is in the air passage duct between the air cleaner housing and the throttle body.

The purpose and function of the intake air temperature sensor is to provide the engine computer (PCM) the temperature of the air entering the engine. The IAT sensor information is used for fuel control (adding or subtracting fuel) and spark timing, depending on the temperature of incoming air.

- If the air temperature is cold, the PCM will modify the amount of fuel delivery and add fuel.
- If the air temperature is hot, the PCM will subtract the calculated amount of fuel.
- Spark timing is also changed, depending on the temperature of the air entering the engine. The timing is advanced if the temperature is cold and retarded from the base-programmed timing if the temperature is hot.
- Cold air is more dense, contains more oxygen, and therefore requires a richer mixture to achieve the proper air–fuel mixture. Air at 32°F (0°C) is 14% denser than air at 100°F (38°C).
- Hot air is less dense, contains less oxygen, and therefore requires less fuel to achieve the proper air–fuel mixture.

The IAT sensor is a low-authority sensor and is used by the computer to modify the amount of fuel and ignition timing as determined by the engine coolant temperature sensor.

The IAT sensor is used by the PCM as a backup in the event that the ECT sensor is determined to be inoperative.

NOTE: Some engines use a throttle-body temperature (TBT) sensor to sense the temperature of the air entering the engine, instead of an intake air temperature sensor.

Engine temperature is most accurately determined by looking at the engine coolant temperature (ECT) sensor. In certain conditions, the IAT has an effect on performance and driveability. One such condition is a warm engine being stopped in very cold weather. In this case, when the engine is restarted, the ECT may be near normal operating temperature such as 200°F (93°C) yet the air temperature could be −20°F (−30°C). In this case, the engine requires a richer mixture due to the cold air than the ECT would seem to indicate.

TECH TIP

Quick and Easy ECT Test

To check that the wiring and the computer are functioning, regarding the ECT sensor, connect a scan tool and look at the ECT temperature display.

STEP 1 Unplug the connector from the ECT sensor. The temperature displayed on the scan tool should read about −40.

NOTE: −40° Celsius is also −40° Fahrenheit. This is the point where both temperature scales meet.

STEP 2 With the connector still removed from the ECT sensor, use a fused jumper lead and connect the two terminals of the connector together. The scan tool should display about 285°F (140°C).

This same test procedure will work for the IAT and most other temperature sensors.

TECH TIP

Poor Fuel Economy? Black Exhaust Smoke? Look at the IAT

If the intake air temperature sensor is defective, it may be signaling the computer that the intake air temperature is extremely cold when in fact it is warm. In such a case the computer will supply a mixture that is much richer than normal.

If a sensor is physically damaged or electrically open, the computer will often set a diagnostic trouble code (DTC). This DTC is based on the fact that the sensor temperature did not change for a certain amount of time, usually about 8 minutes. If, however, the wiring or the sensor itself has excessive resistance, a DTC will not be set and the result will be lower-than-normal fuel economy, and in serious cases, black exhaust smoke from the tailpipe during acceleration.

TESTING THE INTAKE AIR TEMPERATURE SENSOR

If the intake air temperature sensor circuit is damaged or faulty, a diagnostic trouble code (DTC) is set and the malfunction indicator lamp (MIL) may or may not turn on depending on the condition and the type and model of the vehicle. To diagnose the IAT sensor follow these steps:

STEP 1 After the vehicle has been allowed to cool for several hours, use a scan tool, observe the IAT temperature, and compare it to the engine coolant temperature (ECT). The two temperatures should be within 5°F of each other.

STEP 2 Perform a thorough visual inspection of the sensor and the wiring. If the IAT is screwed into the intake manifold, remove the sensor and check for damage.

STEP 3 Check the voltage and compare to the following chart.

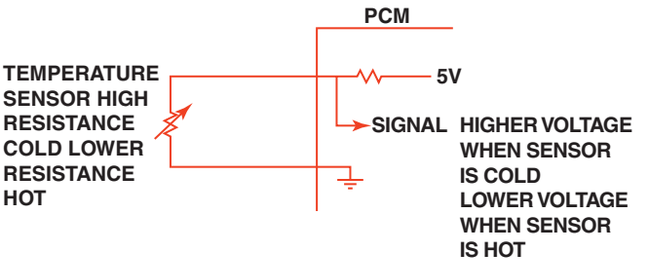

FIGURE 72–9 A typical temperature sensor circuit.

FREQUENTLY ASKED QUESTION

What Exactly Is an NTC Sensor?

A negative temperature coefficient (NTC) thermistor is a semiconductor whose resistance decreases as the temperature increases. In other words, the sensor becomes more electrically conductive as the temperature increases. Therefore, when a voltage is applied, typically 5 volts, the signal voltage is high when the sensor is cold because the sensor has a high resistance and little current flows through to ground. ● **SEE FIGURE 72–9.**

However, when the temperature increases, the sensor becomes more electrically conductive and takes more of the 5 volts to ground, resulting in a lower signal voltage as the sensor warms.

TRANSMISSION FLUID TEMPERATURE SENSOR

The **transmission fluid temperature (TFT),** also called *transmission oil temperature (TOT),* sensor is an important sensor for the proper operation of the automatic transmission. A TFT sensor is a negative temperature coefficient (NTC) thermistor that decreases in resistance as the temperature of the sensor increases.

The transmission fluid temperature signal is used by the Powertrain Control Module (PCM) to perform certain strategies based on the temperature of the automatic transmission fluid. For example:

- If the temperature of the automatic transmission fluid is low (typically below 32°F [0°C]), the shift points may be delayed and overdrive disabled. The torque converter clutch also may not be applied to assist in the heating of the fluid.
- If the temperature of the automatic transmission fluid is high (typically above 260°F [130°C]), the overdrive is disabled and the torque converter clutch is applied to help reduce the temperature of the fluid.

NOTE: Check service information for the exact shift strategy based on high and low transmission fluid temperatures for the vehicle being serviced.

CYLINDER HEAD TEMPERATURE SENSOR

Some vehicles are equipped with **cylinder head temperature (CHT)** sensors.

VW Golf

14°F (−10°C) = 11,600 Ω

68°F (20°C) = 2,900 Ω

176°F (80°C) = 390 Ω

ENGINE FUEL TEMPERATURE (EFT) SENSOR

Some vehicles, such as many Ford vehicles that are equipped with an electronic returnless type of fuel injection, use an **engine fuel temperature (EFT)** sensor to give the PCM information regarding the temperature and, therefore, the density of the fuel.

EXHAUST GAS RECIRCULATION (EGR) TEMPERATURE SENSOR

Some engines, such as Toyota, are equipped with exhaust gas recirculation (EGR) temperature sensors. EGR is a well-established method for reduction of NO_x emissions in internal combustion engines. The exhaust gas contains unburned hydrocarbons, which are recirculated in the combustion process. Recirculation is controlled by valves, which operate as a function of exhaust gas speed, load, and temperature. The gas reaches a temperature of about 850°F (450°C) for which a special heavy-duty glass-encapsulated NTC sensor is available.

The PCM monitors the temperature in the exhaust passage between the EGR valve and the intake manifold. If the temperature increases when the EGR is commanded on, the PCM can determine that the valve or related components are functioning.

ENGINE OIL TEMPERATURE SENSOR

Engine oil temperature sensors are used on many General Motors vehicles and are used as an input to the oil life monitoring system. The computer program inside the PCM calculates engine oil life based on run time, engine RPM, and oil temperature.

THROTTLE POSITION (TP) SENSORS

OBJECTIVES: **After studying Chapter 73, the reader will be able to:** • Prepare for ASE Engine Performance (A8) certification test content area "E" (Computerized Engine Controls Diagnosis and Repair). • Discuss how throttle position sensors work. • List the methods that can be used to test TP sensors. • Describe the symptoms of a failed TP sensor. • List how the operation of the TP sensor affects vehicle operation. • Discuss TP sensor rationality tests.

KEY TERMS: Potentiometer 828 • Skewed 830 • Throttle position (TP) sensor 828

THROTTLE POSITION SENSOR CONSTRUCTION

Most computer-equipped engines use a **throttle position (TP) sensor** to signal to the computer the position of the throttle. ● **SEE FIGURE 73–1.** The TP sensor consists of a **potentiometer,** a type of variable resistor.

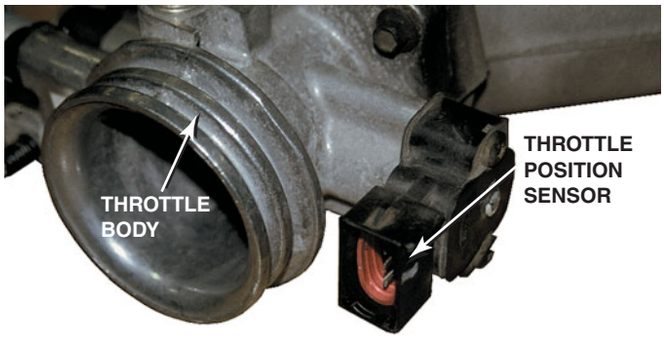

FIGURE 73–1 A typical TP sensor mounted on the throttle plate of this port-injected engine.

POTENTIOMETERS A potentiometer is a variable-resistance sensor with three terminals. One end of the resistor receives reference voltage, while the other end is grounded. The third terminal is attached to a movable contact that slides across the resistor to vary its resistance. Depending on whether the contact is near the supply end or the ground end of the resistor, return voltage is high or low. ● **SEE FIGURE 73–2.**

Throttle position (TP) sensors are among the most common potentiometer-type sensors. The computer uses their input to determine the amount of throttle opening and the rate of change.

A typical sensor has three wires:

- A 5-volt reference feed wire from the computer
- Signal return (A ground wire back to the computer)
- A voltage signal wire back to the computer; as the throttle is opened, the voltage to the computer changes

Normal throttle position voltage on most vehicles is about 0.5 volt at idle (closed throttle) and 4.5 volts at wide-open throttle (WOT).

NOTE: The TP sensor voltage at idle is usually about 10% of the TP sensor voltage when the throttle is wide open, but can vary from as low as 0.3 volt to 1.2 volts, depending on the make and model of vehicle.

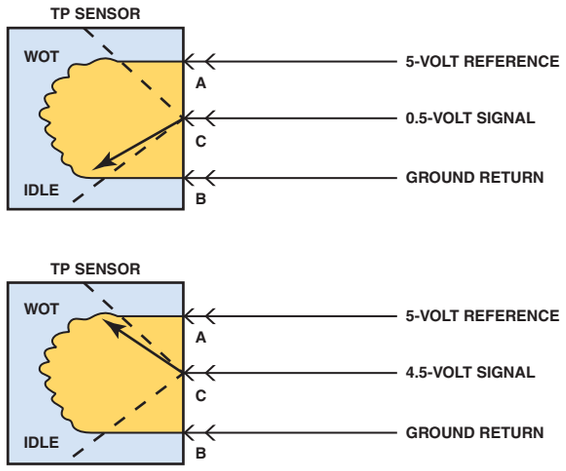

FIGURE 73–2 The signal voltage from a throttle position increases as the throttle is opened because the wiper arm is closer to the 5-volt reference. At idle, the resistance of the sensor winding effectively reduces the signal voltage output to the computer.

TP SENSOR COMPUTER INPUT FUNCTIONS

- The computer senses any change in throttle position and changes the fuel mixture and ignition timing. The actual change in fuel mixture and ignition timing is also partly determined by the other sensors, such as the manifold pressure (engine vacuum), engine RPM, the coolant temperature, and oxygen sensor(s). Some throttle position sensors are adjustable and should be set according to the exact engine manufacturer's specifications.
- The throttle position (TP) sensor used on fuel-injected vehicles acts as an "electronic accelerator pump." This means that the computer will pulse additional fuel from the injectors when the throttle is depressed. Because the air can quickly flow into the engine when the throttle is opened, additional fuel must be supplied to prevent the air–fuel mixture from going lean, causing the engine to hesitate when the throttle is depressed. If the TP sensor is unplugged or defective, the engine may still operate satisfactorily, but hesitate upon acceleration.
- The PCM supplies the TP sensor with a regulated voltage that ranges from 4.8 to 5.1 volts. This reference voltage is usually referred to as a 5-volt reference or "Vref." The TP output signal is an input to the PCM, and the TP sensor ground also flows through the PCM.

See the Ford throttle position (TP) sensor chart for an example of how sensor voltage changes with throttle angle.

Ford Throttle Position (TP) Sensor Chart

Throttle Angle (Degrees)	Voltage (V)
0	0.50
10	0.97
20	1.44
30	1.90
40	2.37
50	2.84
60	3.31
70	3.78
80	4.24

NOTE: Generally, any reading higher than 80% represents wide-open throttle to the computer.

PCM USES FOR THE TP SENSOR

The TP sensor is used by the Powertrain Control Module (PCM) for the following reasons.

CLEAR FLOOD MODE

If the throttle is depressed to the floor during engine cranking, the PCM will either greatly reduce or entirely eliminate any fuel-injector pulses to aid in cleaning a flooded engine. If the throttle is depressed to the floor and the engine is not flooded with excessive fuel, the engine may not start.

TORQUE CONVERTER CLUTCH ENGAGEMENT AND RELEASE

The torque converter clutch will be released if the PCM detects rapid acceleration to help the transmission deliver maximum torque to the drive wheels. The torque converter clutch is applied when the vehicle is lightly accelerating and during cruise conditions to help improve fuel economy.

RATIONALITY TESTING FOR MAP AND MAF SENSORS

As part of the rationality tests for the MAP and/or MAF sensor, the TP sensor signal is compared to the reading from other sensors to determine if they match. For example, if the throttle position sensor is showing wide-open throttle (WOT), the MAP and/or MAF reading should also indicate that this engine is under a heavy load. If not, a diagnostic trouble code could be set for the TP, as well as the MAP and/or MAF sensors.

AUTOMATIC TRANSMISSION SHIFT POINTS

The shift points are delayed if the throttle is opened wide to allow the engine speed to increase, thereby producing more power and aiding in the acceleration of the vehicle. If the throttle is barely open, the shift point occurs at the minimum speed designed for the vehicle.

TARGET IDLE SPEED (IDLE CONTROL STRATEGY)

When the TP sensor voltage is at idle, the PCM then controls idle speed using the idle air control (IAC) and/or spark timing variation to maintain the commanded idle speed. If the TP sensor indicates that the throttle has moved off idle, fuel delivery and spark timing are programmed for acceleration. Therefore, if the throttle linkage is stuck or binding, the idle speed may not be correct.

AIR-CONDITIONING COMPRESSOR OPERATION

The TP sensor is also used as an input sensor for air-conditioning compressor operation. If the PCM detects that the throttle is at or close to wide open, the air-conditioning compressor is disengaged.

BACKS UP OTHER SENSORS

The TP sensor is used as a backup to the MAP sensor and/or MAF in the event the PCM detects that one or both are not functioning correctly. The PCM then calculates fuel needs and spark timing based on the engine speed (RPM) and throttle position.

TESTING THE THROTTLE POSITION SENSOR

TOOLS NEEDED A TP sensor can be tested using one or more of the following tools:

- A digital voltmeter with three test leads connected in series between the sensor and the wiring harness connector or back probing using T-pins or other recommended tool that will not cause harm to the connector or wiring.
- A scan tool or a specific tool recommended by the vehicle manufacturer.
- A breakout box that is connected in series between the computer and the wiring harness connector(s). A typical breakout box includes test points at which TP voltages can be measured with a digital voltmeter.
- An oscilloscope.

Use jumper wires, T-pins to back-probe the wires, or a breakout box to gain electrical access to the wiring to the TP sensor. ● **SEE FIGURE 73–3.**

NOTE: The procedure that follows is the usual method used by many manufacturers. Always refer to service information for the exact recommended procedure and specifications for the vehicle being tested.

TESTING PROCEDURE The procedure for testing the sensor using a digital multimeter is as follows:

1. Turn the ignition switch on (engine off).
2. Set the digital meter to read to DC volts and measure the voltage between the signal wire and ground (reference low) wire. The voltage should be about 0.5 volt.

   NOTE: Consult the service information for exact wire colors or locations.

3. With the engine still not running (but with the ignition still on), slowly increase the throttle opening. The voltage signal from the TP sensor should also increase. Look for any "dead spots" or open circuit readings as the throttle is increased to the wide-open position. ● **SEE FIGURE 73–4** for an example of how a good TP sensor would look when tested with a digital storage oscilloscope (DSO).

   NOTE: Use the accelerator pedal to depress the throttle because this applies the same forces on the TP sensor as the driver does during normal driving. Moving the throttle by hand under the hood may not accurately test the TP sensor.

4. With the voltmeter still connected, slowly return the throttle down to the idle position. The voltage from the TP sensor should also decrease evenly on the return to idle.

The TP sensor voltage at idle should be within the acceptable range as specified by the manufacturer. Some TP sensors can be adjusted by loosening their retaining screws and moving the sensor in relation to the throttle opening. This movement changes the output voltage of the sensor.

TECH TIP

Check Power and Ground Before Condemning a Bad Sensor

Most engine sensors use a 5-volt reference and a ground. If the 5 volts to the sensor is too high (shorted to voltage) or too low (high resistance), then the sensor output will be **skewed** or out of range. Before replacing the sensor that did not read correctly, measure both the 5-volt reference and ground. To measure the ground, simply turn the ignition on (engine off) and touch one test lead of a DMM set to read DC volts to the sensor ground and the other to the negative terminal of the battery. Any reading higher than 0.2 volt (200 mV) represents a poor ground. ● **SEE FIGURES 73–5 AND 73–6.**

FIGURE 73–5 Checking the 5-volt reference from the computer being applied to the TP sensor with the ignition switch on (engine off). The reading for this vehicle (5.02 volts DC) is within the normal range for the 5-volt reference voltage of 4.9 to 5.1 volts.

FIGURE 73–6 Checking the voltage drop between the TP sensor ground and a good engine ground with the ignition on (engine off). A reading of greater than 0.2 volt (200 mV) represents a bad computer ground.

All TP sensors should also provide a smooth transition voltage reading from idle to WOT and back to idle. Replace the TP sensor if erratic voltage readings are obtained or if the correct setting at idle cannot be obtained.

MIN/MAX TESTING Many digital multimeters are capable of recording voltage readings over time and then displaying the minimum, maximum, and average readings. To perform a MIN/MAX test of the TP sensor, manually set the meter to read higher than 4 volts.

STEP 1 Connect the red meter lead to the signal wire and the black meter lead to a good ground or the ground return wire at the TP sensor.

STEP 2 With the ignition on, engine off, slowly depress and release the accelerator pedal from inside the vehicle.

STEP 3 Check the minimum and maximum voltage reading on the meter display. Any 0- or 5-volt reading would indicate a fault or short in the TP sensor.

SCAN TOOL TESTING A scan tool can be used to check for proper operation of the throttle position sensor using the following steps.

STEP 1 With the key on, engine off, the TP sensor voltage display should be about 0.5 volt, but can vary from as low as 0.3 volt to as high as 1.2 volts.

STEP 2 Check the scan tool display for the percentage of throttle opening. The reading should be zero and gradually increase in percentage as the throttle is depressed.

STEP 3 The idle air control (IAC) counts should increase as the throttle is opened and decrease as the throttle is closed. Start the engine and observe the IAC counts as the throttle is depressed.

STEP 4 Start the engine and observe the TP sensor reading. Use a wedge at the throttle stop to increase the throttle opening slightly. The throttle percentage reading should increase. Shut off and restart the engine. If the percentage of throttle opening returns to 0%, the PCM determines that the increased throttle opening is now the new minimum and resets the idle position of the TP sensor. Remove the wedge and cycle the ignition key. The throttle position sensor should again read zero percentage.

NOTE: Some engine computers are not capable of resetting the throttle position sensor.

TP SENSOR DIAGNOSTIC TROUBLE CODES

The diagnostic trouble codes (DTCs) associated with the throttle position sensor include the following.

Diagnostic Trouble Code	Description	Possible Causes
P0122	TP sensor low voltage	• TP sensor internally shorted-to-ground • TP sensor wiring shorted-to-ground • TP sensor or wiring open

FIGURE 74–1 (a) As an engine is accelerated under a load, the engine vacuum drops. This drop in vacuum is actually an increase in absolute pressure in the intake manifold. A MAP sensor senses all pressures greater than that of a perfect vacuum. (b) The relationship between absolute pressure, vacuum, and gauge pressure.

AIR PRESSURE—HIGH AND LOW

Think of an internal combustion engine as a big air pump. As the pistons move up and down in the cylinders, they pump in air and fuel for combustion and pump out exhaust gases. They do this by creating a difference in air pressure. The air outside an engine has weight and exerts pressure, as does the air inside an engine.

As a piston moves down on an intake stroke with the intake valve open, it creates a larger area inside the cylinder for the air to fill. This lowers the air pressure within the engine. Because the pressure inside the engine is lower than the pressure outside, air flows into the engine to fill the low-pressure area and equalize the pressure.

The low pressure within the engine is called **vacuum.** Vacuum causes the higher-pressure air on the outside to flow into the low-pressure area inside the cylinder. The difference in pressure between the two areas is called a **pressure differential.** ● **SEE FIGURE 74–1.**

PRINCIPLES OF PRESSURE SENSORS

Intake manifold pressure changes with changing throttle positions. At wide-open throttle, manifold pressure is almost the same as atmospheric pressure. On deceleration or at idle, manifold pressure is below atmospheric pressure, thus creating a vacuum. In cases where turbo- or supercharging is used, under part- or full-load condition, intake manifold pressure rises above atmospheric pressure. Also, oxygen content and barometric pressure change with differences in altitude, and the computer must be able to compensate by

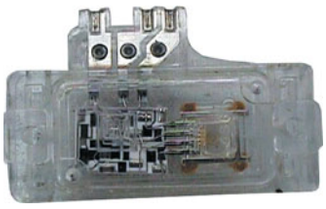

FIGURE 74–2 A clear plastic MAP sensor used for training purposes showing the electronic circuit board and electrical connections.

making changes in the flow of fuel entering the engine. To provide the computer with changing airflow information, a fuel-injection system may use the following:

- Manifold absolute pressure (MAP) sensor
- Manifold absolute pressure (MAP) sensor plus barometric absolute pressure (BARO) sensor
- Barometric and manifold absolute pressure sensors combined (BMAP)

The **manifold absolute pressure (MAP) sensor** may be a ceramic capacitor diaphragm, an aneroid bellows, or a piezoresistive crystal. It has a sealed vacuum reference input on one side; the other side is connected (vented) to the intake manifold. This sensor housing also contains signal conditioning circuitry. ● **SEE FIGURE 74–2.** Pressure changes in the manifold cause the sensor to deflect, varying its analog or digital return signal to the computer. As the air pressure increases, the MAP sensor generates a higher voltage or frequency return signal to the computer.

CONSTRUCTION OF MANIFOLD ABSOLUTE PRESSURE (MAP) SENSORS

The manifold absolute pressure (MAP) sensor is used by the engine computer to sense engine load. The typical MAP sensor consists of a ceramic or silicon wafer sealed on one side with a perfect vacuum and exposed to intake manifold vacuum on the other side. As the engine vacuum changes, the pressure difference on the wafer changes the output voltage or frequency of the MAP sensor.

A manifold absolute pressure (MAP) sensor is used on many engines for the PCM to determine the load on the engine. The relationship among barometer pressure, engine vacuum, and MAP sensor voltage includes:

- Absolute pressure is equal to barometric pressure minus intake manifold vacuum.
- A decrease in manifold vacuum means an increase in manifold pressure.
- The MAP sensor compares manifold vacuum to a perfect vacuum.
- Barometric pressure minus MAP sensor reading equals intake manifold vacuum. Normal engine vacuum is 17–21 in. Hg.
- Supercharged and turbocharged engines require a MAP sensor that is calibrated for pressures above atmospheric, as well as for vacuum.

SILICON-DIAPHRAGM STRAIN GAUGE MAP SENSOR

This is the most commonly used design for a MAP sensor and the output is a DC analog (variable) voltage. One side of a silicon wafer is exposed to engine vacuum and the other side is exposed to a perfect vacuum.

There are four resistors attached to the silicon wafer, which changes in resistance when strain is applied to the wafer. This change in resistance due to strain is called **piezoresistivity.** The resistors are electrically connected to a Wheatstone bridge circuit and then to a differential amplifier, which creates a voltage in proportion to the vacuum applied.

A typical General Motors MAP sensor voltage varies from 0.88 to 1.62 at engine idle.

- 17 in. Hg is equal to about 1.62 volts
- 21 in. Hg is equal to about 0.88 volts

Therefore, a good reading should be about 1.0 volt from the MAP sensor on a sound engine at idle speed. See the following chart that shows engine load, engine vacuum, and MAP.

TECH TIP

If It's Green, It's a Signal Wire

Ford-built vehicles usually use a green wire as the signal wire back to the computer from the sensors. It may not be a solid green, but if there is green somewhere on the wire, then it is the signal wire. The other wires are the power and ground wires to the sensor.

Engine Load	Manifold Vacuum	Manifold Absolute Pressure	MAP Sensor Volt Signal
Heavy (WOT)	Low (almost 0 in. Hg)	High (almost atmospheric)	High (4.6–4.8 V)
Light (idle)	High (17–21 in. Hg)	Low (lower than atmospheric)	Low (0.8–1.6 V)

CAPACITOR-CAPSULE MAP SENSOR

A capacitor-capsule is a type of MAP sensor used by Ford which uses two ceramic (alumina) plates with an insulating washer spacer in the center to create a capacitor. Changes in engine vacuum cause the plates to deflect, which changes the capacitance. The electronics in the sensor then generate a varying digital frequency output signal, which is proportional to the engine vacuum. ● **SEE FIGURE 74–3.** ● **SEE FIGURE 74–4** for a scope waveform of a digital MAP sensor. Also see the Ford MAP sensor chart.

Ford MAP Sensor Chart

MAP Sensor Output (Hz)	Engine Operating Conditions	Intake Manifold Vacuum (in. Hg)
156–159 Hz	Key on, engine off	0 in. Hg
102–109 Hz	Engine at idle (sea level)	17–21 in. Hg
156–159 Hz	Engine at wide-open throttle (WOT)	About 0 in. Hg

CERAMIC DISC MAP SENSOR

The ceramic disc MAP sensor is used by Chrysler and it converts manifold pressure into a capacitance discharge. The discharge controls the amount of voltage delivered by the sensor to the PCM. The output is the same as the previously used strain gauge/Wheatstone bridge design and is interchangeable. ● **SEE FIGURE 74–5.** See the Chrysler MAP sensor chart.

PCM USES OF THE MAP SENSOR

The PCM uses the MAP sensor to determine the following:

- **The load on the engine.** The MAP sensor is used on a **speed density**-type fuel-injection system to determine the load on the engine, and therefore the amount of fuel needed. On engines equipped with a mass air flow (MAF) sensor, the MAP is used as a backup to the MAF, for diagnosis of other sensors, and systems such as the EGR system.

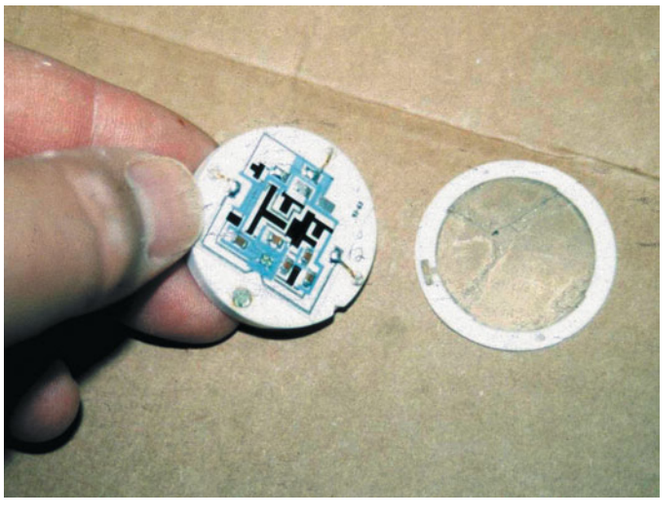

FIGURE 74–5 Shown is the electronic circuit inside a ceramic disc MAP sensor used on many Chrysler engines. The black areas are carbon resistors that are applied to the ceramic, and lasers are used to cut lines into these resistors during testing to achieve the proper operating calibration.

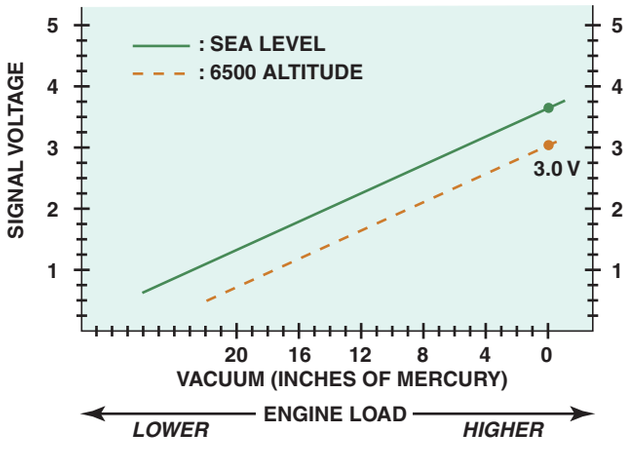

FIGURE 74–6 Altitude affects the MAP sensor voltage.

- **Altitude, fuel, and spark control calculations.** At key on, the MAP sensor determines the altitude (acts as a BARO sensor) and adjusts the fuel delivery and spark timing accordingly.
  - If the altitude is high, generally over 5,000 feet (1,500 meters), the PCM will reduce fuel delivery and advance the ignition timing.
  - The altitude is also reset when the engine is accelerated to wide-open throttle and the MAP sensor is used to reset the altitude reading. ● **SEE FIGURE 74–6.**
- **EGR system operation.** As part of the OBD-II standards, the exhaust gas recirculation (EGR) system must be checked for proper operation. One method used by many vehicle manufacturers is to command the EGR valve on and then watch the MAP sensor signal. The opening of the EGR pintle should decrease engine vacuum. If the MAP sensor does not react with the specified drop in manifold vacuum (increase in manifold pressure), an EGR flow rate problem diagnostic trouble code is set.
- **Detect deceleration (vacuum increases).** The engine vacuum rises when the accelerator is released, which changes the MAP sensor voltage. When deceleration is detected by the PCM, fuel is either stopped or greatly reduced to improve exhaust emissions.

TECH TIP

Use the MAP Sensor as a Vacuum Gauge

A MAP sensor measures the pressure inside the intake manifold compared with absolute zero (perfect vacuum). For example, an idling engine that has 20 inches of mercury (in. Hg) of vacuum has a lower pressure inside the intake manifold than when the engine is under a load and the vacuum is at 10 in. Hg. A decrease in engine vacuum results in an increase in manifold pressure. A normal engine should produce between 17 and 21 in. Hg at idle. Comparing the vacuum reading with the voltage reading output of the MAP sensor indicates that the reading should be between 1.62 and 0.88 volt or 109 to 102 Hz or lower on Ford MAP sensors. Therefore, a digital multimeter (DMM), scan tool, or scope can be used to measure the MAP sensor voltage and be used instead of a vacuum gauge.

NOTE: This chart was developed by testing a MAP sensor at a location about 600 feet above sea level. For best results, a chart based on your altitude should be made by applying a known vacuum, and reading the voltage of a known-good MAP sensor. Vacuum usually drops about 1 inch per 1,000 feet of altitude.

- **Monitor engine condition.** As an engine wears, the intake manifold vacuum usually decreases. The PCM is programmed to detect the gradual change in vacuum and is able to keep the air–fuel mixture in the correct range. If the PCM were not

capable of making adjustments for engine wear, the lower vacuum could be interpreted as increased load on the engine, resulting in too much fuel being injected, thereby reducing fuel economy and increasing exhaust emissions.

- **Load detection for returnless-type fuel injection.** On fuel delivery systems that do not use a return line back to the fuel tank, the engine load calculation for the fuel needed is determined by the signals from the MAP sensor.
- **Altitude and MAP sensor values.** On an engine equipped with a speed-density-type fuel injection, the MAP sensor is the most important sensor needed to determine injection pulse width. Changes in altitude change the air density as well as weather conditions. Barometric pressure and altitude are inversely related:
  - As altitude increases—barometric pressure decreases
  - As altitude decreases—barometric pressure increases

  As the ignition switch is turned from off to the start position, the PCM reads the MAP sensor value to determine atmospheric and air pressure conditions. This barometric pressure reading is updated every time the engine is started and whenever wide-open throttle is detected. The barometric pressure reading at that time is updated. See the chart that compares altitude to MAP sensor voltage.

BAROMETRIC PRESSURE SENSOR

A **barometric pressure (BARO) sensor** is similar in design, but senses more subtle changes in barometric absolute pressure (atmospheric air pressure). It is vented directly to the atmosphere. The **barometric manifold absolute pressure (BMAP) sensor** is actually a combination of a BARO and MAP sensor in the same housing. The BMAP sensor has individual circuits to measure barometric and manifold pressure. This input not only allows the computer to adjust for changes in atmospheric pressure due to weather, but also is the primary sensor used to determine altitude.

NOTE: A MAP sensor and a BARO sensor are usually the same sensor, but the MAP sensor is connected to the manifold and a BARO sensor is open to the atmosphere. The MAP sensor is capable of reading barometric pressure just as the ignition switch is turned to the on position before the engine starts. Therefore, altitude and weather changes are available to the computer. During mountainous driving, it may be an advantage to stop and then restart the engine so that the engine computer can take another barometric pressure reading and recalibrate fuel delivery based on the new altitude. See the Ford/BARO altitude chart for an example of how altitude affects intake manifold pressure. The computer on some vehicles will monitor the throttle position sensor and use the MAP sensor reading at wide-open throttle (WOT) to update the BARO sensor if it has changed during driving.

REAL WORLD FIX

The Cavalier Convertible Story

The owner of a Cavalier convertible stated to a service technician that the "check engine" (MIL) was on. The technician found a diagnostic trouble code (DTC) for a MAP sensor. The technician removed the hose at the MAP sensor and discovered that gasoline had accumulated in the sensor and dripped out of the hose as it was being removed. The technician replaced the MAP sensor and test drove the vehicle to confirm the repair. Almost at once the check engine light came on with the same MAP sensor code. After several hours of troubleshooting without success in determining the cause, the technician decided to start over again. Almost at once, the technician discovered that no vacuum was getting to the MAP sensor where a vacuum gauge was connected with a T-fitting in the vacuum line to the MAP sensor. The vacuum port in the base of the throttle body was clogged with carbon. After a thorough cleaning, and clearing the DTC, the Cavalier again performed properly and the check engine light did not come on again. The technician had assumed that if gasoline was able to reach the sensor through the vacuum hose, surely vacuum could reach the sensor. The technician learned to stop assuming when diagnosing a vehicle and concentrate more on testing the simple things first.

NOTE: Some older Chrysler brand vehicles were equipped with a combination BARO and IAT sensor. The sensor was mounted on the bulkhead (firewall) and sensed the underhood air temperature.

TESTING THE MAP SENSOR

Most pressure sensors operate on 5 volts from the computer and return a signal (voltage or frequency) based on the pressure (vacuum) applied to the sensor. If a MAP sensor is being tested, make certain that the vacuum hose and hose fittings are sound

TECH TIP

Visual Check of the MAP Sensor

A defective vacuum hose to a MAP sensor can cause a variety of driveability problems including poor fuel economy, hesitation, stalling, and rough idle. A small air leak (vacuum leak) around the hose can cause these symptoms and often set a trouble code in the vehicle computer. When working on a vehicle that uses a MAP sensor, make certain that the vacuum hose travels consistently *downward* on its route from the sensor to the source of manifold vacuum. Inspect the hose, especially if another technician has previously replaced the factory-original hose. It should not be so long that it sags down at any point. Condensed fuel and/or moisture can become trapped in this low spot in the hose and cause all types of driveability problems and MAP sensor codes.

When checking the MAP sensor, if anything comes out of the sensor itself, it should be replaced. This includes water, gasoline, or any other substance.

and making a good, tight connection to a manifold vacuum source on the engine.

Four different types of test instruments can be used to test a pressure sensor:

1. A digital voltmeter with three test leads connected in series between the sensor and the wiring harness connector or back-probe the terminals.
2. A scope connected to the sensor output, power, and ground.
3. A scan tool or a specific tool recommended by the vehicle manufacturer.
4. A breakout box connected in series between the computer and the wiring harness connection(s). A typical breakout box includes test points at which pressure sensor values can be measured with a digital voltmeter set on DC volts (or frequency counter, if a frequency-type MAP sensor is being tested).

NOTE: Always check service information for the exact testing procedures and specifications for the vehicle being tested.

TESTING THE MAP SENSOR USING A DMM OR SCOPE

Use jumper wires, T-pins to back-probe the connector, or a breakout box to gain electrical access to the wiring to the pressure sensor. Most pressure sensors use three wires:

1. A 5-volt wire from the computer
2. A variable-signal wire back to the computer
3. A ground or reference low wire

The procedure for testing the sensor is as follows:

1. Turn the ignition on (engine off)
2. Measure the voltage (or frequency) of the sensor output
3. Using a hand-operated vacuum pump (or other variable vacuum source), apply vacuum to the sensor

A good pressure sensor should change voltage (or frequency) in relation to the applied vacuum. If the signal does not change or the values are out of range according to the manufacturers' specifications, the sensor must be replaced.

FIGURE 74–7 A typical hand-operated vacuum pump.

TESTING THE MAP SENSOR USING A SCAN TOOL

A scan tool can be used to test a MAP sensor by monitoring the injector pulse width (in milliseconds) when vacuum is being applied to the MAP sensor using a hand-operated vacuum pump. ● **SEE FIGURE 74–7.**

STEP 1 Apply about 20 in. Hg of vacuum to the MAP sensor and start the engine.

STEP 2 Observe the injector pulse width. On a warm engine, the injector pulse width will normally be 1.5 to 3.5 ms.

STEP 3 Slowly reduce the vacuum to the MAP sensor and observe the pulse width. A lower vacuum to the MAP sensor indicates a heavier load on the engine and the injector pulse width should increase.

NOTE: If 23 in. Hg or more vacuum is applied to the MAP sensor with the engine running, this high vacuum will often stall the engine. The engine stalls because the high vacuum is interpreted by the PCM to indicate that the engine is being decelerated, which shuts off the fuel. During engine deceleration, the PCM shuts off the fuel injectors to reduce exhaust emissions and increase fuel economy.

FUEL-RAIL PRESSURE SENSOR

A fuel-rail pressure (FRP) sensor is used on some vehicles such as Fords that are equipped with electronic returnless fuel injection. This sensor provides fuel pressure information to the PCM for fuel injection pulse width calculations.

MAP/BARO DIAGNOSTIC TROUBLE CODES

The diagnostic trouble codes (DTCs) associated with the MAP and BARO sensors include:

Diagnostic Trouble Code	Description	Possible Causes
P0106	BARO sensor out-of-range at key on	• MAP sensor fault • MAP sensor O-ring damaged or missing

P0108	Map sensor high voltage	• MAP sensor fault • MAP sensor O-ring damaged or missing • MAP sensor signal circuit shorted-to-voltage

MASS AIR FLOW SENSORS

OBJECTIVES: **After studying Chapter 75, the reader will be able to:** • Prepare for ASE Engine Performance (A8) certification test content area "E" (Computerized Engine Controls Diagnosis and Repair). • Discuss how MAF sensors work. • List the methods that can be used to test MAF sensors. • Describe the symptoms of a failed MAF sensor. • List how the operation of the MAF sensor affects vehicle operation. • Discuss MAF sensor rationality tests.

KEY TERMS: False air 843 • Mass airflow (MAF) sensor 840 • Speed density 840 • Tap test 844 • Vane airflow (VAF) sensor 840

AIRFLOW SENSORS

Electronic fuel injection systems that do not use the "**speed density**" system for fuel calculation measure the airflow volume delivered to the engine. Older systems use a movable vane in the intake stream called a vane airflow (VAF) sensor. The vane is part of the **vane airflow (VAF) sensor.** The vane is deflected by intake airflow. ● **SEE FIGURE 75–1.**

The vane airflow sensor used in Bosch L-Jetronic, Ford, and most Japanese electronic port fuel-injection systems is a movable vane connected to a laser-calibrated potentiometer. The vane is mounted on a pivot pin and is deflected by intake airflow proportionate to air velocity. As the vane moves, it also moves the potentiometer. This causes a change in the signal voltage supplied to the computer. ● **SEE FIGURE 75–2.** For example, if the reference voltage is 5 volts, the potentiometer's signal to the computer will vary from a 0 voltage signal (no airflow) to almost a 5-volt signal (maximum airflow). In this way, the potentiometer provides the information the computer needs to vary the injector pulse width proportionate to airflow. There is a special "dampening chamber" built into the VAF to smooth out vane pulsations which would be created by intake manifold air-pressure fluctuations caused by the valve opening and closing. Many vane airflow sensors include a switch to energize the electric fuel pump. This is a safety feature that prevents the operation of the fuel pump if the engine stalls.

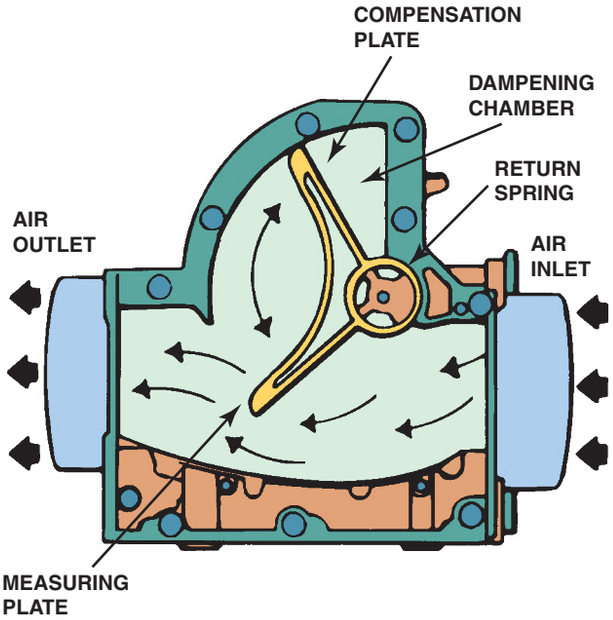

FIGURE 75–1 A vane air flow (VAF) sensor.

MASS AIRFLOW SENSOR TYPES

Most newer fuel injection systems use a **Mass Air Flow (MAF) sensor** to calculate the amount of air volume delivered to the engine.

There are several types of mass airflow sensors.

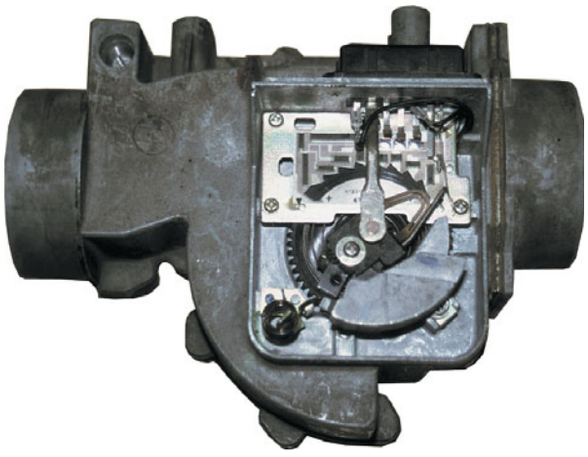

FIGURE 75–2 A typical air vane sensor with the cover removed. The movable arm contacts a carbon resistance path as the vane opens. Many air vane sensors also have contacts that close to supply voltage to the electric fuel pump as the air vane starts to open when the engine is being cranked and air is being drawn into the engine.

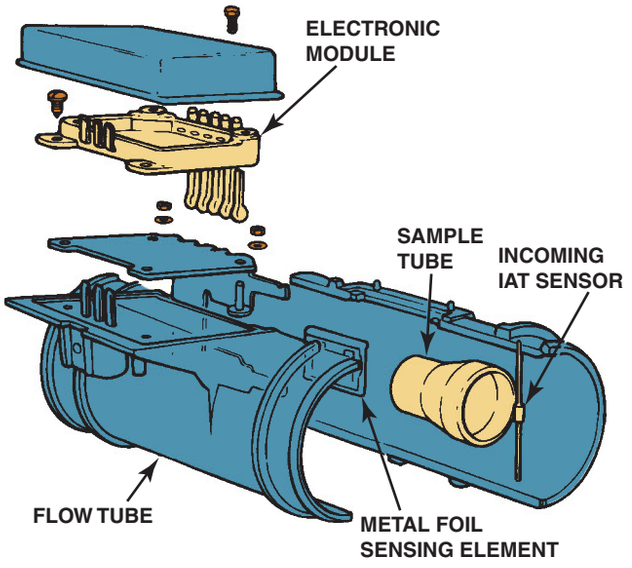

FIGURE 75–3 This five-wire mass air flow sensor consists of a metal foil sensing unit, an intake air temperature (IAT) sensor, and the electronic module.

FREQUENTLY ASKED QUESTION

What Is the Difference Between an Analog and a Digital MAF Sensor?

Some MAF sensors produce a digital DC voltage signal whose frequency changes with the amount of airflow through the sensor. The frequency range also varies with the make of sensor and can range from 0- to 300-Hz for older General Motors MAF sensors to 1,000- to 9,000-Hz for most newer designs.

Some MAF sensors, such as those used by Ford and others, produce a changing DC voltage, rather than frequency, and range from 0- to 5-volts DC.

HOT FILM SENSOR The hot film sensor uses a temperature-sensing resistor (thermistor) to measure the temperature of the incoming air. Through the electronics within the sensor, a conductive film is kept at a temperature 70°C above the temperature of the incoming air. ● **SEE FIGURE 75–3.**

Because the amount and density of the air both tend to contribute to the cooling effect as the air passes through the sensor, this type of sensor can actually produce an output based on the mass of the airflow. Mass equals volume times density. For example, cold air is denser than warm air so a small amount of cold air may have the same mass as a larger amount of warm air. Therefore, a mass airflow sensor is designed to measure the mass, not the volume, of the air entering the engine.

The output of this type of sensor is usually a frequency based on the amount of air entering the sensor. The more air that enters the sensor, the more the hot film is cooled. The electronics inside the sensor, therefore, increase the current flow through the hot film to maintain the 70°C temperature differential between the air temperature and the temperature of the hot film. This change in current flow is converted to a frequency output that the computer can use as a measurement of airflow. Most of these types of sensors are referred to as mass airflow (MAF) sensors because, unlike the air vane sensor, the MAF sensor takes into account relative humidity, altitude, and temperature of the air. The denser the air, the greater the cooling effect on the hot film sensor and the greater the amount of fuel required for proper combustion.

HOT WIRE SENSOR The hot wire sensor is similar to the hot film type, but uses a hot wire to sense the mass airflow instead of the hot film. Like the hot film sensor, the hot wire sensor uses a temperature-sensing resistor (thermistor) to measure the temperature of the air entering the sensor. ● **SEE FIGURE 75–4.** The electronic circuitry within the sensor keeps the temperature of the wire at 70°C above the temperature of the incoming air.

Both designs operate in essentially the same way. A resistor wire or screen installed in the path of intake airflow is heated to a constant temperature by electric current provided by the computer. Air flowing past the screen or wire cools it. The degree of cooling varies with air velocity, temperature, density, and humidity. These factors combine to indicate the mass of air entering the engine. As the screen or wire cools, more current is required to maintain the specified temperature. As the screen or wire heats up, less current is required. The operating principle can be summarized as follows:

- More intake air volume = cooler sensor, more current.
- Less intake air volume = warmer sensor, less current.

The computer constantly monitors the change in current and translates it into a voltage signal that is used to determine injector pulse width.

BURN-OFF CIRCUIT. Some hot wire-type MAF sensors use a burn-off circuit to keep the sensing wire clean of dust and dirt. A high current is passed through the sensing wire for a short time, but long enough to cause the wire to glow due to the heat. The burn-off circuit is turned on when the ignition switch is switched off after the engine has been operating long enough to achieve normal operating temperature.

KARMAN VORTEX SENSORS

In 1912, a Hungarian scientist named Theodore Van Karman observed that vortexes were created when air passed over a pointed surface. This type of sensor sends a sound wave through the turbulence created by incoming air passing through the sensor. Air mass

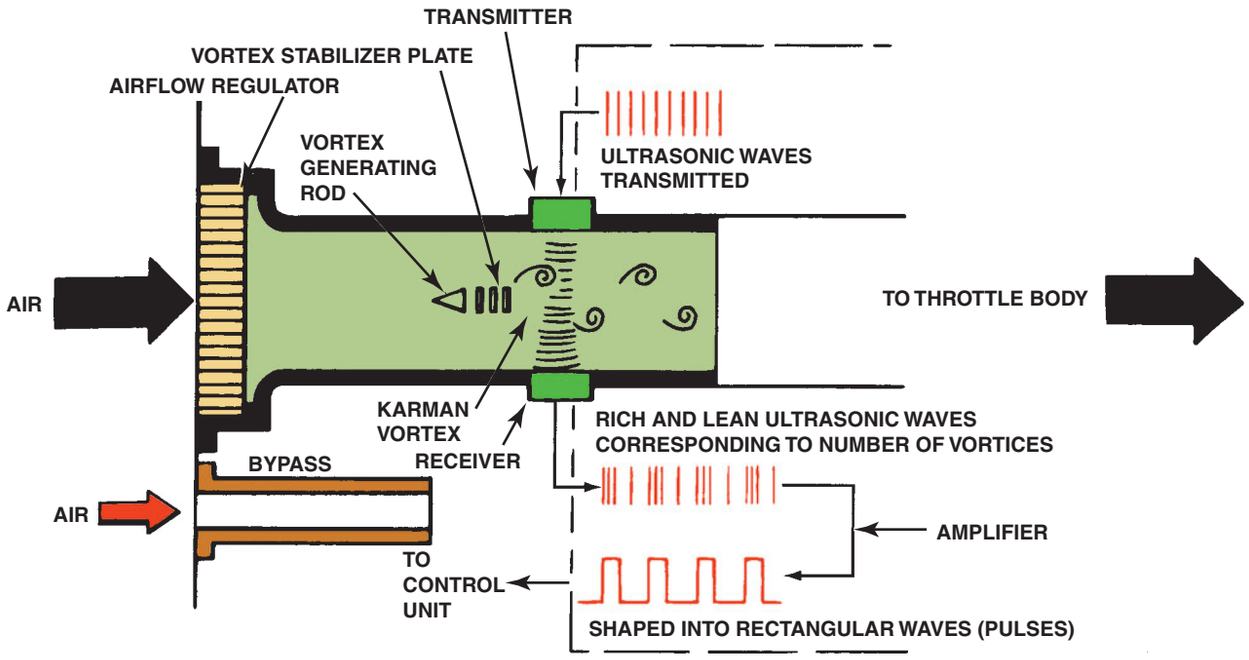

FIGURE 75–5 A Karman Vortex air flow sensor uses a triangle-shaped rod to create vortexes as the air flows through the sensor. The electronics in the sensor itself converts these vortexes to a digital square wave signal.

is calculated based on the time required for the sound waves to cross the turbulent air passage.

There are two basic designs of Karman Vortex air flow sensors. The two types include:

- **Ultrasonic.** This type of sensor uses ultrasonic waves to detect the vortexes that are produced, and produce a digital (on-and-off) signal where frequency is proportional to the amount of air passing through the sensor. ● **SEE FIGURE 75–5.**
- **Pressure-type.** Chrysler uses a pressure-type Karman Vortex sensor that uses a pressure sensor to detect the vortexes. As the airflow through the sensor increases, so do the number of pressure variations. The electronics in the sensor convert these pressure variations to a square wave (digital DC voltage) signal, whose frequency is in proportion to the airflow through the sensor.

PCM USES FOR AIRFLOW SENSORS

The PCM uses the information from the airflow sensor for the following purposes:

- Airflow sensors are used mostly to determine the amount of fuel needed and base pulse-width numbers. The greater the mass of the incoming air, the longer the injectors are pulsed on.
- Airflow sensors back up the TP sensor in the event of a loss of signal or an inaccurate throttle position sensor signal. If the MAF sensor fails, then the PCM will calculate the fuel delivery needs of the engine based on throttle position and engine speed (RPM).

REAL WORLD FIX

The Dirty MAF Sensor Story

The owner of a Buick Park Avenue equipped with a 3800 V-6 engine complained that the engine would hesitate during acceleration, showed lack of power, and seemed to surge or miss at times. A visual inspection found everything to be like new, including a new air filter. There were no stored diagnostic trouble codes (DTCs). A look at the scan data showed airflow to be within the recommended 3 to 7 grams per second. A check of the frequency output showed the problem.

Idle frequency = 2.177 kHz (2,177 Hz)

Normal frequency at idle speed should be 2.37 to 2.52 kHz. Cleaning the hot wire of the MAF sensor restored proper operation. The sensor wire was covered with what looked like fine fibers, possibly from the replacement air filter.

NOTE: Older GM MAF sensors operated at a lower frequency of 32 to 150 Hz, with 32 Hz being the average reading at idle and 150 Hz for wide-open throttle.

TESTING MASS AIRFLOW SENSORS

VISUAL INSPECTION Start the testing of a MAF sensor by performing a thorough visual inspection. Look at all the hoses that direct and send air, especially between the MAF

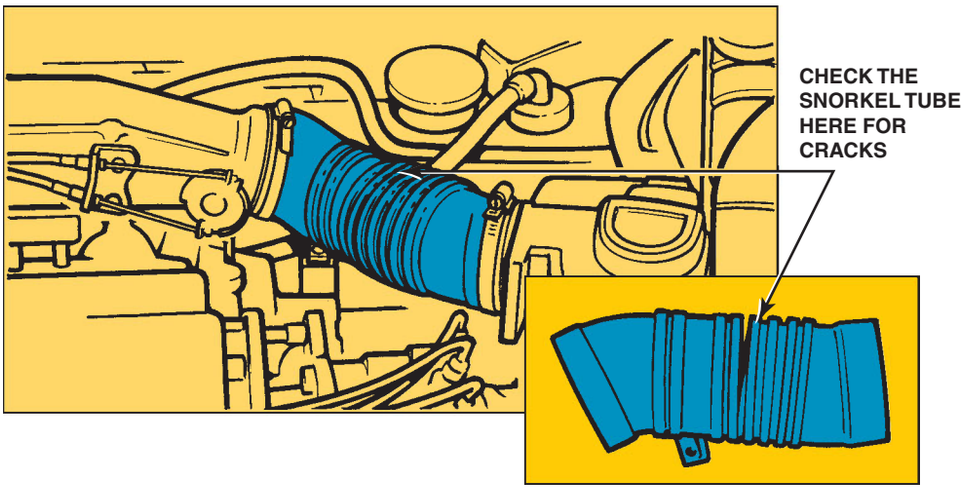

FIGURE 75–6 Carefully check the hose between the MAF sensor and the throttle body assembly for cracks or splits that could create extra (false) air into the engine that is not measured by the MAF sensor.

? FREQUENTLY ASKED QUESTION

What Is Meant By a "High-Authority Sensor"?

A high-authority sensor is a sensor that has a major influence over the amount of fuel being delivered to the engine. For example, at engine start-up, the engine coolant temperature (ECT) sensor is a high-authority sensor and the oxygen sensor (O2S) is a low-authority sensor. However, as the engine reaches operating temperature, the oxygen sensor becomes a high-authority sensor and can greatly affect the amount of fuel being supplied to the engine. See the chart.

High-Authority Sensors	Low-Authority Sensors
ECT (especially when the engine starts and is warming up)	IAT (intake air temperature) sensors modify and back up the ECT
O2S (after the engine reaches closed-loop operation)	TFT (transmission fluid temperature)
MAP	PRNDL (shift position sensor)
MAF	KS (knock sensor)
TP (high authority during acceleration and deceleration)	EFT (engine fuel temperature)

sensor and the throttle body. Also check the electrical connector for:

- Corrosion
- Terminals that are bent or pushed out of the plastic connector
- Frayed wiring

MAF SENSOR OUTPUT TEST

MAF sensors calculate air mass by weight in a given amount of time usually in grams per second (gm/sec). A digital multimeter, set to read DC volts on the signal wire circuit, can be used to check the MAF sensor. See the chart that shows the voltage output compared with the grams per second of airflow through the sensor. Normal airflow is 3 to 7 grams per second.

? FREQUENTLY ASKED QUESTION

What Is False Air?

Airflow sensors and mass airflow (MAF) sensors are designed to measure *all* the air entering the engine. If an air hose between the MAF sensor and throttle body was loose or had a hole, extra air could enter the engine without being measured. This extra air is often called **false air.** ● **SEE FIGURE 75–6.** Because this extra air is unmeasured, the computer does not provide enough fuel delivery and the engine operates too lean, especially at idle. A small hole in the air inlet hose would represent a fairly large percentage of false air at idle, but would represent a very small percentage of extra air at highway speeds.

To diagnose for false air, look at long-term fuel trim numbers at idle and at 3000 RPM.

NOTE: If the engine runs well in reverse, yet runs terrible in any forward gear, carefully look at the inlet hose for air leaks that would open when the engine torque moves the engine slightly on its mounts.

TECH TIP

The Unplug It Test

If a sensor is defective yet still produces a signal to the computer, the computer will often accept the reading and make the required changes in fuel delivery and spark advance. If, however, the sensor is not reading correctly, the computer will process this wrong information and perform an action assuming that information being supplied is accurate. For example, if a mass airflow (MAF) sensor is telling the computer that 12 grams of air per second is going into the engine, the computer will then pulse the injector for 6.4 ms or whatever figure it is programmed to provide. However, if the air going into the engine is actually 14 grams per second, the amount of fuel supplied by the injectors will not be enough to provide proper engine operation. If the MAF sensor is unplugged, the computer knows that the sensor is not capable of supplying airflow information, so it defaults to a fixed amount of fuel based on the values of other sensors such as the TP and MAP sensors. "If in doubt, take it out."

If the engine operates better with a sensor unplugged, then suspect that the sensor is defective. A sensor that is not supplying the correct information is said to be skewed. The computer will not set a diagnostic trouble code for this condition because the computer can often not detect that the sensor is supplying wrong information.

REAL WORLD FIX

The Rich Running Toyota

A Toyota failed an enhanced emission test for excessive carbon monoxide, which is caused by a rich (too much fuel) air–fuel ratio problem. After checking all of the basics and not finding any fault in the fuel system, the technician checked the archives of the International Automotive Technicians Network (*www.iatn.net*) and discovered that a broken spring inside the air flow sensor was a possible cause. The sensor was checked and a broken vane return spring was discovered. Replacing the air flow sensor restored the engine to proper operating conditions and it passed the emission test.

TAP TEST With the engine running at idle speed, gently tap the MAF sensor with the fingers of an open hand. If the engine stumbles or stalls, the MAF sensor is defective. This test is commonly called the **tap test.**

DIGITAL METER TEST OF A MAF SENSOR A digital multimeter can be used to measure the frequency (Hz) output of the sensor and compare the reading with specifications.

The frequency output and engine speed in RPM can also be plotted on a graph to check to see if the frequency and RPM are proportional, resulting in a straight line on the graph.

MAF SENSOR CONTAMINATION

Dirt, oil, silicon, or even spiderwebs can coat the sensing wire. Because it tends to insulate the sensing wire at low airflow rates, a contaminated sensor often overestimates the amount of air entering the engine at idle, and therefore causes the fuel system to go rich. At higher engine speeds near wide-open throttle (WOT), the contamination can cause the sensor to underestimate the amount of air entering the engine. As a result, the fuel system will go lean, causing spark knock and lack of power concerns. To check for contamination, check the fuel trim numbers.

If the fuel trim is negative (removing fuel) at idle, yet is positive (adding fuel) at higher engine speeds, a contaminated MAF sensor is a likely cause. Other tests for a contaminated MAF sensor include:

- At WOT, the grams per second, as read on a scan tool, should exceed 100.
- At WOT, the voltage, as read on a digital voltmeter, should exceed 4 volts for an analog sensor.
- At WOT, the frequency, as read on a meter or scan tool, should exceed 7 kHz for a digital sensor.

If the readings do not exceed these values, then the MAF sensor is contaminated.

MAF-RELATED DIAGNOSTIC TROUBLE CODES

OXYGEN SENSORS

PURPOSE AND FUNCTION

Automotive computer systems use a sensor in the exhaust system to measure the oxygen content of the exhaust. These sensors are called **oxygen sensors (O2S).** The oxygen sensor is installed in the exhaust manifold or located downstream from the manifold in the exhaust pipe. ● **SEE FIGURE 76–1.**

The oxygen sensor is directly in the path of the exhaust gas stream where it monitors oxygen levels in both the exhaust stream and the ambient air. A **zirconia** oxygen sensor is made of **zirconium dioxide (ZrO2),** an electrically conductive material capable of generating a small voltage in the presence of oxygen.

NARROW BAND

A conventional zirconia oxygen sensor (O2S) is only able to detect if the exhaust is richer or leaner than 14.7:1. A conventional oxygen sensor is therefore referred to as the following:

- *Two-step sensor* which is either rich or lean
- *Narrow-band sensor* which informs the PCM whether the exhaust is rich or lean only

The voltage value where a zirconia oxygen sensor switches from rich to lean or from lean to rich is 0.45 V (450 mV).

- Above 0.45 V = rich
- Below 0.45 V = lean

● **SEE FIGURE 76–2.**

CONSTRUCTION

A typical zirconia oxygen sensor has the sensing element in the shape of a thimble; therefore, it is often referred to as one of the following:

- **Thimble design**
- **Cup design**
- **Finger design**

● **SEE FIGURE 76–3.**

A typical zirconia oxygen sensor has a heater inside the thimble and does not touch the inside of the sensor. The sensor is similar to a battery that has two electrodes and an electrolyte. The electrolyte is solid and is the zirconia (zirconium dioxide). There are also two porous platinum electrodes, which have the following functions.

- **Exhaust side electrode** is exposed to the exhaust stream.
- **Ambient side electrode** is exposed to outside (ambient) air and is the **signal electrode,** also called the **reference electrode.**

● **SEE FIGURE 76–4.**

The electrolyte (zirconia) is able to conduct electrons as follows:

- If the exhaust is rich, O_2 from the reference (inner) electrode wants to flow to the exhaust side electrode, which results in the generation of a voltage.
- If the exhaust is lean, O_2 flow is not needed. As a result, there is little if any electron movement and, therefore, no voltage is produced.

OPERATION

Exhaust from the engine passes through the end of the sensor where the gases contact the outer side of the thimble. Atmospheric air enters through the other end of the sensor or through the wire of the sensor and contacts the inner side of the thimble. The inner and outer surfaces of the thimble are plated with platinum. The inner surface becomes a negative electrode and the outer surface is a positive electrode. The atmosphere contains a relatively constant 21% of oxygen. Exhaust gases created by burning a rich air-fuel mixture contain little oxygen. Exhaust gases from burning a lean air-fuel mixture contain more oxygen.

Negatively charged oxygen ions are drawn to the thimble where they collect on both the inner and outer surfaces.

Because the oxygen present in the atmosphere exceeds that in the exhaust gases, the air side of the thimble draws more negative oxygen ions than the exhaust side. The difference between the two sides creates an electrical potential, or voltage. When the concentration of oxygen on the exhaust side of the thimble is low, a high voltage (0.60 to 1.0 V) is generated between the electrodes. As the oxygen concentration on the exhaust side increases, the voltage generated drops low (0.0 to 0.3 V).

An O2S does not send a voltage signal until its tip reaches a temperature of about 572°F (300°C). Also, oxygen sensors provide their fastest response to mixture changes at about 1,472°F (800°C). When the engine starts and the O2S is cold, the PCM operates the engine in the open-loop mode, drawing on prerecorded data in the PROM for fuel control on a cold engine, or when O2S output is not within certain limits.

If the exhaust contains very little oxygen, the PCM assumes that the intake charge is rich (too much fuel) and reduces fuel delivery. However, when the oxygen level is high, the PCM assumes that the intake charge is lean (not enough fuel) and increases fuel delivery. ● **SEE FIGURE 76–5.**

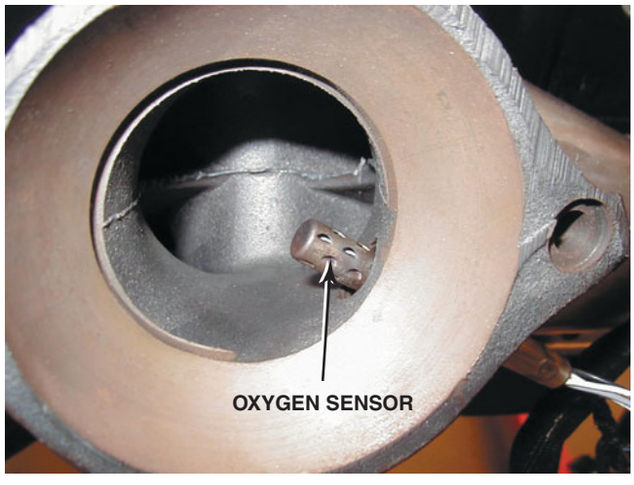

FIGURE 76–1 Many oxygen sensors are located in the exhaust manifold near its outlet so that the sensor can detect the presence or absence of oxygen in the exhaust stream for all cylinders that feed into the manifold.

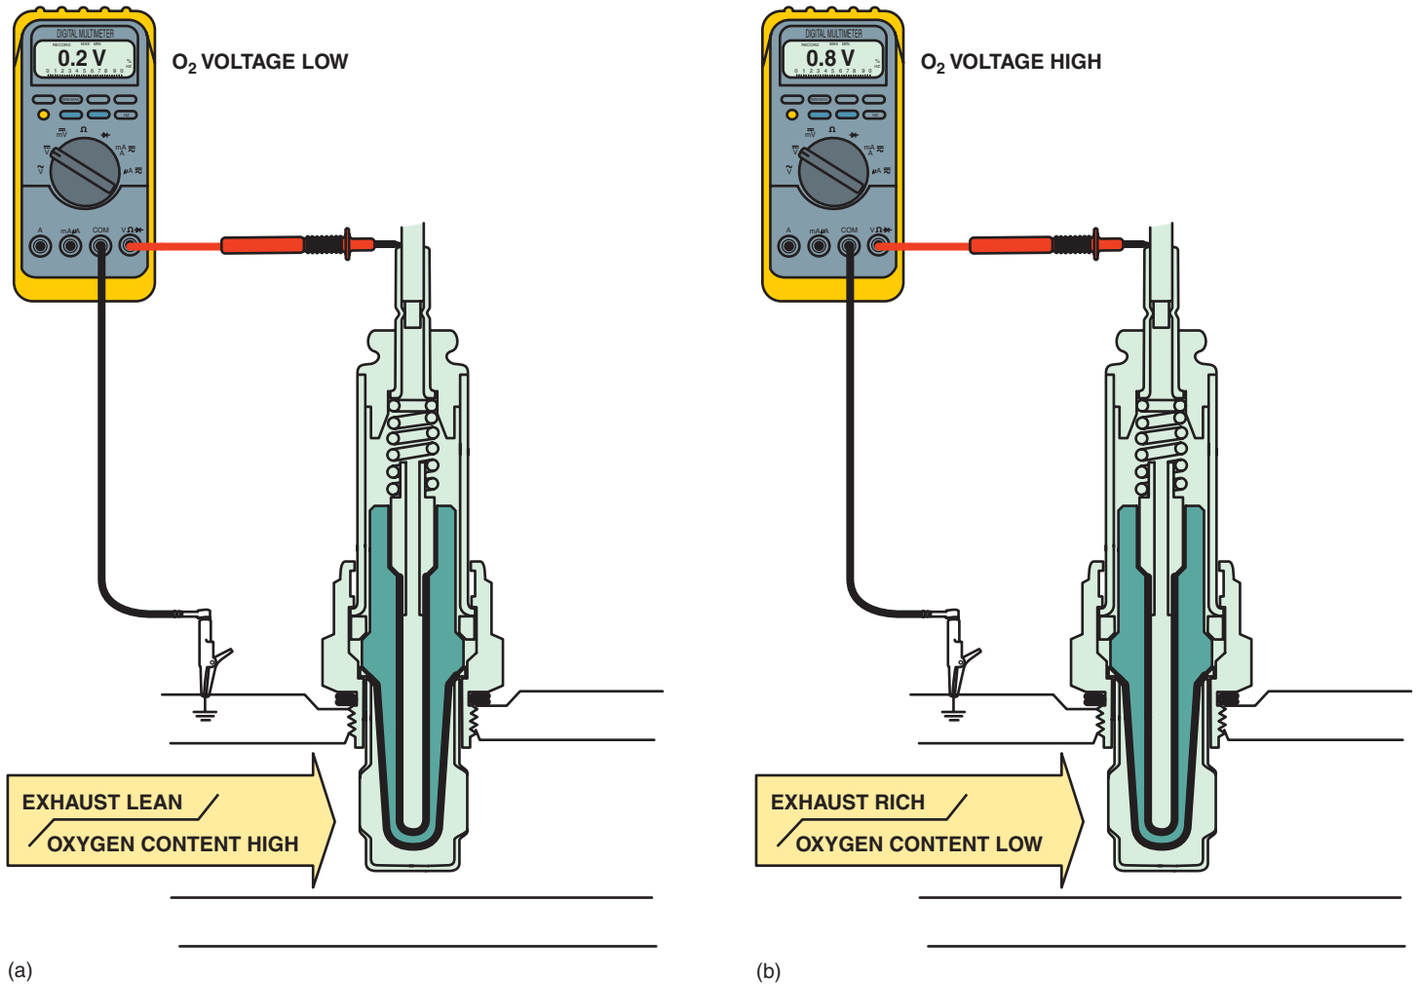

FIGURE 76–2 (a) When the exhaust is lean, the output of a zirconia oxygen sensor is below 450 mV. (b) When the exhaust is rich, the output of a zirconia oxygen sensor is above 450 mV.

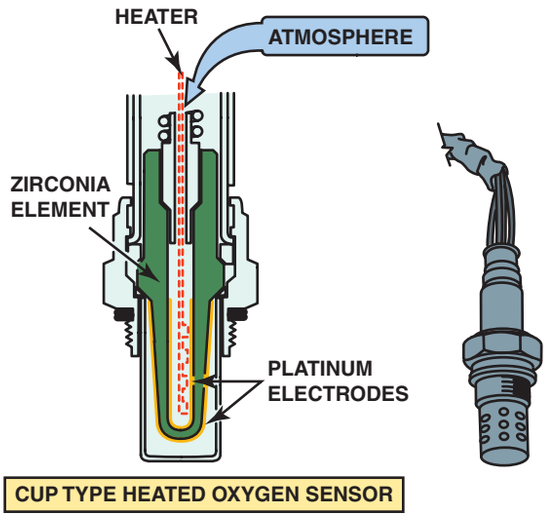

FIGURE 76–3 Most conventional zirconia oxygen sensors and some wide-band oxygen sensors use the cup (finger) type of design.

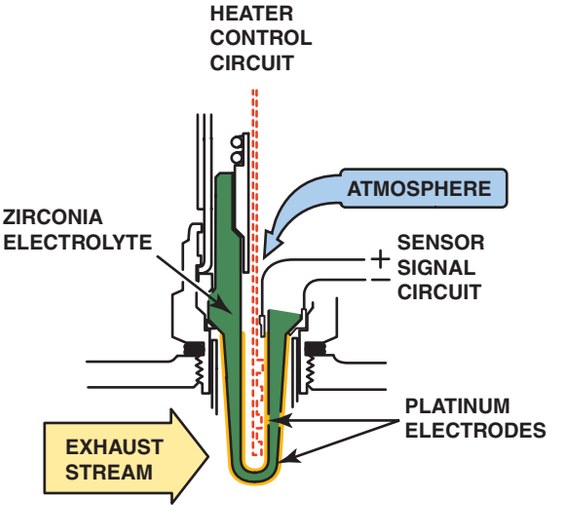

FIGURE 76–4 A typical heated zirconia oxygen sensor, showing the sensor signal circuit that uses the outer (exhaust) electrode as the negative and the ambient air side electrode as the positive.

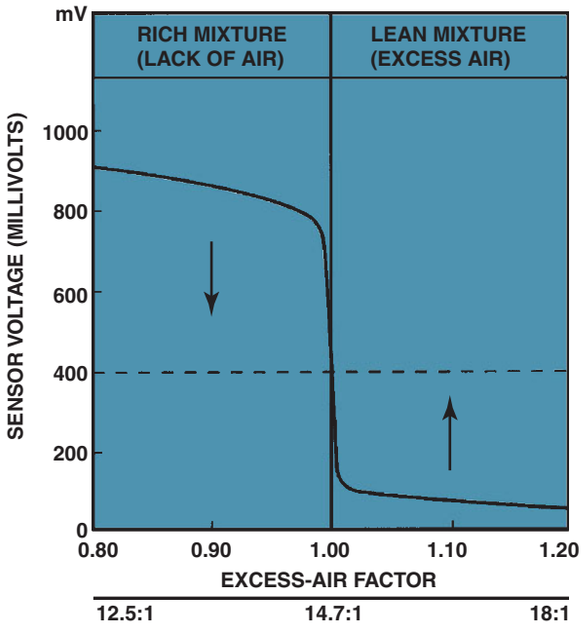

FIGURE 76–5 The oxygen sensor provides a quick response at the stoichiometric air-fuel ratio of 14.7:1.

There are several different designs of oxygen sensors, including:

- **One-wire oxygen sensor.** The single wire of the one-wire oxygen sensor is the O2S signal wire. The ground for the O2S is through the shell and threads of the sensor and through the exhaust manifold.
- **Two-wire oxygen sensor.** The two-wire sensor has a signal wire and a ground wire for the O2S.
- **Three-wire oxygen sensor.** The three-wire sensor design uses an electric resistance heater to help get the O2S up to temperature more quickly and to help keep the sensor at operating temperature even at idle speeds. The three wires include the O2S signal, the power, and ground for the heater.
- **Four-wire oxygen sensor.** The four-wire sensor is a **heated O2S (HO2S)** that uses an O2S signal wire and signal ground. The other two wires are the power and ground for the heater.

HEATER CIRCUITS The heater circuit on conventional oxygen sensors requires 0.8 to 2.0 amperes and keeps the sensor at about 600°F (315°C).

A wide-band oxygen sensor operates at a higher temperature than a conventional HO2S, from 1,200°F to 1,400°F (650°C to 760°C). The amount of electrical current needed for a wide-band oxygen sensor is about 8 to 10 amperes.

FREQUENTLY ASKED QUESTION

What Happens to the Bias Voltage?

Some vehicle manufacturers such as General Motors Corporation have the PCM apply 450 mV (0.45 V) to the O2S signal wire. This voltage is called the **bias voltage** and represents the threshold voltage for the transition from rich to lean.

This bias voltage is displayed on a scan tool when the ignition switch is turned on with the engine off. When the engine is started, the O2S becomes warm enough to produce a usable voltage, and bias voltage "disappears" as the O2S responds to a rich and lean mixture. What happens to the bias voltage that the PCM applies to the O2S? The voltage from the O2S simply overcomes the very weak voltage signal from the PCM. This bias voltage is so weak that even a 20 megohm impedance DMM will affect the strength enough to cause the voltage to drop to 426 mV. Other meters with only 10 megohms of impedance will cause the bias voltage to read less than 400 mV.

Therefore, even though the O2S voltage is relatively low powered, it is more than strong enough to override the very weak bias voltage the PCM sends to the O2S.

REAL WORLD FIX

The Chevrolet Pickup Truck Story

The owner of a 1996 Chevrolet pickup truck complained that the engine ran terribly. It would hesitate and surge, yet there were no diagnostic trouble codes (DTCs). After hours of troubleshooting, the technician discovered while talking to the owner that the problem started after the transmission had been repaired. However, the transmission shop said that the problem was an engine problem and not related to the transmission.

A thorough visual inspection revealed that the front and rear oxygen sensor connectors had been switched. The PCM was trying to compensate for an air-fuel mixture condition that did not exist. Reversing the O2S connectors restored proper operation of the truck.

TITANIA OXYGEN SENSOR

The **titania** (titanium dioxide) oxygen sensor does not produce a voltage but rather changes resistance due to the presence of oxygen in the exhaust. All titania oxygen sensors use a four-terminal variable resistance unit with a heating element. A titania sensor samples exhaust air only and uses a reference voltage from the PCM. Titania oxide oxygen sensors use a 14 mm thread and are not interchangeable with zirconia oxygen sensors, which use an 18 mm thread. One volt is applied to the sensor; the changing resistance of the titania oxygen sensor changes the voltage of the sensor circuit. As with a zirconia oxygen sensor, the voltage signal is above 450 mV when the exhaust is rich and low (below 450 mV) when the exhaust is lean.

FREQUENTLY ASKED QUESTION

Where Is HO2S1?

Oxygen sensors are numbered according to their location in the engine. On a V-type engine, heated oxygen sensor number 1 (HO2S1) is located in the exhaust manifold on the side of the engine where cylinder 1 is located. ● **SEE FIGURE 76–6.**

REAL WORLD FIX

The Oxygen Sensor Is Lying to You

A technician was trying to solve a driveability problem with an older V-6 passenger car. The car idled roughly, hesitated, and accelerated poorly. A thorough visual inspection did not indicate problems and there were no diagnostic trouble codes stored.

The technician checked the oxygen sensor activity using a DMM. The voltage stayed above 600 mV most of the time. If the technician removed a large vacuum hose, the oxygen sensor voltage would temporarily drop to below 450 mV and then return to a reading of over 600 mV. Remember:

- High O2S readings = rich exhaust (low O_2 content in the exhaust)
- Low O2S readings = lean exhaust (high O_2 content in the exhaust)

As part of a thorough visual inspection, the technician removed and inspected the spark plugs. All the spark plugs were white, indicating a lean mixture, not the rich mixture that the oxygen sensor was indicating. The high O2S reading signaled the PCM to reduce the amount of fuel, resulting in an excessively lean operation.

After replacing the oxygen sensor, the engine ran great. But what killed the oxygen sensor? The technician finally learned from the owner that the head gasket had been replaced over a year ago. The silicate and phosphate additives in the antifreeze coolant had coated the oxygen sensor. Because the oxygen sensor was coated, the oxygen content of the exhaust could not be detected, resulting in a false rich signal from the oxygen sensor.

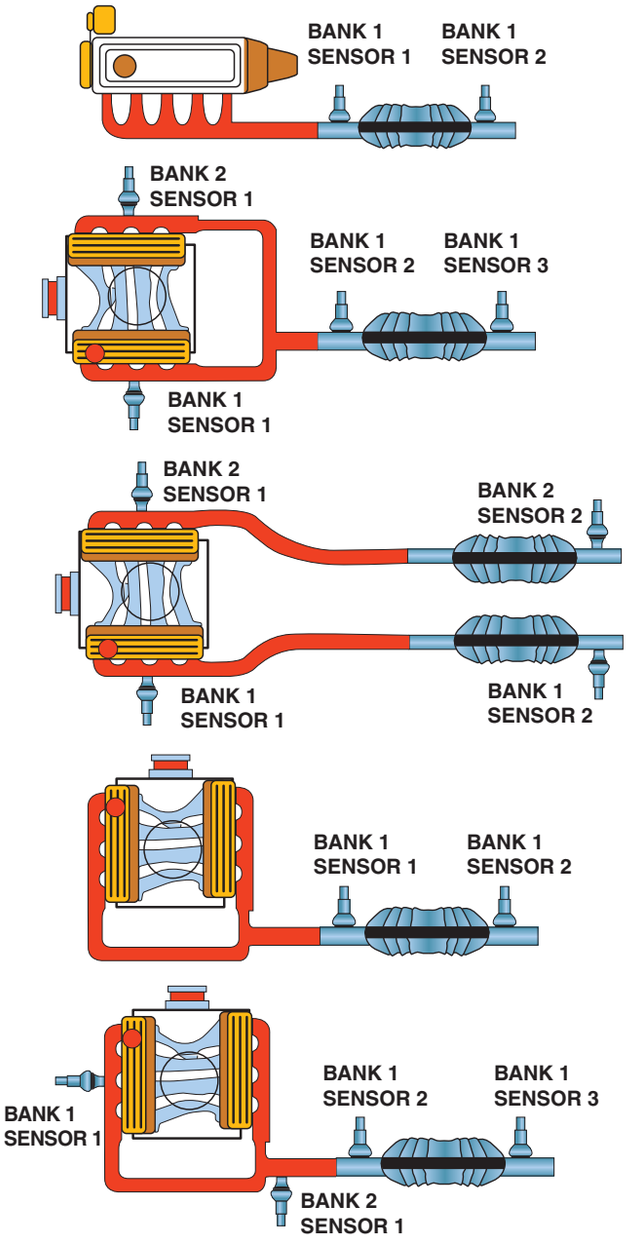

FIGURE 76–6 Number and label designations for oxygen sensors. Bank 1 is the bank where cylinder 1 is located.

PCM USES OF THE OXYGEN SENSOR

FUEL CONTROL The amount of fuel delivered to an engine is determined by the powertrain control module (PCM) based on inputs from the engine coolant temperature (ECT), throttle position (TP) sensor, and others until the oxygen sensor is capable of supplying a usable signal. When the PCM alone is determining the amount of fuel needed, it is called **open-loop** operation. As soon as the oxygen sensor (O2S) is capable of supplying rich and lean signals, PCM adjustments can be made to fine-tune the correct air-fuel mixture. This checking and adjusting of the PCM is called **closed-loop** operation.

The upstream oxygen sensors are among the high-authority sensors used for fuel control while operating in closed loop. Before the oxygen sensors are hot enough to give accurate exhaust oxygen information to the PCM, fuel control is determined by other sensors and the anticipated injector pulse width determined by those sensors. After the control system achieves closed-loop status, the oxygen sensor provides feedback to actual exhaust gas oxygen content.

FUEL TRIM The **fuel trim** numbers are determined from the signals by the oxygen sensor(s). If the engine has been operating too lean, short-term and long-term fuel time programming inside the

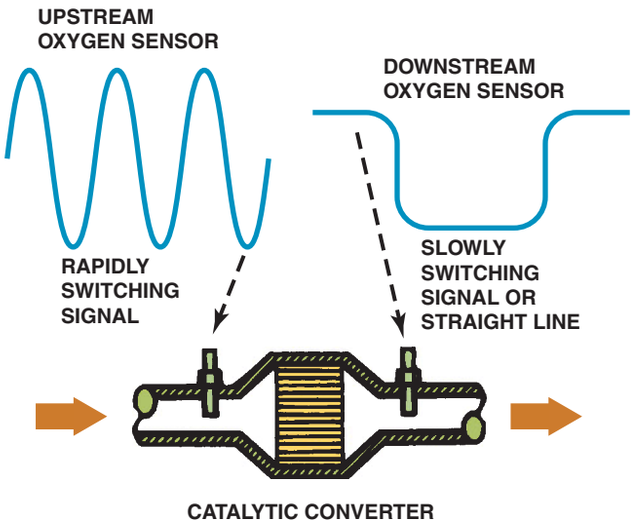

FIGURE 76–7 The OBD-II catalytic converter monitor compares the signals of the upstream and downstream oxygen sensor to determine converter efficiency.

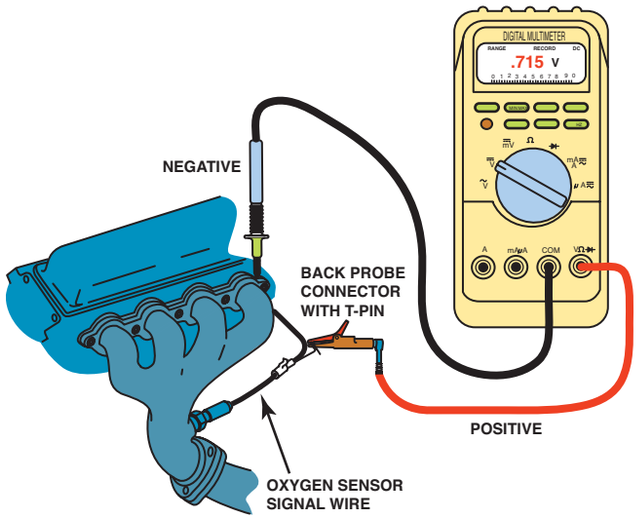

FIGURE 76–8 Testing an oxygen sensor using a DMM set on DC volts. With the engine operating in closed loop, the oxygen voltage should read over 800 mV and lower than 200 mV and be constantly fluctuating.

PCM can cause an increase in the commanded injector pulse width to bring the air-fuel mixture back into the proper range. Fuel trim can be negative (subtracting fuel) or positive (adding fuel).

OXYGEN SENSOR DIAGNOSIS

PCM SYSTEM TESTS The oxygen sensors are used for diagnosis of other systems and components. For example, the exhaust gas recirculation (EGR) system is tested by the PCM, by commanding the EGR valve to open during the test. Some PCMs determine whether enough exhaust gas flows into the engine by looking at the oxygen sensor response (fuel trim numbers). The upstream and downstream oxygen sensors are also used to determine the efficiency of the catalytic converter. Therefore, if a fault occurs with an oxygen sensor, the PCM may not be able to test other systems. ● **SEE FIGURE 76–7.**

VISUAL INSPECTION Whenever an oxygen sensor is replaced, the old sensor should be carefully inspected to help determine the cause of the failure. This is an important step because if the cause of the failure is not discovered, it could lead to another sensor failure.

Inspection may reveal the following:

1. Black sooty deposits usually indicate a rich air-fuel mixture.
2. White chalky deposits are characteristic of silica contamination. Usual causes for this type of sensor failure include silica deposits in the fuel or a technician having used the wrong type of silicone sealant during the servicing of the engine.
3. White sandy or gritty deposits are characteristic of antifreeze (ethylene glycol) contamination. A defective cylinder head or intake manifold gasket could be the cause, or a cracked cylinder head or engine block. Antifreeze may also cause the oxygen sensor to become green as a result of the dye used in antifreeze.
4. Dark brown deposits indicate excessive oil consumption. Possible causes include a defective positive crankcase ventilation (PCV) system or a mechanical engine problem such as defective valve stem seals or piston rings.

REAL WORLD FIX

The Missing Ford

A Ford was being analyzed for poor engine operation. The engine ran perfectly during the following conditions.

1. Engine cold or operating in open loop
2. Engine at idle
3. Engine operating at or near wide-open throttle

After hours of troubleshooting, the technician determined the cause to be a poor ground connection for the oxygen sensor. The engine ran okay during times when the PCM ignored the oxygen sensor. Unfortunately, the service technician did not have a definite plan during the diagnostic process and as a result checked and replaced many unnecessary parts. An oxygen sensor test early in the diagnostic procedure would have indicated that the oxygen (O2S) signal was not correct. The poor ground caused the oxygen sensor voltage level to be too high, indicating to the PCM that the mixture was too rich. The PCM then subtracted fuel which caused the engine to miss and run roughly as the result of the now too lean air-fuel mixture.

DIGITAL VOLTMETER TESTING The oxygen sensor can be checked for proper operation using a digital high-impedance voltmeter.

1. With the engine off, connect the red lead of the meter to the oxygen sensor signal wire and the black meter lead to a good engine ground. ● **SEE FIGURE 76–8.**
2. Start the engine and allow it to reach closed-loop operation.
3. In closed-loop operation, the oxygen sensor voltage should be constantly changing as the fuel mixture is being controlled.

The results should be interpreted as follows:

- If the oxygen sensor fails to respond, and its voltage remains at about 450 mV, the sensor may be defective and require replacement. Before replacing the oxygen sensor, check the manufacturer's recommended procedures.

TECH TIP

Do Not Solder Oxygen Sensor Wires

Oxygen sensors must have outside oxygen to compare with the oxygen content in the exhaust. Most oxygen sensors breathe through the signal wire and, if soldered, would block the flow of outside air to the sensor. If a replacement oxygen sensor is used, always use the factory replacement, using the original connectors or a crimp-and-seal connector that will seal out any moisture and still allow air to flow through the connector.

- If the oxygen sensor reads high all the time (above 550 mV), the fuel system could be supplying too rich a fuel mixture or the oxygen sensor may be contaminated. An oxygen sensor reading that is high could be due to other things besides a rich air-fuel mixture. When the O2S reads high as a result of other factors besides a rich mixture, it is often called a **false rich** indication.

False rich indications (high O2S readings) can be attributed to the following:

- Contaminated O2S due to additives in the engine coolant or due to silicon poisoning
- A stuck open EGR valve (especially at idle)
- A spark plug wire too close to the oxygen sensor signal wire, which can induce a higher than normal voltage in the signal wire, thereby indicating to the PCM a false rich condition
- A loose oxygen sensor ground connection, which can cause a higher than normal voltage and a false rich signal
- A break or contamination of the wiring and its connectors, which could prevent reference oxygen from reaching the oxygen sensor, resulting in a false rich indication (All oxygen sensors require an oxygen supply inside the sensor itself for reference to be able to sense exhaust gas oxygen.)

If the oxygen sensor voltage remains low (below 350 mV), the oxygen sensor itself could be bad or the fuel system could be supplying too lean a fuel mixture. Check for a vacuum leak or partially clogged fuel injector(s). Before replacing the oxygen sensor, check the manufacturer's recommended procedures. If an oxygen sensor reads low as a result of a factor besides a lean mixture, it is often called a **false lean** indication.

False lean indications (low O2S readings) can be attributed to the following:

1. **Ignition misfires.** An ignition misfire due to a defective spark plug wire, fouled spark plug, and so forth, causes no burned air and fuel to be exhausted past the O2S. The O2S "sees" the oxygen (not the unburned gasoline) and the O2S voltage is low.
2. **Exhaust leak in front of the O2S.** An exhaust leak between the engine and the oxygen sensor causes outside oxygen to be drawn into the exhaust and past the O2S. This oxygen is "read" by the O2S and produces a lower than normal voltage. The PCM interprets the lower than normal voltage signal from the O2S as meaning that the air-fuel mixture is lean. The PCM will cause the fuel system to deliver a richer air-fuel mixture.
3. **Spark plug misfire.** The PCM does not know that the extra oxygen going past the oxygen sensor is not due to a lean air-fuel mixture. The PCM commands a richer mixture, which could cause the spark plugs to foul, increasing the rate of misfiring.

FREQUENTLY ASKED QUESTION

Why Does the Oxygen Sensor Voltage Read 5 Volts on Many Chrysler Vehicles?

Many Chrysler vehicles apply a 5 volt reference to the signal wire of the oxygen sensor. The purpose of this voltage is to allow the PCM to detect if the oxygen sensor signal circuit is open or grounded.

- If the voltage on the signal wire is 4.5 volts or more, the PCM assumes that the sensor is open.
- If the voltage on the signal wire is zero, the PCM assumes that the sensor is shorted-to-ground.

If either condition exists, the PCM can set a diagnostic trouble code (DTC).

TECH TIP

The Key On, Engine Off Oxygen Sensor Test

This test works on General Motors vehicles and may work on others if the PCM applies a bias voltage to the oxygen sensors. Zirconia oxygen sensors become more electrically conductive as they get hot. To perform this test, be sure that the vehicle has not run for several hours.

STEP 1 Connect a scan tool and get the display ready to show oxygen sensor data.

STEP 2 Key the engine on *without* starting the engine. The heater in the oxygen sensor will start heating the sensor.

STEP 3 Observe the voltage of the oxygen sensor. The applied bias voltage of 450 mV should slowly decrease for all oxygen sensors as they become more electrically conductive as the bias voltage is flowing to ground.

STEP 4 A good oxygen sensor should indicate a voltage of less than 100 mV after three minutes. Any sensor that displays a higher than usual voltage or seems to stay higher longer than the others could be defective or skewed high.

MIN/MAX TESTING A digital meter set on DC volts can be used to record the minimum and maximum voltage with the engine running. A good oxygen sensor should be able to produce a value of less than 300 mV and a maximum voltage above 800 mV. ● **SEE FIGURE 76–9.**

Replace any oxygen sensor that fails to go above 700 mV or lower than 300 mV. ● **SEE CHART 76–1.**

SCAN TOOL TESTING A good oxygen sensor should sense the oxygen content and change voltage outputs rapidly. How fast an oxygen sensor switches from high (above 450 mV) to low (below 350 mV) is measured as frequency, or the number of times the voltage switches per second.

NOTE: On a fuel-injected engine at 2000 engine RPM, 1 to 5 Hz (one to five switches per second) is normal.

Using a scan tool, observe the oxygen sensor voltages with the engine running at 2000 RPM. Look for numbers higher than 800 mV and lower than 200 mV.

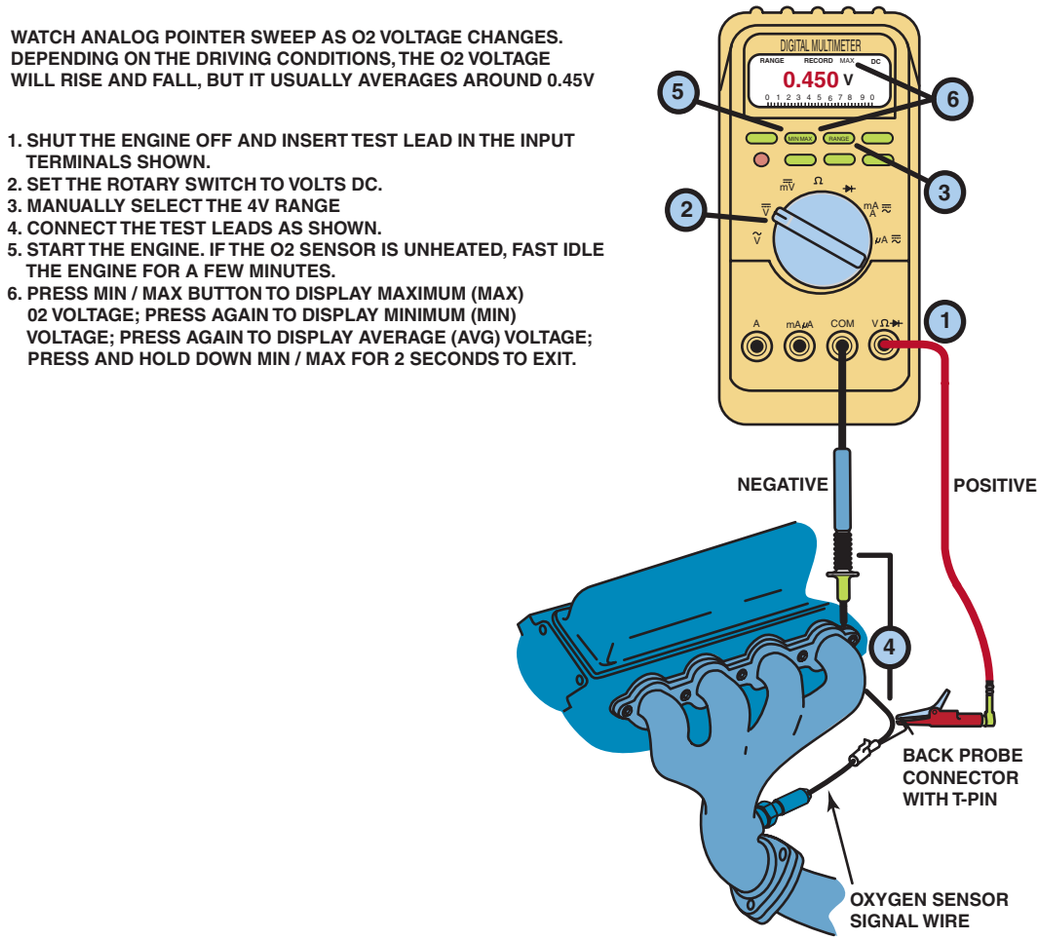

FIGURE 76–9 Using a digital multimeter to test an oxygen sensor using the MIN/MAX record function of the meter.

MIN/MAX OXYGEN SENSOR TEST CHART

MINIMUM VOLTAGE	MAXIMUM VOLTAGE	AVERAGE VOLTAGE	TEST RESULTS
Below 200 mV	Above 800 mV	400 to 500 mV	Oxygen sensor is okay.
Above 200 mV	Any reading	400 to 500 mV	Oxygen sensor is defective.
Any reading	Below 800 mV	400 to 500 mV	Oxygen sensor is defective.
Below 200 mV	Above 800 mV	Below 400 mV	System is operating lean.*
Below 200 mV	Below 800 mV	Below 400 mV	System is operating lean. (Add propane to the intake air to see if the oxygen sensor reacts. If not, the sensor is defective.)
Below 200 mV	Above 800 mV	Above 500 mV	System is operating rich.
Above 200 mV	Above 800 mV	Above 500 mV	System is operating rich. (Remove a vacuum hose to see if the oxygen sensor reacts. If not, the sensor is defective.)

CHART 76–1

The test results of using a digital meter set to read minimum and maximum values while testing a narrow-band oxygen sensor.
*Check for an exhaust leak upstream from the O2S or ignition misfire that can cause a false lean indication before further diagnosis.

If the frequency of switching is low, the oxygen sensor may be contaminated, or the fuel delivery system is delivering a constant rich or lean air-fuel mixture. If the frequency of switching is higher than 5 Hz, look for misfire conditions.

1. Connect the scan tool and start the engine.
2. Operate the engine at a fast idle (2,500 RPM) for two minutes to allow time for the oxygen sensor to warm to operating temperature.
3. Observe the oxygen sensor activity on the scan tool to verify closed-loop operation. Select the "snapshot" mode, hold the engine speed steady, and start recording.
4. Play back snapshot and place a mark beside each range of oxygen sensor voltage for each frame of the snapshot.

A good oxygen sensor and PCM should result in the most snapshot values at both ends (0 to 300 mV and 600 to 1,000 mV). If most of the readings are in the middle, the oxygen sensor is not working correctly.

SCOPE TESTING A scope can also be used to test an oxygen sensor. Connect the scope to the signal wire and ground for the sensor (if it is so equipped). ● **SEE FIGURE 76–10.**

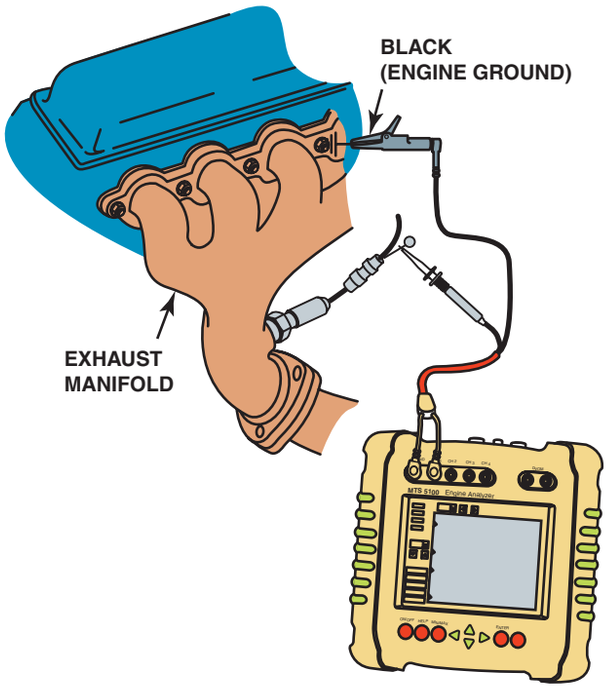

FIGURE 76–10 Connecting a handheld digital storage oscilloscope to an oxygen sensor signal wire. Check the instructions for the scope as some require the use of a filter to be installed in the test lead to reduce electromagnetic interference that can affect the oxygen sensor waveform.

With the engine operating in closed loop, the voltage signal of the sensor should be constantly changing. ● **SEE FIGURE 76–11.**

Check for rapid switching from rich to lean and lean to rich and change between once every two seconds and five times per second (0.5 to 5.0 Hz).

NOTE: General Motors warns not to base the diagnosis of an oxygen sensor problem solely on its scope pattern. The varying voltage output of an oxygen sensor can easily be mistaken for a fault in the sensor itself, rather than a fault in the fuel delivery system.

POST CATALYTIC CONVERTER OXYGEN SENSOR TESTING

The oxygen sensor located behind the catalytic converter is used on OBD-II vehicles to monitor converter efficiency. A changing air-fuel mixture is required for the most efficient operation of the converter. If the converter is working correctly, the oxygen content after the converter should be fairly constant. ● **SEE FIGURE 76–12.**

The post catalytic converter oxygen sensor also is used to modify the amount of fuel delivered to the engine to allow the converter to work efficiently. If, for example, the rear oxygen sensor voltage stayed high, the PCM will try to increase the amount of oxygen entering the converter by leaning the air-fuel mixture to the engine. This process is often called the target upstream fuel trim. Therefore, instead of the PCM commanding a target air-fuel mixture of 14.7:1, the new target may specify an air-fuel ratio of 14.9:1 or slightly leaner than normal to help provide a little extra oxygen for use by the catalytic converter. This target air-fuel ratio or fuel trim is displayed on scan tools.

TECH TIP

The Propane Oxygen Sensor Test

Adding propane to the air inlet of a running engine is an excellent way to check if the oxygen sensor is able to react to changes in air-fuel mixture. Follow these steps in performing the propane trick.

1. Connect a digital storage oscilloscope to the oxygen sensor signal wire.
2. Start and operate the engine until it reaches operating temperature and is in closed-loop fuel control.
3. While watching the scope display, add some propane to the air inlet. The scope display should read full rich (over 800 mV).
4. Shut off the propane. The waveform should drop to less than 200 mV (0.2 V).
5. Quickly add some propane while the oxygen sensor is reading low and watch for a rapid transition to rich. The transition should occur in less than 100 milliseconds (ms).

REAL WORLD FIX

How Could Using Silicone Sealer on a Valve Cover Gasket Affect the Oxygen Sensor?

The wrong type of silicone **room temperature vulcanization (RTV)** sealer on a valve cover gasket gives off harmful silica fumes during the curing process. These fumes enter the crankcase area by way of the oil drainback holes in the cylinder head as well as through pushrod openings and other passages in the engine. During engine operation, these fumes are drawn into the intake manifold through the positive crankcase ventilation (PCV) system and are burned in the engine. The harmful silica then exits through the exhaust system, where the contamination affects the oxygen sensor.

NOTE: Be careful not to spray any silicone lubricant near the engine vacuum, which might draw the fumes into the engine and cause silica damage to the oxygen sensor.

WIDE-BAND OXYGEN SENSORS

TERMINOLOGY **Wide-band oxygen sensors** have been used since 1992 on some Hondas. Today, they are used by most vehicle manufacturers to ensure that the exhaust emissions can meet the current standard. Wide-band oxygen sensors have various names, depending on the vehicle and/or oxygen sensor manufacturer, including:

- Wide-band oxygen sensor
- Broadband oxygen sensor
- Wide-range oxygen sensor
- Air-fuel ratio (AFR) sensor

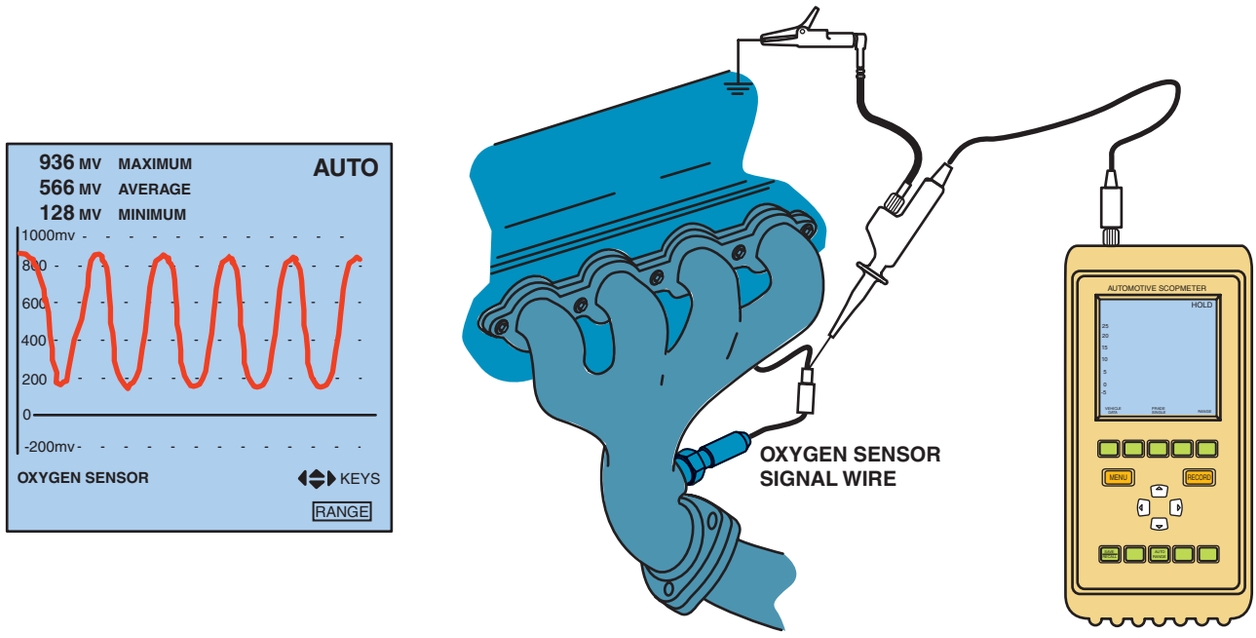

FIGURE 76–11 The waveform of a good oxygen sensor as displayed on a digital storage oscilloscope (DSO). Note that the maximum reading is above 800 mV and the minimum reading is less than 200 mV.

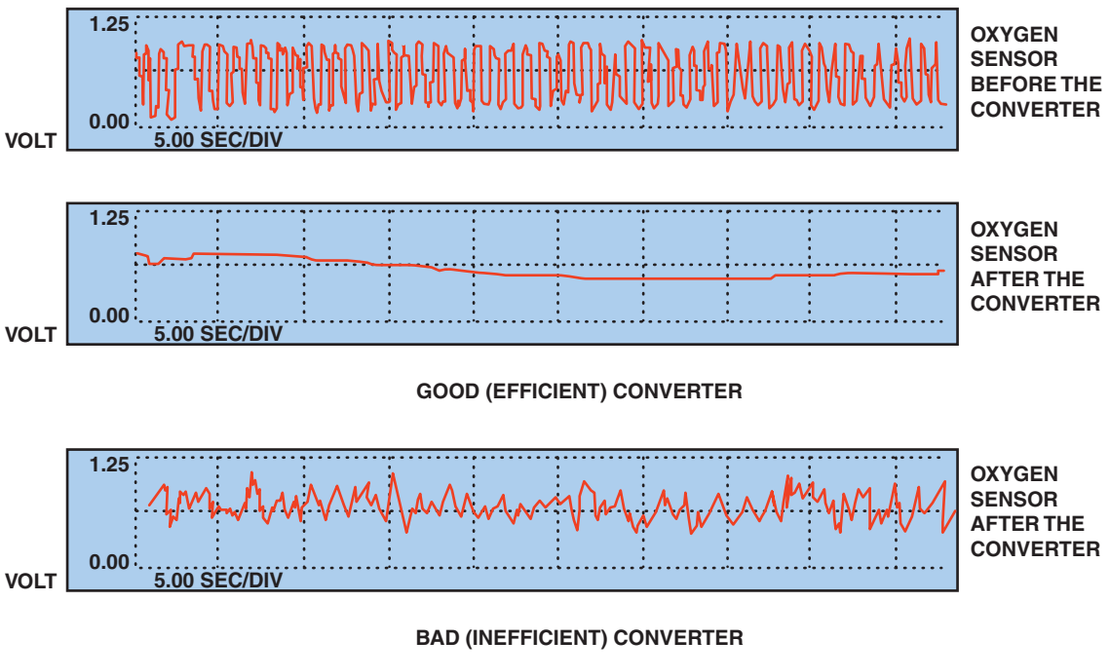

FIGURE 76–12 The post catalytic converter oxygen sensor should display very little activity if the catalytic converter is efficient.

- Wide-range air-fuel (WRAF) sensor
- Lean-air fuel (LAF) sensor
- Air-fuel (AF) sensor

Wide-band oxygen sensors are also manufactured in dual cell and single cell designs.

INTRODUCTION A conventional zirconia oxygen sensor reacts to an air-fuel mixture that is either richer or leaner than 14.7:1. This means that the sensor cannot be used to detect the exact air-fuel mixture. ● **SEE FIGURE 76–13.**

The need for more stringent exhaust emission standards such as the natural low emission vehicle (NLEV), plus the ultra low emission

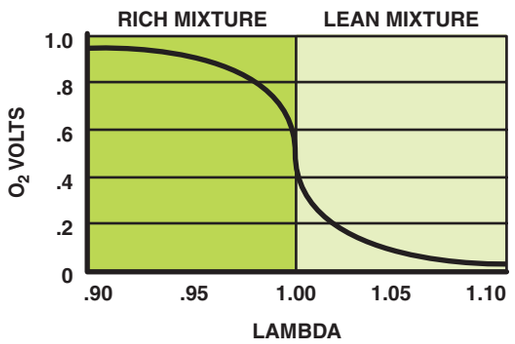

FIGURE 76–13 A conventional zirconia oxygen sensor can only reset to exhaust mixtures that are richer or leaner than 14.7:1 (lambda 1.00).

vehicle (ULEV) and the super ultra low emission vehicle (SULEV) require more accurate fuel control than can be provided by a traditional oxygen sensor.

PURPOSE AND FUNCTION A wide-band oxygen sensor is capable of supplying air-fuel ratio information to the PCM over a much broader range. Compared with a conventional zirconia oxygen sensor, the wide-band oxygen sensor has the following features.

1. The ability to detect exhaust air-fuel ratio from as rich as 10:1 to as lean as 23:1 in some cases
2. Cold start activity within as little as 10 seconds

PLANAR DESIGN In 1998, Bosch introduced a wide-band oxygen sensor that is flat and thin (1.5 mm or 0.006 in.), known as a **planar** design and not in the shape of a thimble as previously constructed. Now several manufacturers produce a similar planar design wide-band oxygen sensor. Its thin design makes it easier to heat than older styles of oxygen sensors and, as a result, it can achieve closed loop in less than 10 seconds. This fast heating, called **light-off time (LOT),** helps improve fuel economy and reduces cold-start exhaust emissions. The type of construction is not noticed by the technician, nor does it affect the testing procedures.

A conventional oxygen sensor can also be constructed using a planar design instead of the thimble-type design. A planar design has the following features.

- The elements including the zirconia electrolyte and the two electrodes and heater are stacked together in a flat-type design.
- It allows faster warm-up because the heater is in direct contact with the other elements.
- Planar oxygen sensors are the most commonly used. Some planar designs are used as a conventional narrow-band oxygen sensor.

The sandwich-type designs of the planar style of oxygen sensor have the same elements and operate the same, but are stacked in the following way from the exhaust side to the ambient air side.

Exhaust stream
Outer electrode
Zirconia (Zr_2) (electrolyte)
Inner electrode (reference or signal)
Outside (ambient) air
Heater

● **SEE FIGURE 76–14.**

Another name for a conventional oxygen sensor is a **Nernst cell,** named for Walther Nernst, 1864–1941, a German physicist known for his work in electrochemistry.

FREQUENTLY ASKED QUESTION

How Quickly Can a Wide-Band Oxygen Sensor Achieve Closed Loop?

In a Toyota Highlander hybrid electric vehicle, the operation of the gasoline engine is delayed for a short time when the vehicle is first driven. During this time of electric operation, the oxygen sensor heaters are turned on in readiness for the gasoline engine starting. The gasoline engine often achieves closed-loop operation during *cranking* because the oxygen sensors are fully warm and ready to go at the same time the engine is started. Having the gasoline engine achieve closed loop quickly, allows it to meet the stringent SULEV standards.

DUAL CELL PLANAR WIDE-BAND SENSOR OPERATION

CONSTRUCTION In a conventional zirconia oxygen sensor, a bias or reference voltage can be applied to the two platinum electrodes, and then oxygen ions can be forced (pumped) from the ambient reference air side to the exhaust side of the sensor. If the polarity is reversed, the oxygen ion can be forced to travel in the opposite direction.

A **dual cell** planar-type wide-band oxygen sensor is made like a conventional planar O2S, or Nernst cell. Above the Nernst cell is another zirconia layer with two electrodes, called the **pump cell.** The two cells share a common ground, called the **reference.**

There are two internal chambers:

- The air reference chamber is exposed to ambient air.
- The diffusion chamber is exposed to the exhaust gases.

Platinum electrodes are on both sides of the zirconia electrolyte elements, which separate the air reference chamber and the exhaust exposed diffusion chamber.

OPERATION The basic principle of operation of a typical wide-band oxygen sensor is that it uses a positive or negative voltage signal to keep a balance between two sensors. Oxygen sensors do not measure the quantity of free oxygen in the exhaust. Instead, oxygen sensors produce a voltage that is based on the ion flow between the platinum electrodes of the sensor to maintain a stoichiometric balance.

For example:

- If there is a lean exhaust, there is oxygen in the exhaust and the ion flow from the ambient side to the exhaust side is low.
- If there is rich exhaust, the ion flow is increased to help maintain balance between the ambient air side and the exhaust side of the sensor.

The PCM can apply a small current to the pump cell electrodes, which causes oxygen ions through the zirconia into or out of the diffusion chamber. The PCM pumps O_2 ions in and out of the diffusion chamber to bring the voltage back to 0.45 V, using the pump cell.

The operation of a wide-band oxygen sensor is best described by looking at what occurs when the exhaust is stoichiometric, rich, and lean. ● **SEE FIGURE 76–15.**

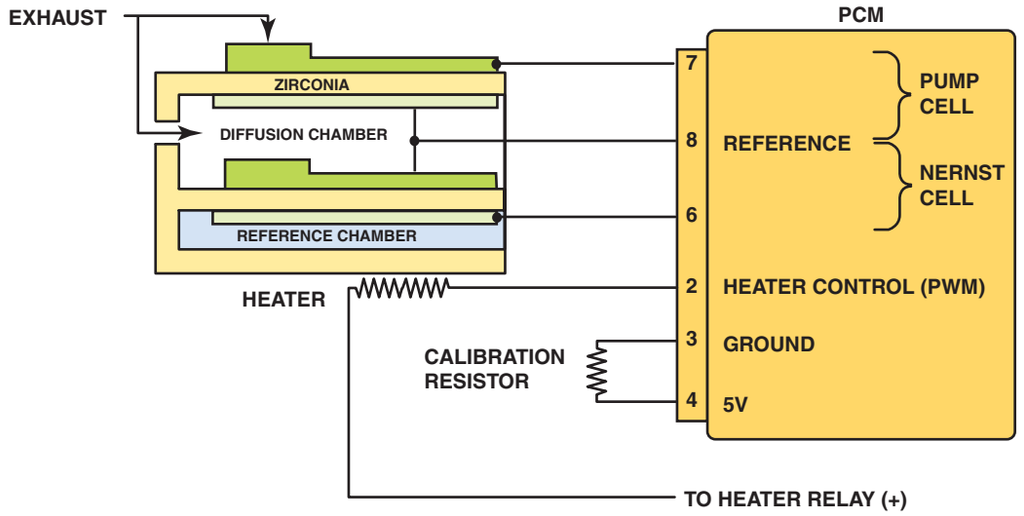

FIGURE 76–15 The reference electrodes are shared by the Nernst cell and the pump cell.

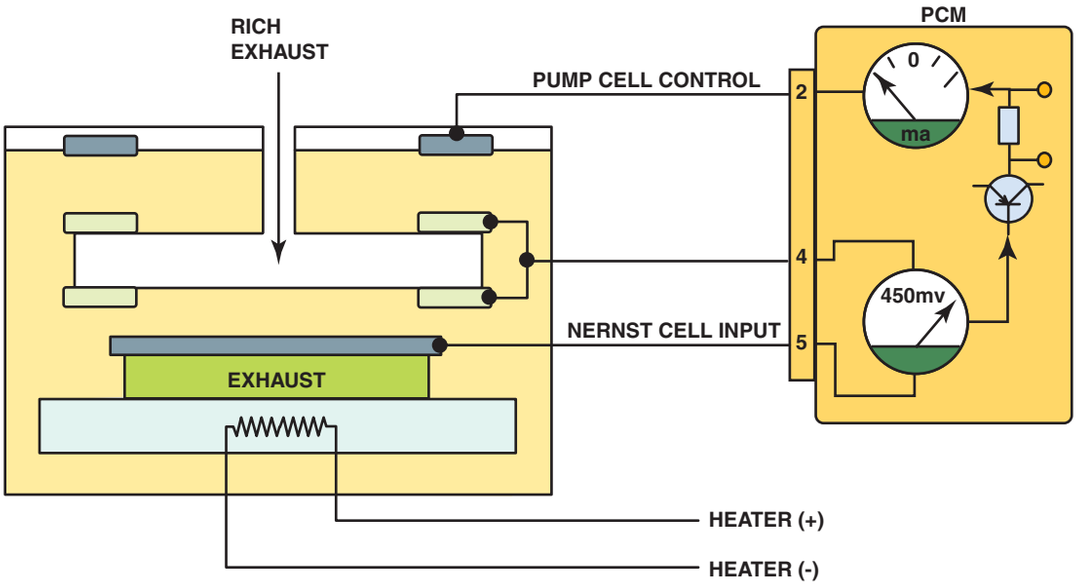

FIGURE 76–16 When the exhaust is rich, the PCM applies a negative current into the pump cell.

STOICHIOMETRIC

- When the exhaust is at stoichiometric (14.7:1 air-fuel ratio), the voltage of the Nernst cell is 450 mV (0.45 V).
- The voltage between the diffusion chamber and the air reference chamber changes from 0.45 V. This voltage will be:
  - Higher if the exhaust is rich
  - Lower if the exhaust is lean

The reference voltage remains constant, usually at 2.5 V, but can vary depending on the year, make, and model of vehicle and the type of sensor. Typical reference voltages include:

- 2.2 V
- 2.5 V
- 2.7 V
- 3.3 V
- 3.6 V

RICH EXHAUST. When the exhaust is rich, the voltage between the common (reference) electrode and the Nernst cell electrode that is exposed to ambient air is higher than 0.45 V. The PCM applies a negative current in milliamperes to the pump cell electrode to bring the circuit back into balance. ● **SEE FIGURE 76–16.**

LEAN EXHAUST. When the exhaust is lean, the voltage between the common (reference) electrode and the Nernst cell electrode is lower than 0.45 V. The PCM applies a positive current in milliamperes to the pump cell to bring the circuit back into balance. ● **SEE FIGURE 76–17.**

DUAL CELL DIAGNOSIS

SCAN TOOL DIAGNOSIS Most service information specifies that a scan tool be used to check the wide-band oxygen sensor, because the PCM performs tests of the unit and can identify faults. However, even wide-band oxygen sensors can be fooled if there is an exhaust manifold leak or other fault which could lead to false or inaccurate readings. If the oxygen sensor reading is false, the PCM will command an incorrect amount of fuel. The scan data shown on a generic (global) OBD-II scan tool will often be different than the reading on the factory scan tool. ● **SEE CHART 76–2** for an example of a

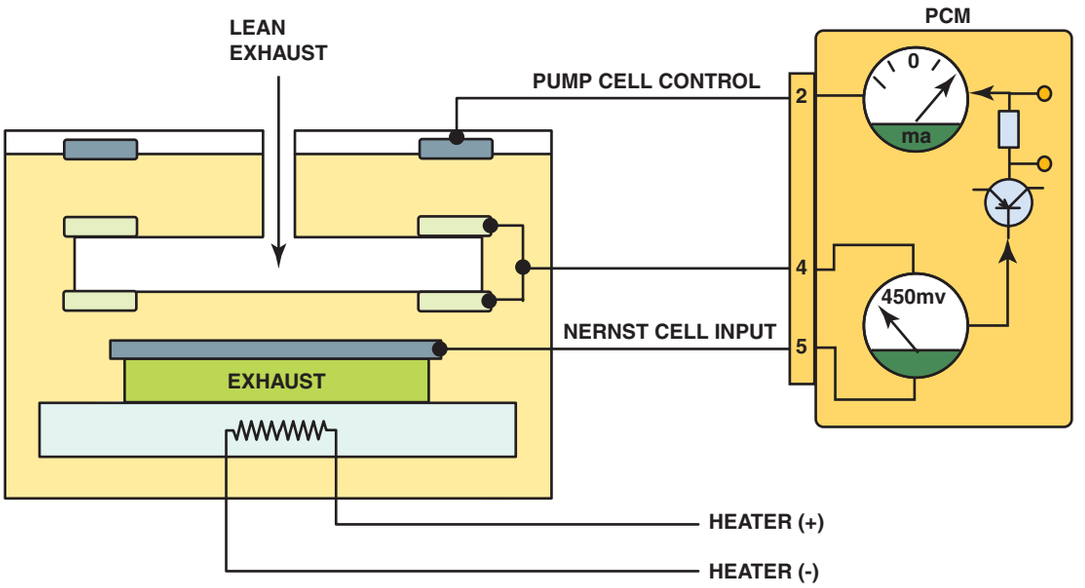

FIGURE 76–17 When the exhaust is lean, the PCM applies a positive current into the pump cell.

FACTORY SCAN TOOL	OBD II SCAN TOOL	AIR-FUEL RATIO
2.50 V	0.50 V	12.5:1
3.00 V	0.60 V	14.0:1
3.30 V	0.66 V	14.7:1
3.50 V	0.70 V	15.5:1

CHART 76–2

A comparison showing what a factory scan tool and a generic OBD-II scan tool might display at various air-fuel ratios.

SCAN TOOL DATA (PID) The following information will be displayed as a scan tool when looking at data for a wide-band oxygen sensor.

H02S1 = _____ mA ÷	If the current is positive, this means that the PCM is pumping current in the diffusion gap due to a rich exhaust. If the current is negative, the PCM is pumping current out of the diffusion gap due to a lean exhaust.
Air-fuel ratio = _____	Usually expressed in lambda. One means that the exhaust is at stoichiometric (14.7:1 air-fuel ratio) and numbers higher than one indicate a lean exhaust and numbers lower than one indicate a rich exhaust.

DIGITAL METER TESTING When testing a wide-band oxygen sensor for proper operation, perform the following steps.

STEP 1 Check service information and determine the circuit and connector terminal identification.

STEP 2 Measure the calibration resistor. While the value of this resistor can vary widely depending on the type of sensor, the calibrating resistor should still be checked for opens and shorts.

NOTE: The calibration resistor is usually located within the connector itself.

- If open, the ohmmeter will read OL (infinity ohms).
- If shorted, the ohmmeter will read zero or close to zero.

STEP 3 Measure the heater circuit for proper resistance or current flow.

STEP 4 Measure the reference voltage relative to ground. This can vary but is generally 2.4 to 2.6 V.

STEP 5 Using jumper wires, connect an ammeter and measure the current in the pump cell control wire.

RICH EXHAUST When the exhaust is rich (lambda less than 1.00), the Nernst cell voltage will move higher than 0.45 V. The PCM will pump oxygen from the exhaust into the diffusion gap by applying a negative voltage to the pump cell.

LEAN EXHAUST When the exhaust is lean (lambda higher than 1.00), the Nernst cell voltage will move lower than 0.45 V. The PCM will pump oxygen out of the diffusion gap by applying a positive voltage to the pump cell.

Pump cell is used to pump oxygen into the diffusion gap when the exhaust is rich. The pump cell applies a negative voltage to do this.

- Positive current = lean exhaust
- Negative current = rich exhaust

SINGLE CELL WIDE-BAND OXYGEN SENSORS

CONSTRUCTION A typical **single cell** wide-band oxygen sensor looks similar to a conventional four-wire zirconia oxygen sensor. The typical single cell wide-band oxygen sensor, usually called an **air-fuel ratio sensor,** has the following construction features.

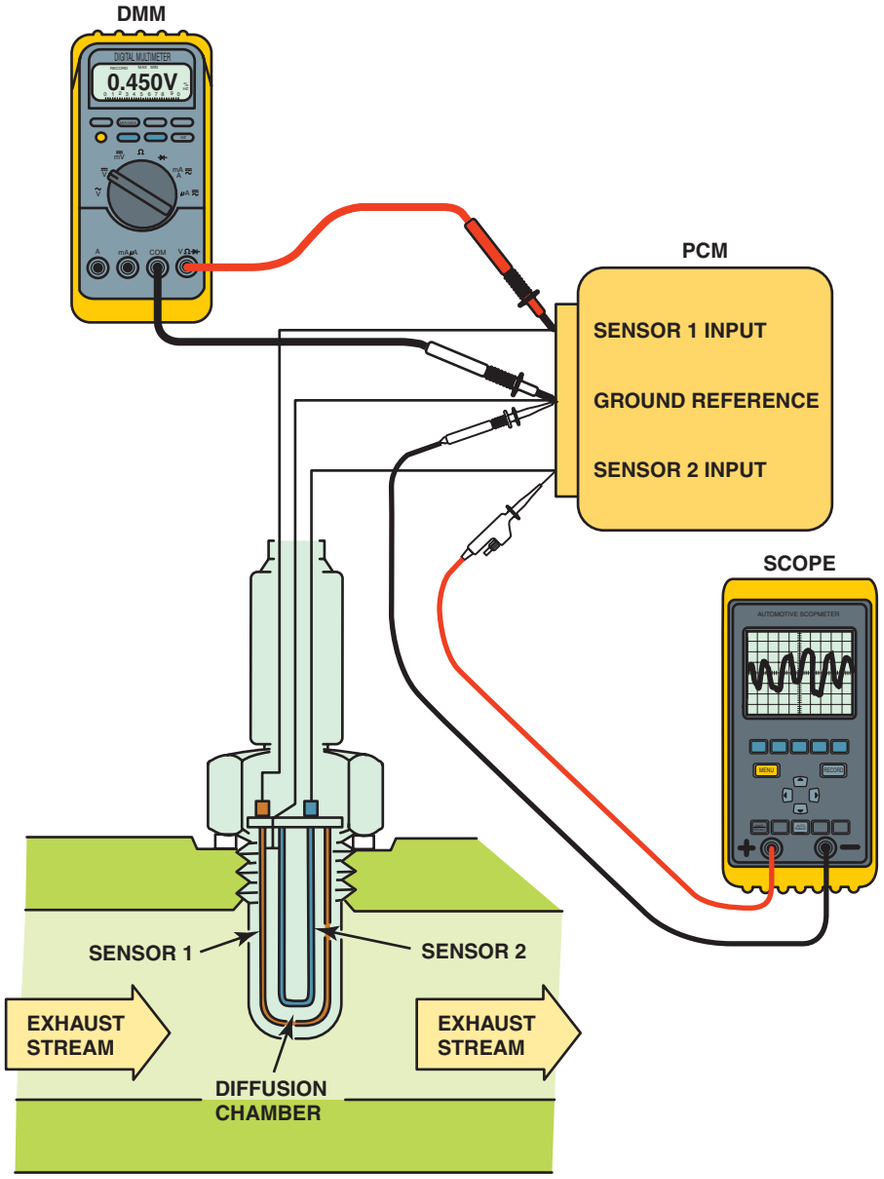

FIGURE 76–18 Testing a dual cell wide-band oxygen sensor can be done using a voltmeter or a scope. The meter reading is attached to the Nernst cell and should read stoichiometric (450 mV) at all times. The scope is showing activity to the pump cell with commands from the PCM to keep the Nernst cell at 14.7:1 air-fuel ratio.

- It can be made using the cup or planar design.
- Oxygen (O_2) is pumped into the diffusion layer similar to the operation of a dual cell wide-band oxygen sensor. ● **SEE FIGURE 76–19.**
- Current flow reverses positive and negative.
- There are two cell wires and two heater wires (power and ground).
- The heater usually requires 6 amperes and the ground side is pulse-width modulated.

MILLIAMMETER TESTING

The PCM controls the single cell wide-band oxygen sensor by maintaining a voltage difference of 300 mV (0.3 V) between the two sensor leads. The PCM keeps the voltage difference constant under all operating conditions by increasing or decreasing current between the element of the cell.

- Zero (0 mA) represents lambda or stoichiometric air-fuel ratio of 14.7:1
- +10 mA indicates a lean condition
- −10 mA indicates a rich condition

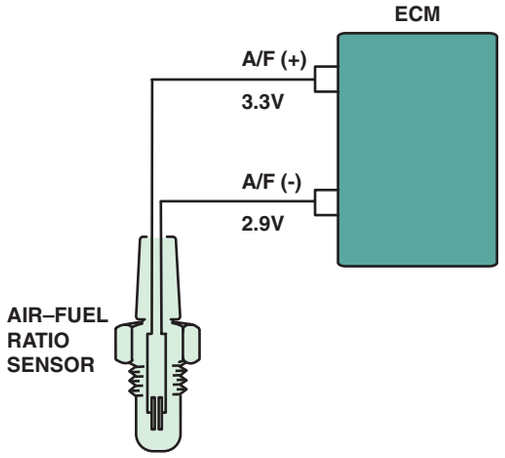

FIGURE 76–19 A single cell wide-band oxygen sensor has four wires with two for the heater and two for the sensor itself. The voltage applied to the sensor is 0.4 V (3.3 − 2.9 = 0.4) across the two leads of the sensor.

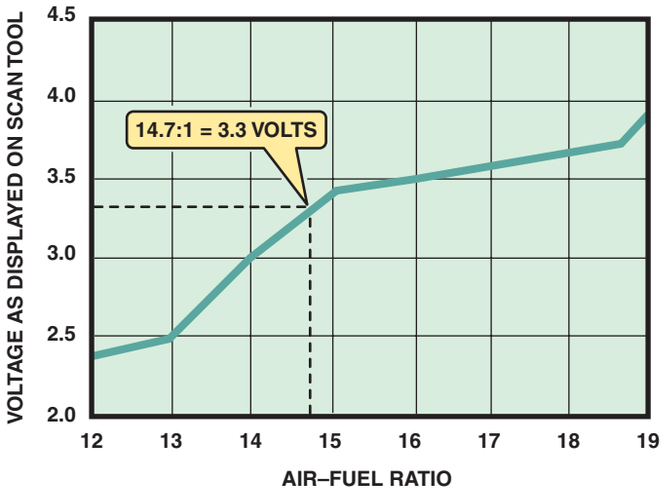

FIGURE 76–20 The scan can display various voltages but will often show 3.3 V because the PCM is controlling the sensor through applying a low current to the sensor to achieve balance.

SCAN TOOL TESTING A scan tool will display a voltage reading but can vary depending on the type and maker of scan tool. ● **SEE FIGURE 76–20.**

WIDE-BAND OXYGEN PATTERN FAILURES

Wide-band oxygen sensors have a long life, but they can fail. Most of the failures will cause a diagnostic trouble code (DTC) to set, usually causing the malfunction indicator (check engine) lamp to light.

However, one type of failure may not set a DTC, such as when the following occurs.

1. Voltage from the heater circuit bleeds into the Nernst cell.
2. This voltage will cause the engine to operate extremely lean and may or may not set a diagnostic trouble code.
3. When testing indicates an extremely lean condition, unplug the connector to the oxygen sensor. If the engine starts to operate correctly with the sensor unplugged, this is confirmation that the wide-band oxygen sensor has failed and requires replacement.

OXYGEN SENSOR–RELATED DIAGNOSTIC TROUBLE CODES

Diagnostic trouble codes (DTCs) associated with the oxygen sensor include the following:

Diagnostic Trouble Codes	Description	Possible Causes
P0131	Upstream HO2S grounded	• Exhaust leak upstream of HO2S (bank 1) • Extremely lean air-fuel mixture • HO2S defective or contaminated • HO2S signal wire shorted-to-ground
P0132	Upstream HO2S shorted	• Upstream HO2S (bank 1) shorted • Defective HO2S • Fuel-contaminated HO2S
P0133	Upstream HO2S slow response	• Open or short in heater circuit • Defective or fuel-contaminated HO2S • EGR or fuel system fault

FUEL DELIVERY SYSTEM

Creating and maintaining a correct air–fuel mixture requires a properly functioning fuel and air **delivery system.** Fuel delivery (and return) systems use many if not all of the following components to make certain that fuel is available under the right conditions to the fuel-injection system:

- Fuel storage tank, filler neck, and gas cap
- Fuel tank pressure sensor
- Fuel pump
- Fuel filter(s)
- Fuel delivery lines and fuel rail
- Fuel-pressure regulator
- Fuel return line (if equipped with a return-type fuel delivery system)

FUEL TANKS

A vehicle fuel tank is made of corrosion-resistant steel or polyethylene plastic. Some models, such as sport utility vehicles (SUVs) and light trucks, may have an auxiliary fuel tank.

Tank design and capacity are a compromise between available space, filler location, fuel expansion room, and fuel movement. Some later-model tanks deliberately limit tank capacity by extending the filler tube neck into the tank low enough to prevent complete filling, or by providing for expansion room. ● **SEE FIGURE 77–1.** A vertical **baffle** in fuel tanks limits fuel sloshing as the vehicle moves.

Regardless of size and shape, all fuel tanks incorporate most if not all of the following features:

- Inlet or filler tube through which fuel enters the tank
- Filler cap with pressure holding and relief features

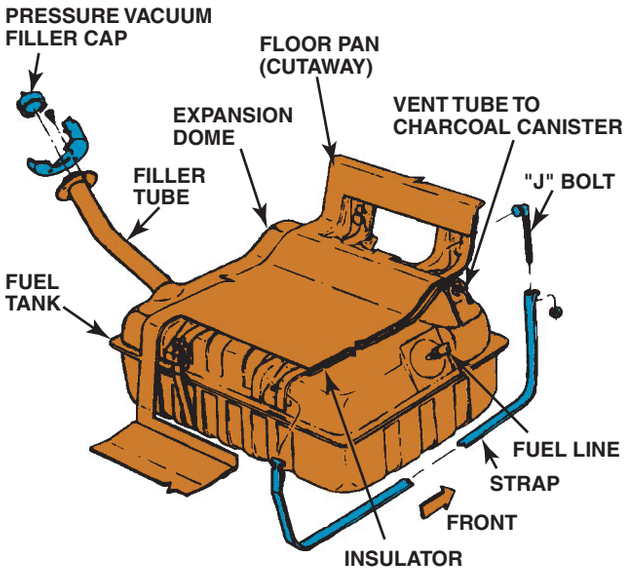

FIGURE 77–1 A typical fuel tank installation.

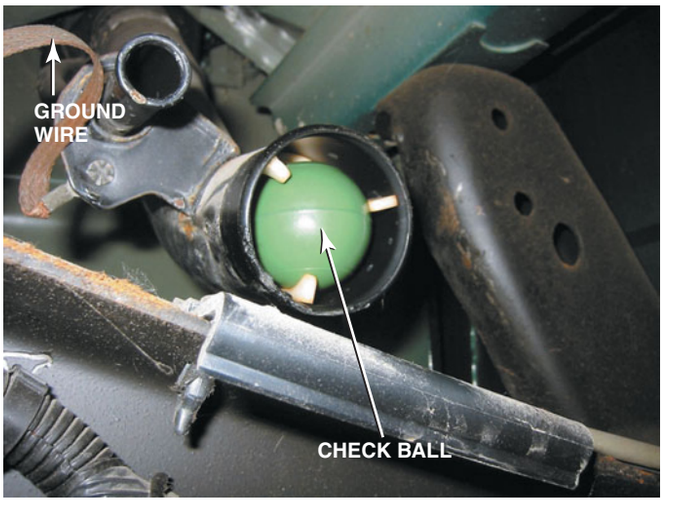

FIGURE 77–3 A view of a typical filler tube with the fuel tank removed. Notice the ground strap used to help prevent the buildup of static electricity as the fuel flows into the plastic tank. The check ball looks exactly like a ping-pong ball.

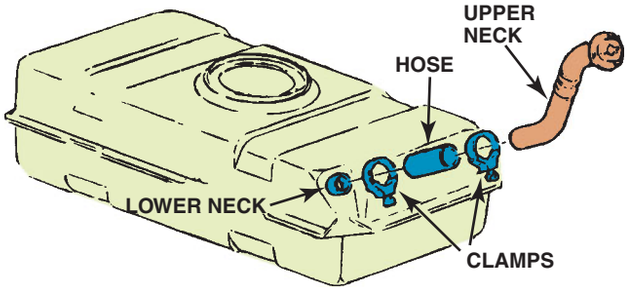

FIGURE 77–2 A three-piece filler tube assembly. The main three parts include the upper neck, hose, and lower neck.

FIGURE 77–4 Vehicles equipped with onboard refueling vapor recovery usually have a reduced-size fill tube.

- Fuel pump mounted within the tank
- Tank vent system

TANK LOCATION AND MOUNTING Most vehicles use a horizontally suspended fuel tank, usually mounted below the rear of the floor pan, just ahead of or behind the rear axle. Fuel tanks are located there so that frame rails and body components protect the tank in the event of a crash. To prevent squeaks, some models have insulated strips cemented on the top or sides of the tank wherever it contacts the underbody.

Fuel inlet location depends on the tank design and filler tube placement. It is located behind a filler cap and is often a hinged door in the outer side of either rear fender panel.

Generally, a pair of metal retaining straps holds a fuel tank in place. Underbody brackets or support panels hold the strap ends using bolts. The free ends are drawn underneath the tank to hold it in place, then bolted to other support brackets or to a frame member on the opposite side of the tank.

FILLER TUBES Fuel enters the tank through a large tube extending from the tank to an opening on the outside of the vehicle. ● **SEE FIGURE 77–2.**

Effective in 1993, federal regulations require manufacturers to install a device to prevent fuel from being siphoned through the filler neck. Federal authorities recognized methanol as a poison, and methanol used in gasoline is a definite health hazard. Additionally, gasoline is a suspected carcinogen (cancer-causing agent). To prevent siphoning, manufacturers welded a filler-neck check-ball tube in fuel tanks. To drain check-ball-equipped fuel tanks, a technician must disconnect the check-ball tube at the tank and attach a siphon directly to the tank. ● **SEE FIGURE 77–3.**

Onboard refueling vapor recovery (ORVR) systems have been developed to reduce evaporative emissions during refueling. ● **SEE FIGURE 77–4.** These systems add components to the filler neck and the tank. One ORVR system utilizes a tapered filler neck with a smaller diameter tube and a check valve. When fuel flows down the neck, it opens the normally closed check valve. The vapor passage to the charcoal canister is opened. The decreased size neck and the opened air passage allow fuel and vapor to flow rapidly into the tank and the canister respectively. When the fuel has reached a predetermined level, the check valve closes, and the fuel tank pressure increases. This forces the nozzle to shut off, thereby preventing the tank from being overfilled.

PRESSURE-VACUUM FILLER CAP Fuel and vapors are sealed in the tank by the safety filler cap. The safety cap must release excess pressure or excess vacuum. Either condition could cause fuel tank damage, fuel spills, and vapor escape. Typically, the cap will release if the pressure is over 1.5 to 2.0 PSI (10 to 14 kPa) or if the vacuum is 0.15 to 0.30 PSI (1 to 2 kPa).

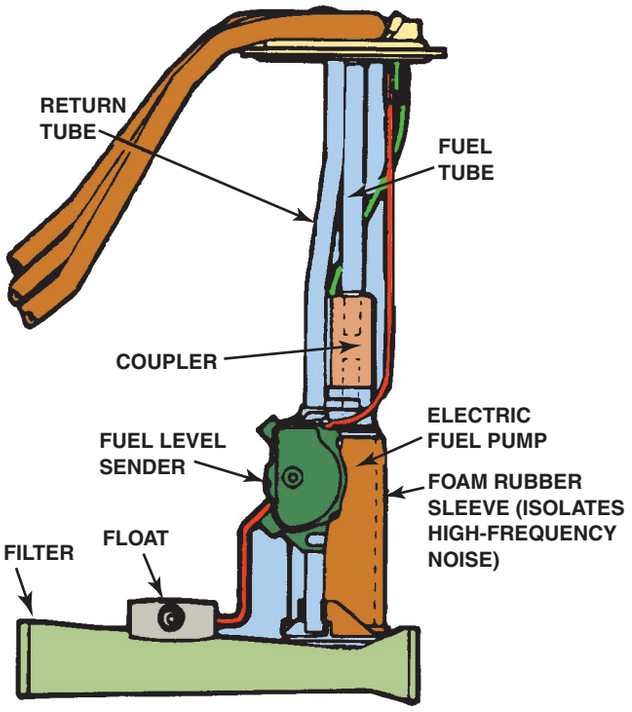

FIGURE 77–5 The fuel pickup tube is part of the fuel sender and pump assembly.

FUEL PICKUP TUBE The fuel pickup tube is usually a part of the fuel sender assembly or the electric fuel pump assembly. Since dirt and sediment eventually gather on the bottom of a fuel tank, the fuel pickup tube is fitted with a filter sock or strainer to prevent contamination from entering the fuel lines. The woven plastic strainer also acts as a water separator by preventing water from being drawn up with the fuel. The filter sock usually is designed to filter out particles that are larger than 70 to 100 microns, or 30 microns if a gerotor-type fuel pump is used. One micron is 0.000039 in. ● **SEE FIGURE 77–5.**

NOTE: The human eye cannot see anything smaller than about 40 microns.

The filter is made from woven Saran resin (copolymer of vinylidene chloride and vinyl chloride. The filter blocks any water that may be in the fuel tank, unless it is completely submerged in water. In that case, it will allow water through the filter. This filter should be replaced whenever the fuel pump is replaced.

TANK VENTING REQUIREMENTS Fuel tanks must be vented to prevent a **vacuum lock** as fuel is drawn from the tank. As fuel is used and its level drops in the tank, the space above the fuel increases. As the air in the tank expands to fill this greater space, its pressure drops. Without a vent, the air pressure inside the tank would drop below atmospheric pressure, developing a vacuum which prevents the flow of fuel. Under extreme pressure variance, the tank could collapse. Venting the tank allows outside air to enter as the fuel level drops, preventing a vacuum from developing.

An EVAP system vents gasoline vapors from the fuel tank directly to a charcoal-filled vapor storage canister, and uses an unvented filler cap. Many filler caps contain valves that open to relieve pressure or vacuum above specified safety levels. Systems that use completely sealed caps have separate pressure and vacuum relief valves for venting.

Because fuel tanks are not vented directly to the atmosphere, the tank must allow for fuel expansion, contraction, and overflow that can result from changes in temperature or overfilling. One way is to use a dome in the top of the tank. Many General Motors vehicles use a design that includes a vertical slosh baffle which reserves up to 12% of the total tank capacity for fuel expansion.

ROLLOVER LEAKAGE PROTECTION

All vehicles have one or more devices to prevent fuel leaks in case of vehicle rollover or a collision in which fuel may spill.

Variations of the basic one-way **check valve** may be installed in any number of places between the fuel tank and the engine. The valve may be installed in the fuel return line, vapor vent line, or fuel tank filler cap.

In addition to the rollover protection devices, some vehicles use devices to ensure that the fuel pump shuts off when an accident occurs. On some air vane sensors, a microswitch is built into the sensor to switch on the fuel pump as soon as intake airflow causes the vane to lift from its rest position. ● **SEE FIGURE 77–6.**

Ford vehicles use an **inertia switch.** ● **SEE FIGURE 77–7.** The inertia switch is installed in the rear of the vehicle between the electric fuel pump and its power supply. With any sudden impact, such as a jolt from another vehicle in a parking lot, the inertia switch opens and shuts off power to the fuel pump. The switch must be reset manually by pushing a button to restore current to the pump.

FUEL LINES

Fuel and vapor lines made of steel, nylon tubing, or fuel-resistant rubber hoses connect the parts of the fuel system. Fuel lines supply fuel to the throttle body or fuel rail. They also return excess fuel and vapors to the tank. Depending on their function, fuel and vapor lines may be either rigid or flexible.

Fuel lines must remain as cool as possible. If any part of the line is located near too much heat, the gasoline passing through it vaporizes and **vapor lock** occurs. When this happens, the fuel pump supplies only vapor that passes into the injectors. Without liquid gasoline, the engine stalls and a hot restart problem develops.

The fuel delivery system supplies 10 to 15 PSI (69 to 103 kPa) or up to 35 PSI (241 kPa) to many throttle-body injection units and up to 60 PSI (414 kPa) for multiport fuel-injection systems. Fuel-injection systems retain residual or rest pressure in the lines for a half hour or longer when the engine is turned off to prevent hot engine restart problems. Higher-pressure systems such as these require special fuel lines.

RIGID LINES All fuel lines fastened to the body, frame, or engine are made from nylon reinforced plastic or seamless steel tubing. Steel springs may be wound around the tubing at certain points to protect against impact damage.

Only steel tubing, or that recommended by the manufacturer, should be used when replacing rigid fuel lines. *Never substitute copper or aluminum tubing for steel tubing*. These materials do not withstand normal vehicle vibration and could combine with the fuel to cause a chemical reaction.

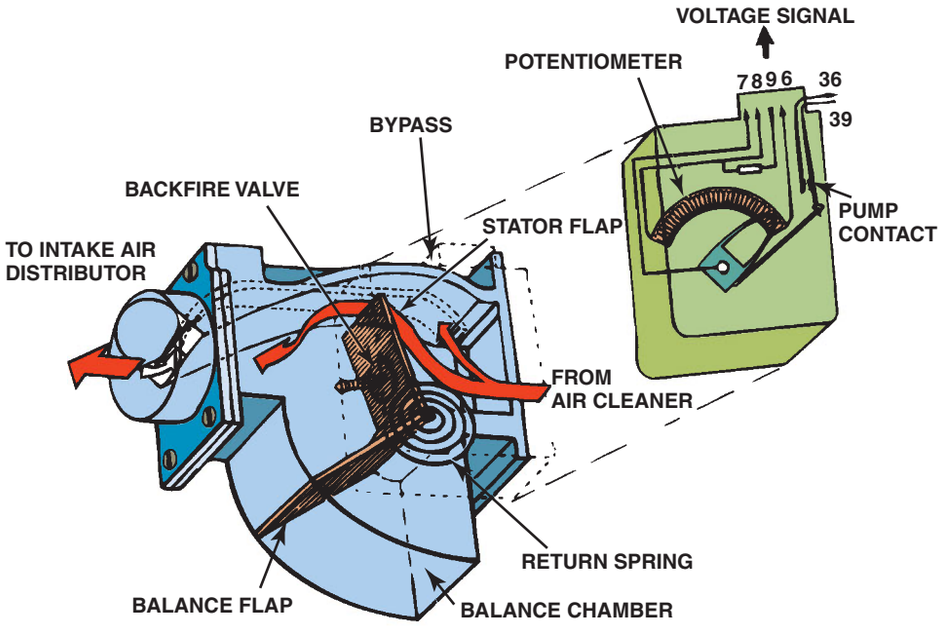

FIGURE 77–6 On some vehicles equipped with an airflow sensor, a switch is used to energize the fuel pump. In the event of a collision, the switch opens and the fuel flow stops.

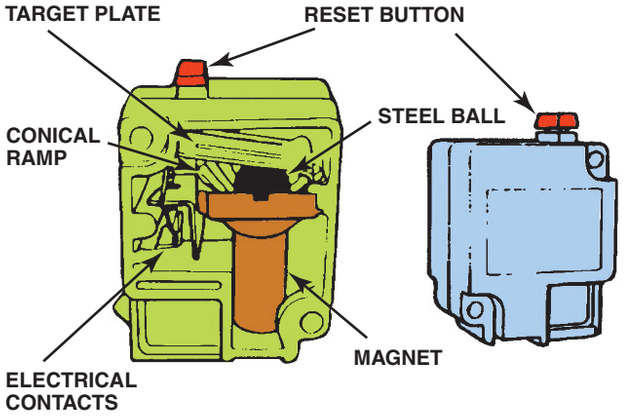

FIGURE 77–7 Ford uses an inertia switch to turn off the electric fuel pump in an accident.

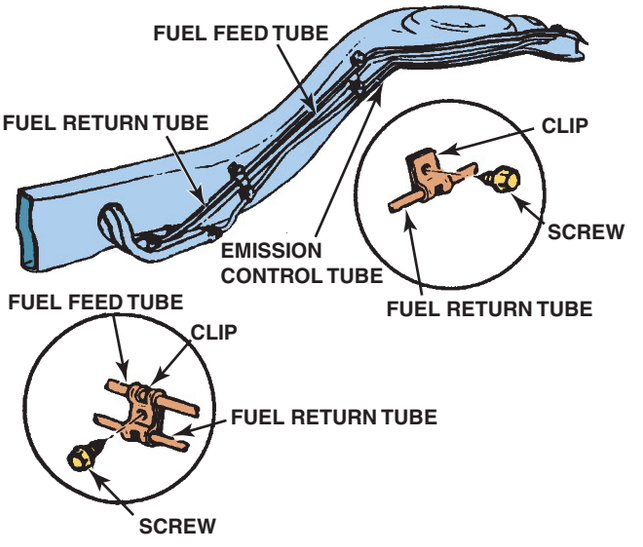

FIGURE 77–8 Fuel lines are routed along the frame or body and secured with clips.

FLEXIBLE LINES Most fuel systems use synthetic rubber hose sections where flexibility is needed. Short hose sections often connect steel fuel lines to other system components. The fuel delivery hose inside diameter (ID), is usually 3/16" or 3/8" (8 or 10 millimeters) and the return line ID is normally 1/4" (6 millimeters).

Fuel-injection systems require special-composition reinforced hoses specifically made for these higher-pressure systems. Similarly, vapor vent lines must be made of materials that resist fuel vapors. Replacement vent hoses are usually marked with the designation "EVAP" to indicate their intended use.

FUEL LINE MOUNTING Fuel supply lines from the tank to a throttle body or fuel rail are routed to follow the frame along the underbody of the vehicle. Vapor and return lines may be routed with the fuel supply line. All rigid lines are fastened to the frame rail or underbody with screws and clamps, or clips. ● **SEE FIGURE 77–8.**

FUEL-INJECTION LINES AND CLAMPS Hoses used for fuel-injection systems are made of materials with high resistance to oxidation and deterioration. Replacement hoses for injection systems should always be equivalent to original equipment manufacturer (OEM) hoses.

Screw-type clamps are essential on injected engines and should have rolled edges to prevent hose damage.

CAUTION: ***Do not use spring-type clamps on fuel-injected engines—they cannot withstand the fuel pressures involved.***

FUEL-INJECTION FITTINGS AND NYLON LINES Because of their operating pressures, fuel-injection systems often use special kinds of fittings to ensure leakproof connections. Some high-pressure fittings on GM vehicles with port fuel-injection systems use O-ring seals instead of the traditional flare connections. When disconnecting such a fitting, inspect the O-ring for damage and replace it if necessary. *Always* tighten O-ring fittings to the specified torque value to prevent damage.

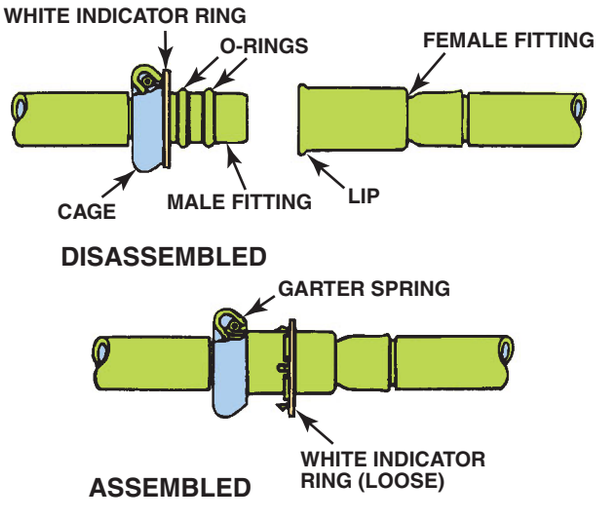

FIGURE 77–9 Some Ford metal line connections use spring-locks and O-rings.

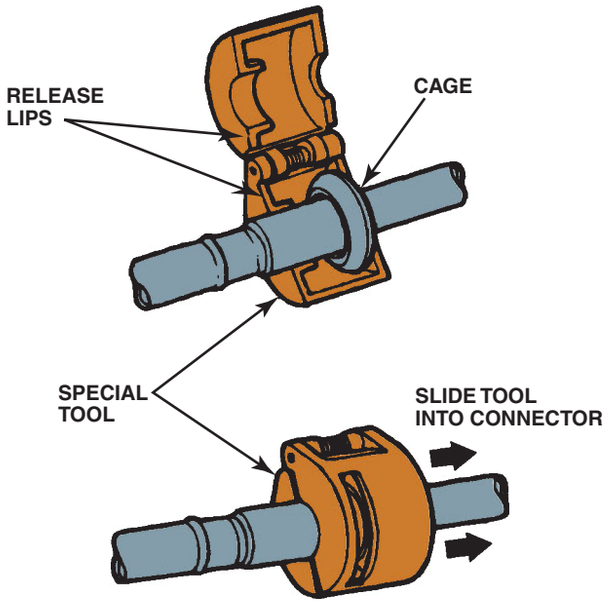

FIGURE 77–10 Ford spring-lock connectors require a special tool for disassembly.

? FREQUENTLY ASKED QUESTION

Just How Much Fuel Is Recirculated?

Approximately 80% of the available fuel-pump volume is released to the fuel tank through the fuel pressure regulator at idle speed. As an example, a passenger vehicle cruising down the road at 60 mph gets 30 mpg. With a typical return-style fuel system pumping about 30 gallons per hour from the tank, it would therefore burn 2 gallons per hour, and return about 28 gallons per hour to the tank!

? FREQUENTLY ASKED QUESTION

How Can an Electric Pump Work Inside a Gas Tank and Not Cause a Fire?

Even though fuel fills the entire pump, no burnable mixture exists inside the pump because there is no air and no danger of commutator brush arcing, igniting the fuel.

Other manufacturers also use O-ring seals on fuel line connections. In all cases, the O-rings are made of special materials that withstand contact with gasoline and oxygenated fuel blends. Some manufacturers specify that the O-rings be replaced every time the fuel system connection is opened. When replacing one of these O-rings, a new part specifically designed for fuel system service must be used.

Ford also uses spring-lock connectors to join male and female ends of steel tubing. ● **SEE FIGURE 77–9.** The coupling is held together by a garter spring inside a circular cage. The flared end of the female fitting slips behind the spring to lock the coupling together.

General Motors has used nylon fuel lines with quick-connect fittings at the fuel tank and fuel filter since the early 1990s. Like the GM threaded couplings used with steel lines, nylon line couplings use internal O-ring seals. Unlocking the metal connectors requires a special quick-connector separator tool; plastic connectors can be released without the tool. ● **SEE FIGURES 77–10 AND 77–11.**

FUEL LINE LAYOUT Fuel pressures have tended to become higher to prevent vapor lock, and a major portion of the fuel routed to the fuel-injection system returns to the tank by way of a fuel return line or return-type systems. This allows better control, within limits, of heat absorbed by the gasoline as it is routed through the engine compartment. Throttle-body and multiport injection systems have typically used a pressure regulator to control fuel pressure in the throttle body or fuel rail, and also allow excess fuel not used by the injectors to return to the tank. However, the warmer fuel in the tank may create problems, such as an excessive rise in fuel vapor pressures in the tank.

With late-model vehicles, there has been some concern about too much heat being sent back to the fuel tank, causing rising in-tank temperatures and increases in fuel vaporization and **volatile organic compound (VOC)** (hydrocarbon) emissions. To combat this problem, manufacturers have placed the pressure regulator back by the tank instead of under the hood on mechanical returnless systems. In this way, returned fuel is not subjected to the heat generated by the engine and the underhood environment. To prevent vapor lock in these systems, pressures have been raised in the fuel rail, and injectors tend to have smaller openings to maintain control of the fuel spray under pressure.

Not only must the fuel be filtered and supplied under adequate pressure, but there must also be a consistent *volume* of fuel to assure smooth engine performance even under the heaviest of loads.

ELECTRIC FUEL PUMPS

The electric fuel pump is a pusher unit. When the pump is mounted in the tank, the entire fuel supply line to the engine can be pressurized. Because the fuel, when pressurized, has a higher boiling point, it is unlikely that vapor will form to interfere with fuel flow.

Most vehicles use the impeller or turbine pumps. ● **SEE FIGURE 77–12.** All electrical pumps are driven by a small electric motor, but the turbine pump turns at higher speeds and is quieter than the others.

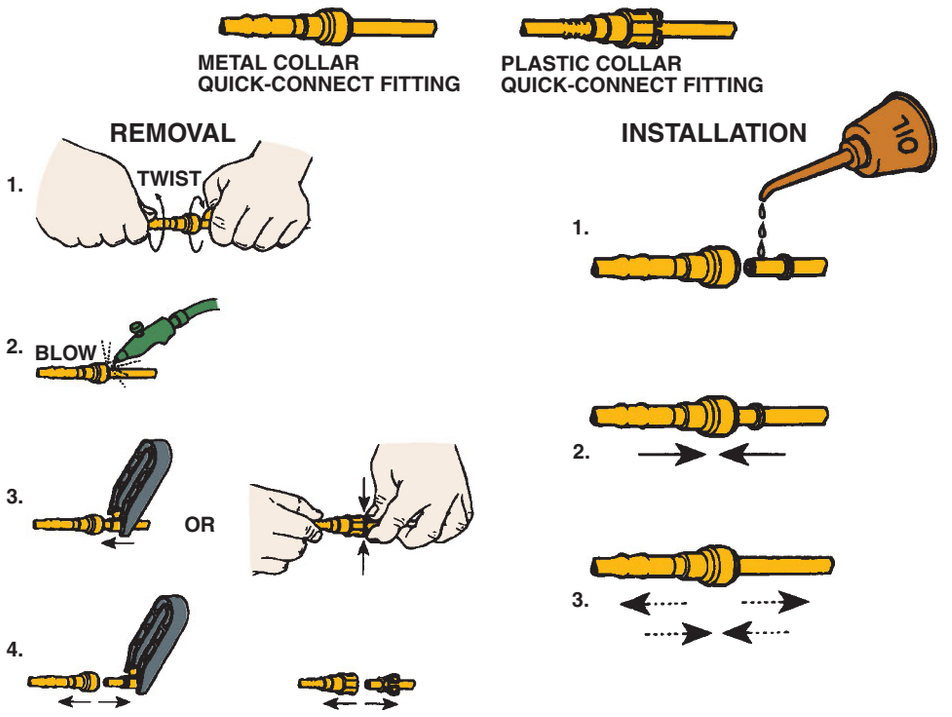

FIGURE 77–11 Typical quick-connect steps.

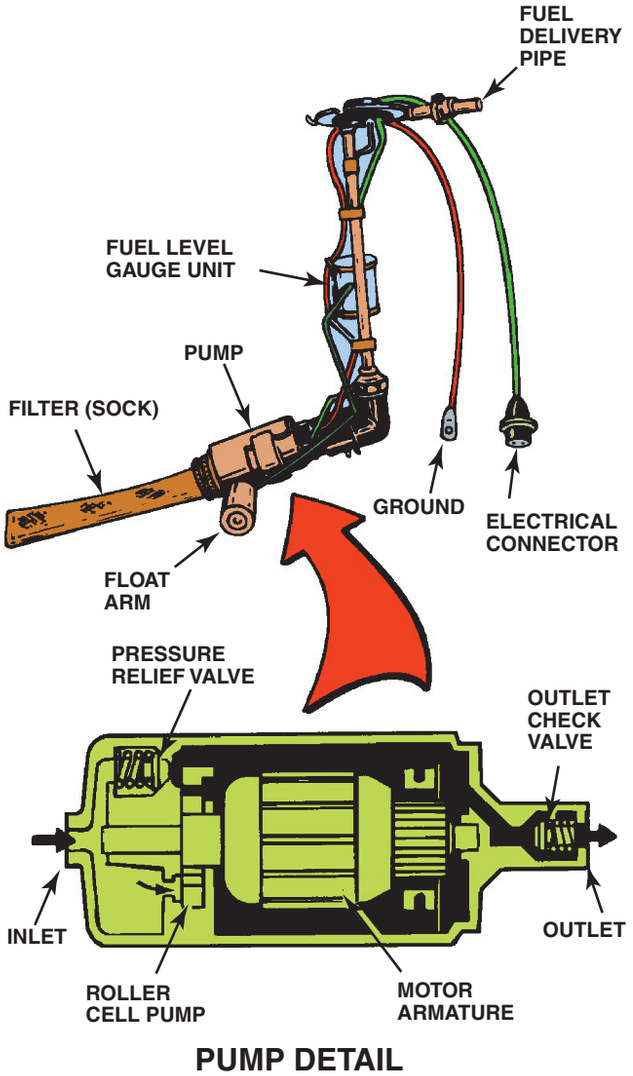

FIGURE 77–12 A roller cell-type electric fuel pump.

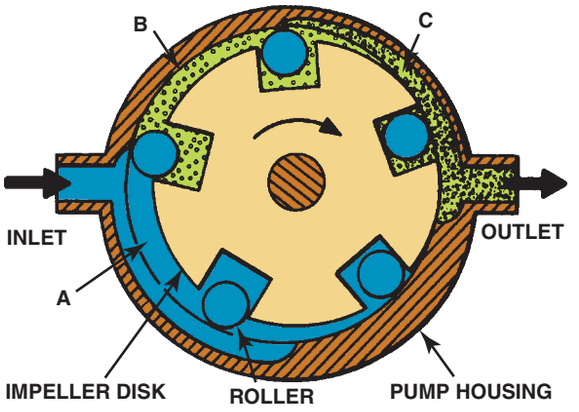

FIGURE 77–13 The pumping action of an impeller or rotary vane pump.

POSITIVE DISPLACEMENT PUMP

A positive displacement pump is a design that forces everything that enters the pump to leave the pump.

In the **roller cell** or vane pump, the impeller draws fuel into the pump, and then pushes it out through the fuel line to the injection system. All designs of pumps use a variable-sized chamber to draw in fuel. When the maximum volume has been reached, the supply port closes and the discharge opens. Fuel is then forced out the discharge as this volume decreases. The chambers are formed by rollers or gears in a rotor plate. Because this type of pump uses no valves to move the fuel, the fuel flows steadily through the entire pump housing, including the electrical portion which keeps the pump cool. Usually, only when a vehicle runs out of fuel is there a risk of pump damage.

Most electric fuel pumps are equipped with a fuel outlet check valve that closes to maintain fuel pressure when the pump shuts off. **Residual or rest pressure** prevents vapor lock and hot-start problems on these systems.

● **FIGURE 77–13** shows the pumping action of a **rotary vane pump.** The pump consists of a central impeller disk, several rollers

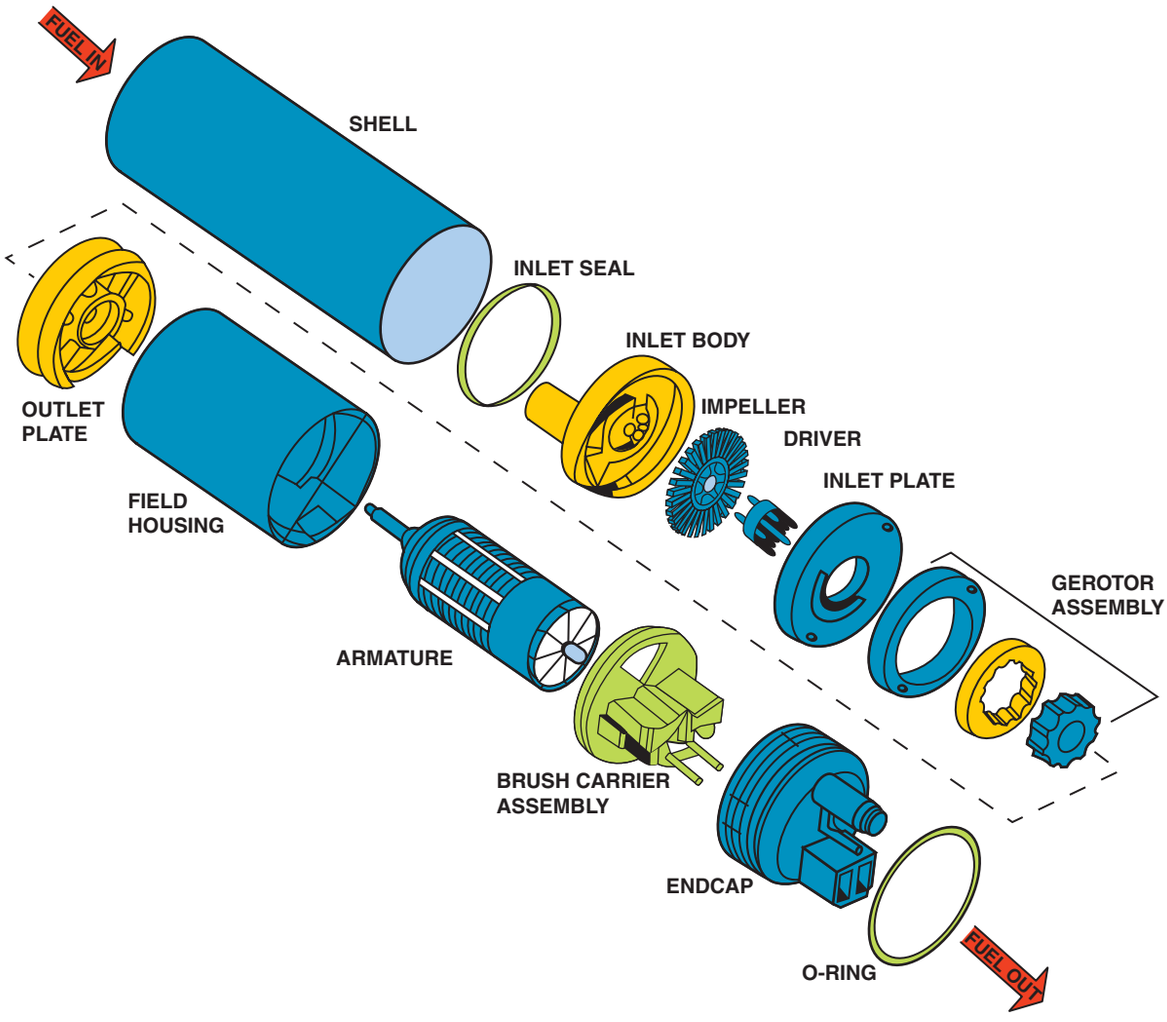

FIGURE 77–14 An exploded view of a gerotor electric fuel pump.

or vanes that ride in notches in the impeller, and a pump housing that is offset from the impeller centerline. The impeller is mounted on the end of the motor armature and spins whenever the motor is running. The rollers are free to slide in and out within the notches in the impeller to maintain sealing contact. Unpressurized fuel enters the pump, fills the spaces between the rollers, and is trapped between the impeller, the housing, and two rollers. An internal gear pump, called a **gerotor,** is another type of positive displacement pump that is often used in engine oil pumps. It uses the meshing of internal and external gear teeth to pressurize the fuel. ● **SEE FIGURE 77–14** for an example of a gerotor-type fuel pump that uses an impeller as the first stage and is used to move the fuel gerotor section where it is pressurized.

HYDROKINETIC FLOW PUMP DESIGN The word *hydro* means liquid and the term *kinetic* refers to motion, so the term **hydrokinetic pump** means that this design of pump rapidly moves the fuel to create pressure. This design of pump is a nonpositive displacement pump design.

A **turbine pump** is the most common because it tends to be less noisy. Sometimes called **turbine, peripheral,** and **side-channel,** these units use an impeller that accelerates the fuel particles before actually discharging them into a tract where they generate pressure via pulse exchange. Actual pump volume is controlled by using a different number of impeller blades, and in some cases a higher number of impellers, or different shapes along the side discharge channels. These units are fitted more toward lower operating pressures of less than 60 PSI. ● **SEE FIGURE 77–15** for an example of a two-stage turbine pump. The turbine impeller has a staggered blade design to minimize pump harmonic noise and to separate vapor from the liquid fuel. The end cap assembly contains a pressure relief valve and a radio-frequency interference (RFI) suppression module. The check valve is usually located in the upper fuel pipe connector assembly.

After fuel passes the strainer, it is drawn into the lower housing inlet port by the impellers. It is pressurized and delivered to the convoluted fuel tube for transfer through a check valve into the fuel feed pipe. A typical electric fuel pump used on a fuel-injection system delivers about 40 to 50 gallons per hour or 0.6 to 0.8 gallons per minute at a pressure of 70 to 90 PSI.

MODULAR FUEL SENDER ASSEMBLY The modular fuel sender consists of a fuel level sensor, a turbine pump, and a jet pump. The reservoir housing is attached to the cover containing fuel pipes and the electrical connector. Fuel is transferred from the pump to the fuel pipe through a convoluted (flexible) fuel pipe. The convoluted fuel pipe eliminates the need for rubber hoses, nylon pipes, and clamps. The reservoir dampens fuel slosh to maintain a constant fuel level available to the roller vane pump; it also reduces noise.

Some of the flow, however, is returned to the jet pump for recirculation. Excess fuel is returned to the reservoir through one of the three hollow support pipes. The hot fuel quickly mixes with the cooler fuel in the reservoir; this minimizes the possibility of vapor lock. In these modules, the reservoir is filled by the jet pump. Some of the fuel from the pump is sent through the jet pump to lift fuel from the tank into the reservoir.

? FREQUENTLY ASKED QUESTION

Why Are Many Fuel-Pump Modules Spring-Loaded?

Fuel modules that contain the fuel pickup sock, fuel pump, and fuel level sensor are often spring-loaded when fitted to a plastic fuel tank. The plastic material shrinks when cold and expands when hot, so having the fuel module spring-loaded ensures that the fuel pickup sock will always be the same distance from the bottom of the tank. ● **SEE FIGURE 77–16.**

FIGURE 77–16 A typical fuel-pump module assembly, which includes the pickup strainer and fuel pump, as well as the fuel-pressure sensor and fuel level sensing unit.

ELECTRIC PUMP CONTROL CIRCUITS

Fuel-pump circuits are controlled by the fuel-pump relay. Fuel-pump relays are activated initially by turning the ignition key to on, which allows the pump to pressurize the fuel system. As a safety precaution, the relay de-energizes after a few seconds until the key is moved to the crank position. Once an ignition coil signal, or "tach" signal, is received by the engine control computer, indicating the engine is rotating, the relay remains energized even with the key released to the run position.

CHRYSLER. On Chrysler vehicles, the PCM must receive an engine speed (RPM) signal during cranking before it can energize a circuit driver inside the power module to activate an automatic shutdown (ASD) relay to power the fuel pump, ignition coil, and injectors. As a safety precaution, if the RPM signal to the logic module is interrupted, the logic module signals the power module to deactivate the ASD, turning off the pump, coil, and injectors. In some vehicles, the oil pressure switch circuit may be used as a safety circuit to activate the pump in the ignition switch run position.

GENERAL MOTORS. General Motors systems energize the pump with the ignition switch to initially pressurize the fuel lines, but then deactivate the pump if an RPM signal is not received within one or two seconds. The pump is reactivated as soon as engine cranking is detected. The oil pressure sending unit serves as a backup to the fuel-pump relay on some vehicles. In case of pump relay failure, the oil pressure switch will operate the fuel pump once oil pressure reaches about 4 PSI (28 kPa).

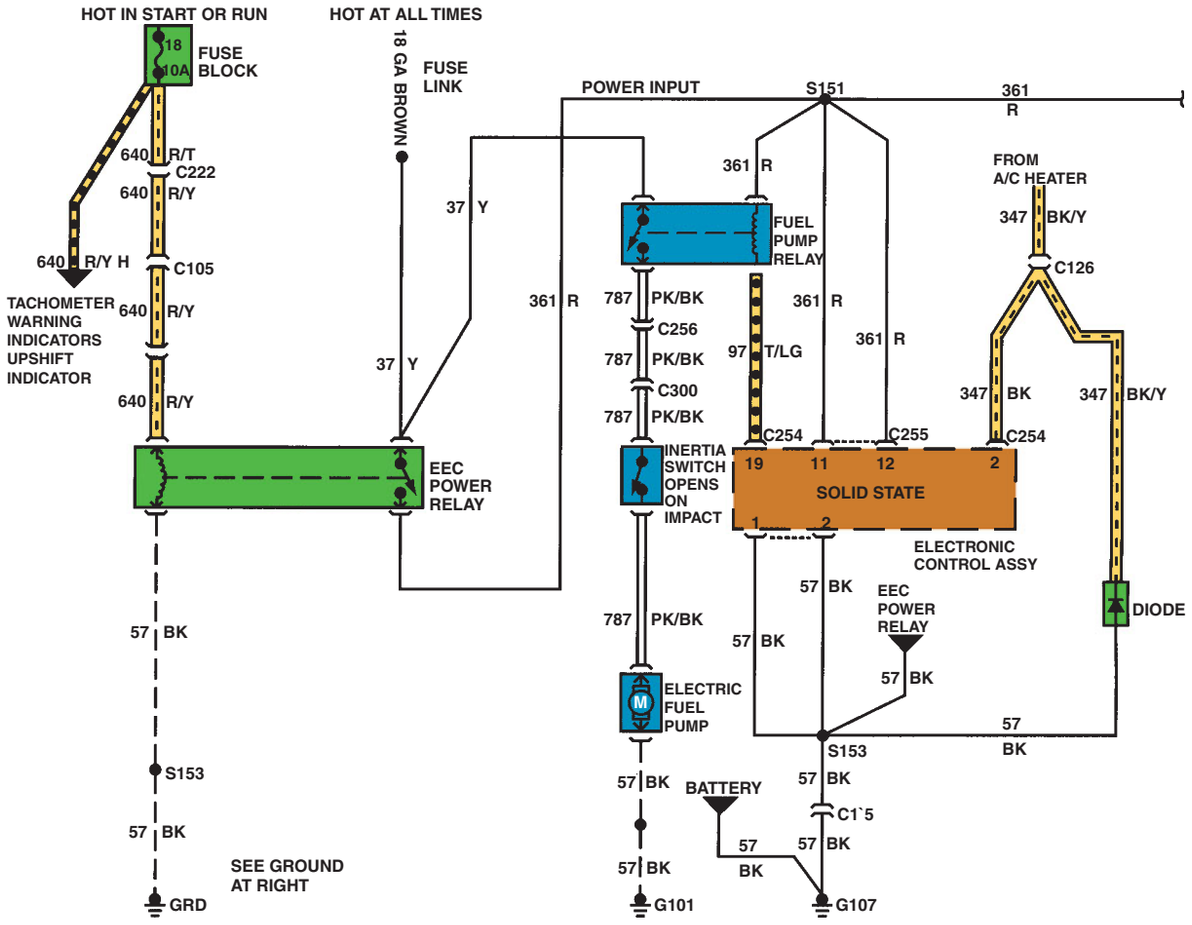

FIGURE 77–17 A schematic showing that an inertia switch is connected in series between the fuel-pump relay and the fuel pump.

FORD. Most Ford vehicles with fuel injection have an inertia switch between the fuel-pump relay and fuel pump. When the ignition switch is turned to the On position, the electronic engine control (EEC) power relay energizes, providing current to the fuel-pump relay and a timing circuit in the EEC module. If the RPM signal is not received by the PCM within one second, within about one second, the timing circuit opens the ground circuit to de-energize the fuel-pump relay and shut down the pump. This circuit is designed to prepressurize the system. Once the key is turned to the start position, power to the pump is sent through the relay and inertia switch.

The inertia switch opens under a specified impact, such as a collision. When the switch opens, current to the pump shuts off because the fuel-pump relay will not energize. The switch must be reset manually by opening the trunk and depressing the reset button before current flow to the pump can be restored. ● **SEE FIGURE 77–17** for a schematic of a typical fuel system that uses an inertia switch in the power feed circuit to the electric fuel pump.

PUMP PULSATION DAMPENING

Some manufacturers use an **accumulator** in the system to reduce pressure pulses and noise. Others use a pulsator located at the outlet of the fuel pump to absorb pressure pulsations that are created by the pump. These pulsators are usually used on roller vane pumps and are a source of many internal fuel leaks. ● **SEE FIGURE 77–18.**

NOTE: Some experts suggest that the pulsator be removed and replaced with a standard section of fuel line to prevent the loss of fuel pressure that results when the connections on the pulsator loosen and leak fuel back into the tank.

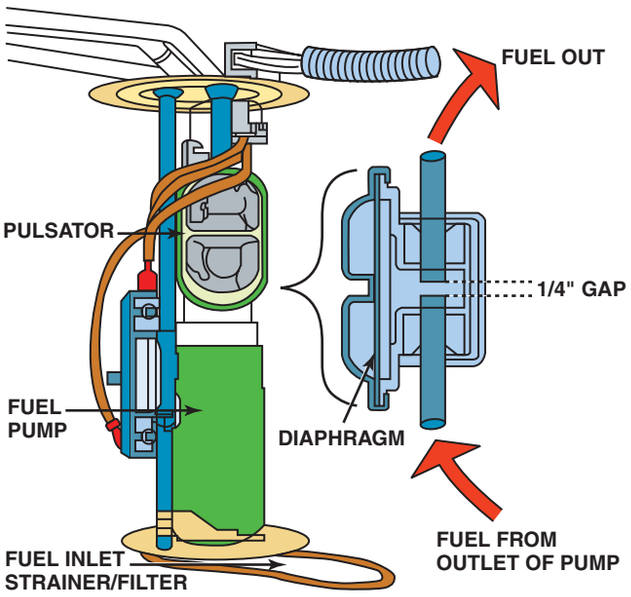

FIGURE 77–18 A typical fuel pulsator used mostly with roller vane-type pumps to help even out the pulsation in pressure that can cause noise.

VARIABLE SPEED PUMPS

Another way to help reduce noise, current draw, and pump wear is to reduce the speed of the pump when less than maximum output is required. Pump speed and pressure can be regulated by controlling the voltage supplied to the pump with a resistor switched into the circuit, or by letting the engine-control

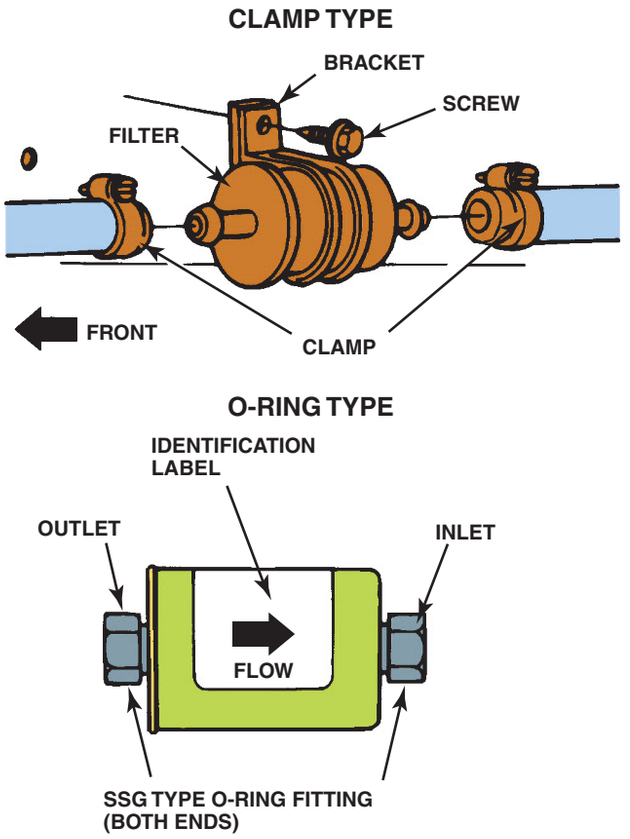

FIGURE 77–19 Inline fuel filters are usually attached to the fuel line with screw clamps or threaded connections. The fuel filter must be installed in the proper direction or a restricted fuel flow can result.

computer pulse-width modulate (PWM) the voltage supply to the pump, through a separate fuel pump driver electronic module. With slower pump speed and pressure, less noise is produced.

FUEL FILTERS

Despite the care generally taken in refining, storing, and delivering gasoline, some impurities get into the automotive fuel system. Fuel filters remove dirt, rust, water, and other contamination from the gasoline before it can reach the fuel injectors. Most fuel filters are designed to filter particles that are 10 to 20 microns or larger in size.

The useful life of many filters is limited, but vehicles that use a returnless-type fuel injection system usually use filters that are part of the fuel pump assembly and do have any specified replacement interval. This means that they should last the life of the vehicle. If fuel filters are not replaced according to the manufacturer's recommendations, they can become clogged and restrict fuel flow.

In addition to using several different types of fuel filters, a single fuel system may contain two or more filters. The inline filter is located in the line between the fuel pump and the throttle body or fuel rail. ● **SEE FIGURE 77–19.** This filter protects the system from contamination, but does not protect the fuel pump. The inline filter usually is a metal or plastic container with a pleated paper element sealed inside.

Fuel filters may be mounted on a bracket on the fender panel, a shock tower, or another convenient place in the engine compartment. They may also be installed under the vehicle near the fuel tank. Fuel filters should be replaced according to the vehicle manufacturer's recommendations, which range from every 30,000 miles (48,000 km) to 100,000 miles (160,000 km) or longer. Fuel filters that are part of the fuel-pump module assemblies usually do not have any specified service interval.

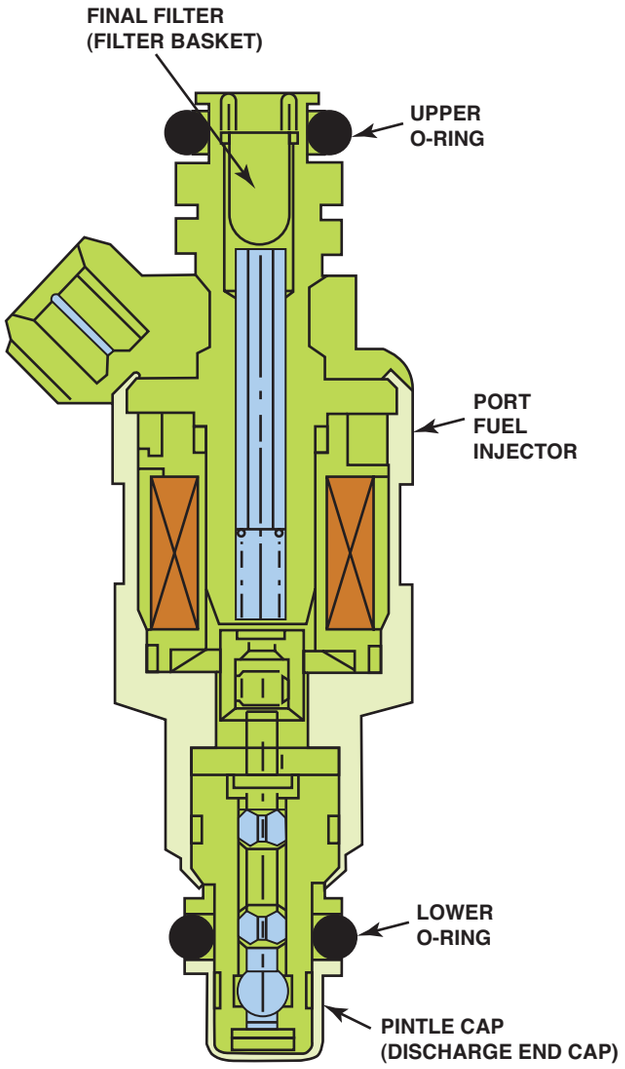

FIGURE 77–20 The final filter, also called a **filter basket,** is the last filter in the fuel system.

TECH TIP

Be Sure That the Fuel Filter Is Installed Correctly

The fuel filter has flow direction and if it is installed backwards, the vehicle will most likely have a restricted exhaust (low power at higher engine speeds and loads).

All injectors, throttle body or port, are fitted with one or more filter screens or strainers to remove any particles (generally 10 microns or 0.00039 in.) that might have passed through the other filters. These screens, which surround the fuel inlet, are on the side of throttle-body injectors and are inserted in the top of port injectors. ● **SEE FIGURE 77–20.**

(b)

FIGURE 77–21 (a) A funnel helps in hearing if the electric fuel pump inside the gas tank is working. (b) If the pump is not running, check the wiring and current flow before going through the process of dropping the fuel tank to remove the pump.

TECH TIP

The Ear Test

No, this is not a test of your hearing, but rather using your ear to check that the electric fuel pump is operating. The electric fuel pump inside the fuel tank is often difficult to hear running, especially in a noisy shop environment. A commonly used trick to better hear the pump is to use a funnel in the fuel filter neck. ● **SEE FIGURE 77–21.**

FUEL-PUMP TESTING

Fuel-pump testing includes many different tests and procedures. Even though a fuel pump can pass one test, it does not mean that there is not a fuel-pump problem. For example, if the pump motor is rotating slower than normal, it may be able to produce the specified pressure, but not enough volume to meet the needs of the engine while operating under a heavy load.

TESTING FUEL-PUMP PRESSURE Fuel-pump-regulated pressure has become more important than ever with a more exact fuel control. Although an increase in fuel pressure does increase fuel volume to the engine, this is *not* the preferred method to add additional fuel as some units will not open correctly at the increased fuel pressure. On the other side of the discussion, many newer engines will not start when fuel pressure is just a few PSI low. Correct fuel pressure is very important for proper engine operation. Most fuel-injection systems operate at either a low pressure of about 10 PSI or a high pressure of between 35 and 45 PSI.

Normal Operating Pressure	(PSI)	Maximum Pump Pressure (PSI)
Low-pressure TBI units	9–13	18–20
High-pressure TBI units	25–35	50–70
Port fuel-injection systems	35–45	70–90
Central port fuel injection (GM)	55–64	90–110

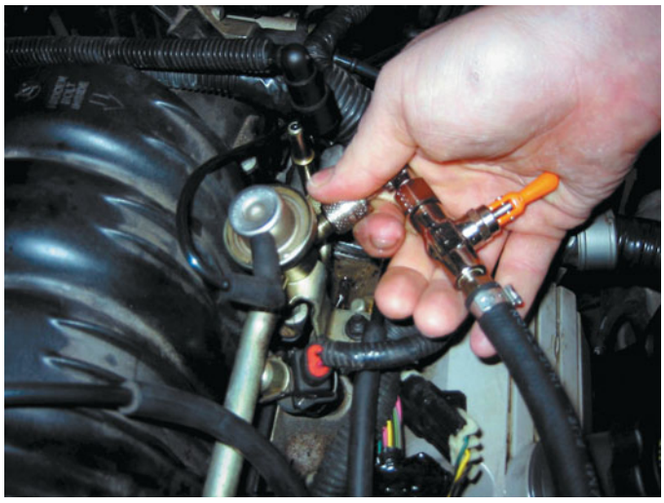

FIGURE 77–22 The Schrader valve on this General Motors 3800 V-6 is located next to the fuel-pressure regulator.

TECH TIP

The Rubber Mallet Trick

Often a no-start condition is due to an inoperative electric fuel pump. A common trick is to tap on the bottom of the fuel tank with a rubber mallet in an attempt to jar the pump motor enough to work. Instead of pushing a vehicle into the shop, simply tap on the fuel tank and attempt to start the engine. This is not a repair, but rather a confirmation that the fuel pump does indeed require replacement.

In both types of systems, maximum fuel-pump pressure is about double the normal operating pressure to ensure that a continuous flow of cool fuel is being supplied to the injector(s) to help prevent vapor from forming in the fuel system. Although vapor or foaming in a fuel system can greatly affect engine operation, the cooling and lubricating flow of the fuel must be maintained to ensure the durability of injector nozzles.

To measure fuel-pump pressure, locate the Schrader valve and attach a fuel-pressure gauge. ● **SEE FIGURE 77–22.**

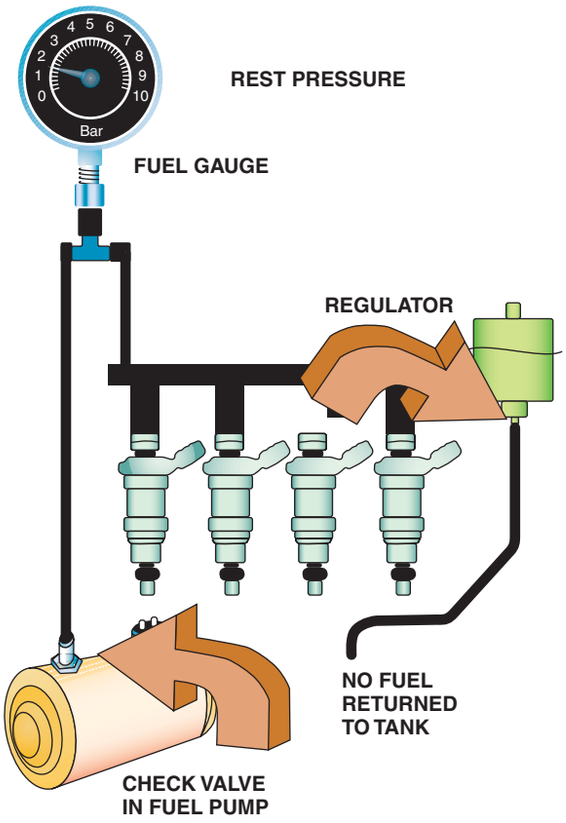

FIGURE 77–23 The fuel system should hold pressure if the system is leak free.

NOTE: Some vehicles, such as those with General Motors TBI fuel-injection systems, require a specific fuel-pressure gauge that connects to the fuel system. Always follow the manufacturers' recommendations and procedures.

REST PRESSURE TEST If the fuel pressure is acceptable, then check the system for leakdown. Observe the pressure gauge after five minutes. ● **SEE FIGURE 77–23.** The pressure should be the same as the initial reading. If not, then the pressure regulator, fuel-pump check valve, or the injectors are leaking.

DYNAMIC PRESSURE TEST To test the pressure dynamically, start the engine. If the pressure is vacuum referenced, then the pressure should change when the throttle is cycled. If it does not, then check the vacuum supply circuit. Remove the vacuum line from the regulator and inspect for any presence of fuel. ● **SEE FIGURE 77–24.** There should never be any fuel present on the vacuum side of the regulator diaphragm. When the engine speed is increased, the pressure reading should remain within the specifications.

TECH TIP

The Fuel-Pressure Stethoscope Test

When the fuel pump is energized and the engine is not running, fuel should be heard flowing back to the fuel tank at the outlet of the fuel-pressure regulator. ● **SEE FIGURE 77–25.** If fuel is heard flowing through the return line, the fuel-pump pressure is higher than the regulator pressure. If no sound of fuel is heard, either the fuel pump or the fuel-pressure regulator is at fault.

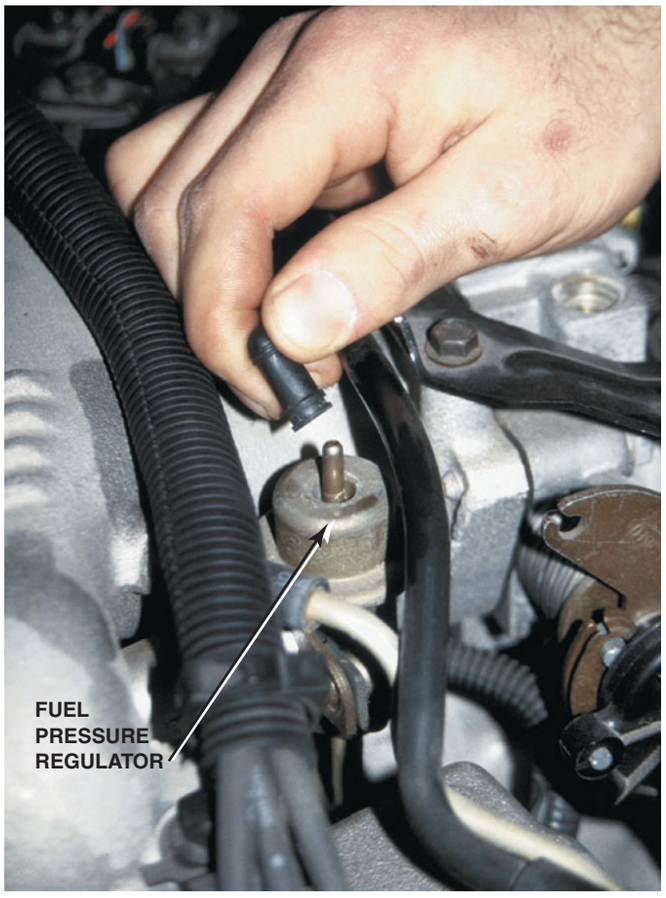

FIGURE 77–24 If the vacuum hose is removed from the fuel-pressure regulator when the engine is running, the fuel pressure should increase. If it does not increase, then the fuel pump is not capable of supplying adequate pressure or the fuel-pressure regulator is defective. If gasoline is visible in the vacuum hose, the regulator is leaking and should be replaced.

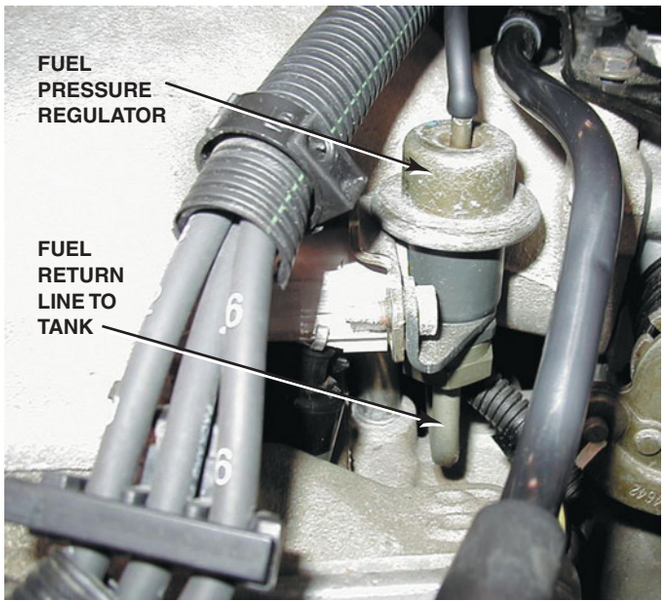

FIGURE 77–25 Fuel should be heard returning to the fuel tank at the fuel return line if the fuel pump and fuel-pressure regulator are functioning correctly.

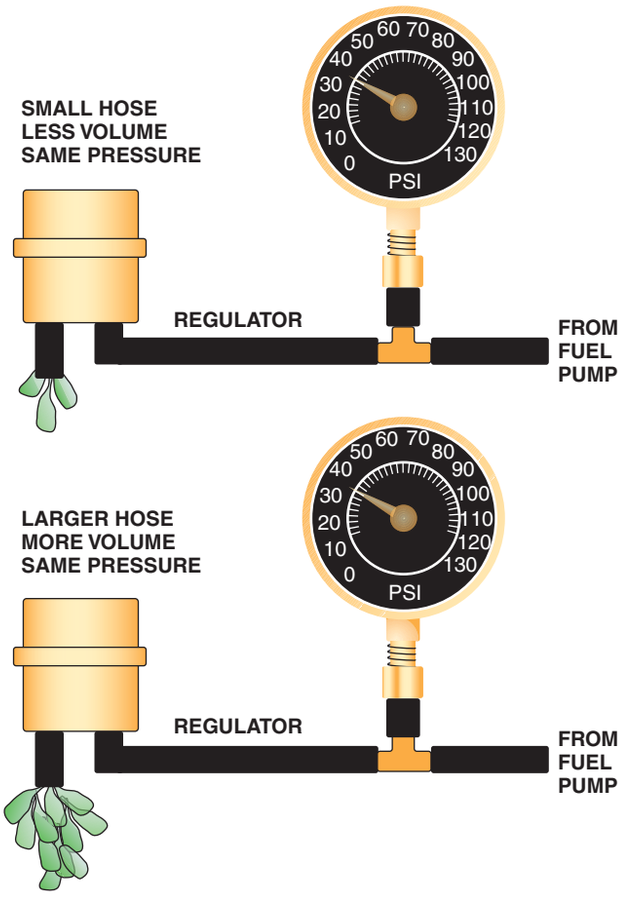

FIGURE 77–26 A fuel-pressure reading does not confirm that there is enough fuel volume for the engine to operate correctly.

Some engines do not use a vacuum-referenced regulator. The running pressure remains constant, which is typical for a mechanical returnless-type fuel system. On these systems, the pressure is higher than on return-type systems to help reduce the formation of fuel vapors in the system.

TESTING FUEL-PUMP VOLUME

Fuel pressure alone is not enough for proper engine operation. ● **SEE FIGURE 77–26.** Sufficient fuel capacity (flow) should be at least 2 pints (1 liter) every 30 seconds or 1 pint in 15 seconds. Fuel flow specifications are usually expressed in gallons per minute. A typical specification would be 0.5 gallons per minute or more. Volume testing is shown in ● **FIGURE 77–27.**

All fuel must be filtered to prevent dirt and impurities from damaging the fuel system components and/or engine. The first filter is inside the gas tank and is usually not replaceable separately but is attached to the fuel pump (if the pump is electric) and/or fuel gauge sending unit. The replaceable fuel filter is usually located between the fuel tank and the fuel rail or inlet to the fuel-injection system. Most vehicle manufacturers state in service information when to replace the fuel filter. Most newer vehicles, that use returnless-type fuel injection systems, do not have replaceable filters as they are built into the fuel pump module assembly. (Check the vehicle manufacturers' recommendations for exact time and mileage intervals.)

If the fuel filter becomes partially clogged, the following are likely to occur:

1. There will be low power at higher engine speeds. The vehicle usually will not go faster than a certain speed (engine acts as if it has a built-in speed governor).
2. The engine will cut out or miss on acceleration, especially when climbing hills or during heavy-load acceleration.

FIGURE 77–27 A fuel system tester connected in series in the fuel system so all of the fuel used flows through the meter which displays the rate-of-flow and the fuel pressure.

TECH TIP

Quick and Easy Fuel Volume Test

Testing for pump volume involves using a specialized tester or a fuel-pressure gauge equipped with a hose to allow the fuel to be drawn from the system into a container with volume markings to allow for a volume measurement. This test can be hazardous because of flammable gasoline vapors. An alternative test involves connecting a fuel-pressure gauge to the system with the following steps:

STEP 1 Start the engine and observe the fuel-pressure gauge. The reading should be within factory specifications (typically between 35 PSI and 45 PSI).

STEP 2 Remove the hose from the fuel-pressure regulator. The pressure should increase if the system uses a demand-type regulator.

STEP 3 Rapidly accelerate the engine while watching the fuel-pressure gauge. If the fuel volume is okay, the fuel pressure should not drop more than 2 PSI. If the fuel pressure drops more than 2 PSI, replace the fuel filter and retest.

STEP 4 After replacing the fuel filter, accelerate the engine and observe the pressure gauge. If the pressure drops more than 2 PSI, replace the fuel pump.

NOTE: The fuel pump could still be delivering less than the specified volume of fuel, but as long as the volume needed by the engine is met, the pressure will not drop. If, however, the vehicle is pulling a heavy load, the demand for fuel volume may exceed the capacity of the pump.

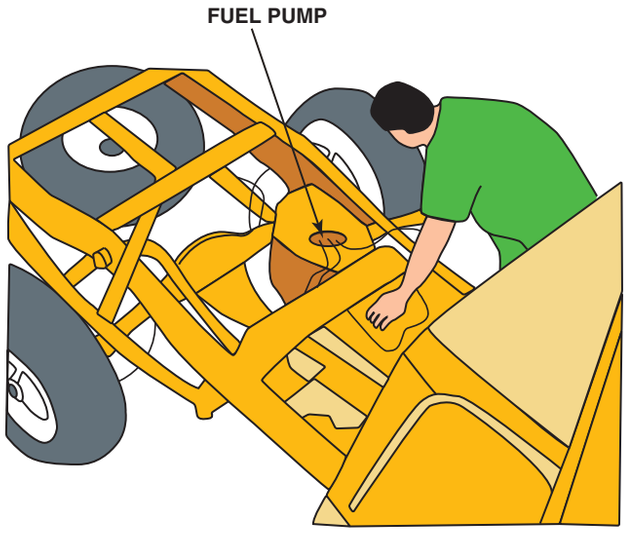

FIGURE 77–28 Removing the bed from a pickup truck makes gaining access to the fuel pump a lot easier.

TECH TIP

Remove the Bed to Save Time?

The electric fuel pump is easier to replace on many General Motors pickup trucks if the bed is removed. Access to the top of the fuel tank, where the access hole is located, for the removal of the fuel tank sender unit and pump is restricted by the bottom of the pickup truck bed. Rather than drop the tank, it is often much easier to use an engine hoist or a couple of other technicians to lift the bed from the frame after removing only a few fasteners. ● **SEE FIGURE 77–28.**

CAUTION: Be sure to clean around the fuel pump opening so that dirt or debris does not enter the tank when the fuel pump is removed.

A weak or defective fuel pump can also be the cause of the symptoms just listed. If an electric fuel pump for a fuel-injected engine becomes weak, additional problems include the following:

1. The engine may be hard to start.
2. There may be a rough idle and stalling.
3. There may be erratic shifting of the automatic transmission as a result of engine missing due to lack of fuel-pump pressure and/or volume.

CAUTION: Be certain to consult the vehicle manufacturers' recommended service and testing procedures before attempting to test or replace any component of a high-pressure electronic fuel-injection system.

FUEL-PUMP CURRENT DRAW TEST

Another test that can and should be performed on a fuel pump is to measure the current draw in amperes. This test is most often performed by connecting a digital multimeter set to read DC amperes and test the current draw. ● **SEE FIGURE 77–29** for the hookup for vehicles equipped with a fuel-pump relay. Compare the reading to factory specifications. See the chart for an example of typical fuel-pump current draw readings.

NOTE: Testing the current draw of an electric fuel pump may not indicate whether the pump is good. A pump that is not rotating may draw normal current.

Using a mini clamp-on ammeter is a quick and easy way to measure fuel pump current. Clamp the inductive probe around a wire to the fuel pump or add a fused jumper wire to replace the fuel pump fuse. Start the engine and read the meter display.

FUEL-PUMP REPLACEMENT

The following recommendations should be followed whenever replacing an electric fuel pump:

- Clean around the fuel pump retainer area before removing the fuel pump assembly.
- The fuel-pump strainer (sock) should be replaced with the new pump.
- If the original pump had a defector shield, it should always be used to prevent fuel return bubbles from blocking the inlet to the pump.
- Always check the interior of the fuel tank for evidence of contamination or dirt.
- Double-check that the replacement pump is correct for the application.
- Check that the wiring and electrical connectors are clean and tight.

ELECTRONIC FUEL-INJECTION OPERATION

Electronic fuel-injection systems use the powertrain control module (PCM) to control the operation of fuel injectors and other functions based on information sent to the PCM from the various sensors. Most electronic fuel-injection systems share the following:

1. Electric fuel pump (usually located inside the fuel tank)
2. Fuel-pump relay (usually controlled by the computer)
3. Fuel-pressure regulator (mechanically operated spring-loaded rubber diaphragm maintains proper fuel pressure)
4. Fuel-injector nozzle or nozzles

SEE FIGURE 78–1. Most electronic fuel-injection systems use the computer to control these aspects of their operation:

1. **Pulsing the fuel injectors on and off.** The longer the injectors are held open, the greater the amount of fuel injected into the cylinder.
2. **Operating the fuel pump relay circuit.** The computer usually controls the operation of the electric fuel pump located inside (or near) the fuel tank. The computer uses signals from the ignition switch and RPM signals from the ignition module or system to energize the fuel-pump relay circuit.

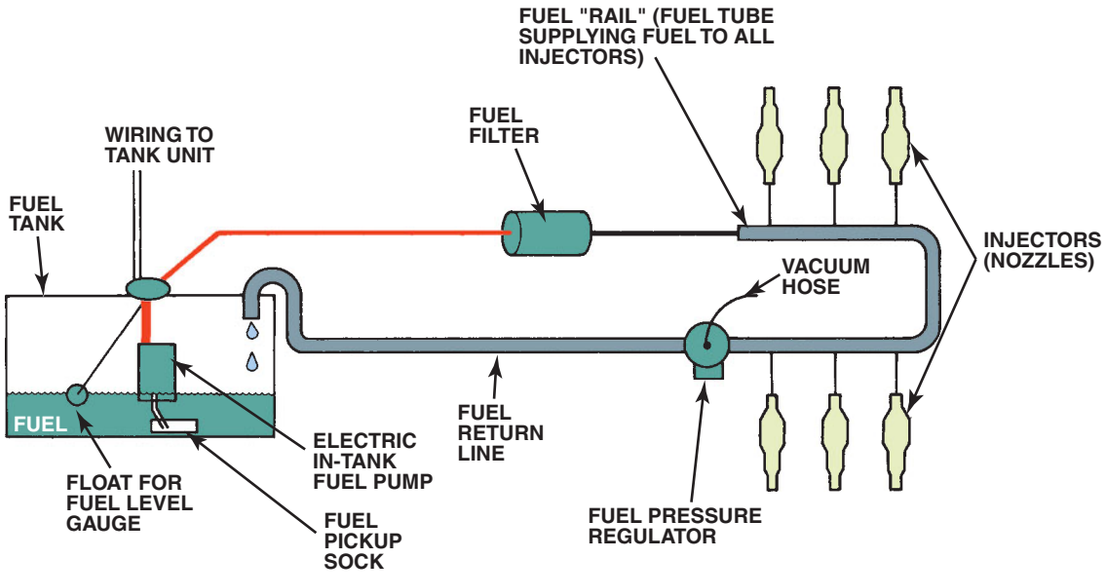

FIGURE 78–1 Typical port fuel-injection system, indicating the location of various components. Notice that the fuel-pressure regulator is located on the fuel return side of the system. The computer does not control fuel pressure. But does control the operation of the electric fuel pump (on most systems) and the pulsing on and off of the injectors.

FIGURE 78–2 A dual-nozzle TBI unit on a Chevrolet 4.3-L V-6 engine. The fuel is squirted above the throttle plate where the fuel mixes with air before entering the intake manifold.

NOTE: This is a safety feature, because if the engine stalls and the tachometer (engine speed) signal is lost, the computer will shut off (de-energize) the fuel-pump relay and stop the fuel pump.

Computer-controlled fuel-injection systems are normally reliable systems if the proper service procedures are followed. Fuel-injection systems use the gasoline flowing through the injectors to lubricate and cool the injector electrical windings and pintle valves.

NOTE: The fuel does not actually make contact with the electrical windings because the injectors have O-rings at the top and bottom of the winding spool to keep fuel out.

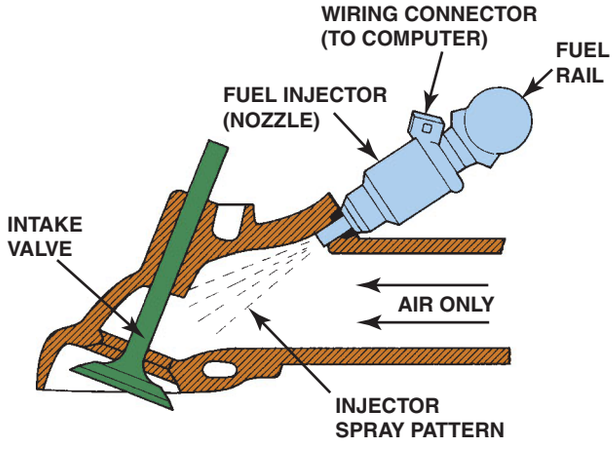

FIGURE 78–3 A typical port fuel-injection system squirts fuel into the low pressure (vacuum) of the intake manifold, about 2 to 3 in. (70 to 100 mm) from the intake valve.

There are two types of electronic fuel-injection systems:

- **Throttle-body-injection (TBI)** type. A TBI system delivers fuel from a nozzle(s) into the air above the throttle plate. ● **SEE FIGURE 78–2.**
- **Port fuel-injection**-type. A port fuel-injection design uses a nozzle for each cylinder and the fuel is squirted into the intake manifold about 2 to 3 inches (70 to 100 mm) from the intake valve. ● **SEE FIGURE 78–3.**

SPEED-DENSITY FUEL-INJECTION SYSTEMS

Fuel-injection computer systems require a method for measuring the amount of air the engine is breathing in, in order to match the correct fuel delivery. There are two basic methods used:

1. Speed density
2. Mass airflow

TECH TIP

"Two Must-Do's"

For long service life of the fuel system always do the following:

1. Avoid operating the vehicle on a near-empty tank of fuel. The water or alcohol that may be in the tank becomes more concentrated when the fuel level is low. Dirt that settles near the bottom of the fuel tank can be drawn through the fuel system and cause damage to the pump and injector nozzles.
2. Replace the fuel filter at regular service intervals.

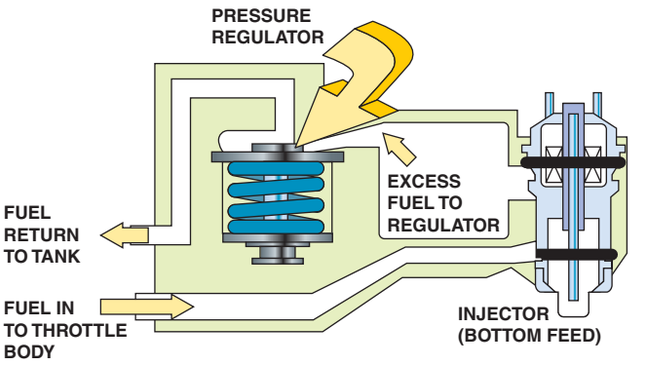

FIGURE 78–4 The tension of the spring in the fuel-pressure regulator determines the operating pressure on a throttle-body fuel-injection unit.

The speed-density method does not require an air quantity sensor, but rather calculates the amount of fuel required by the engine. The computer uses information from sensors such as the MAP and TP to calculate the needed amount of fuel.

- **MAP sensor.** The value of the intake (inlet) manifold pressure (vacuum) is a direct indication of engine load.
- **TP sensor.** The position of the throttle plate and its rate of change are used as part of the equation to calculate the proper amount of fuel to inject.
- **Temperature sensors.** Both engine coolant temperature (ECT) and intake air temperature (IAT) are used to calculate the density of the air and the need of the engine for fuel. A cold engine (low-coolant temperature) requires a richer air–fuel mixture than a warm engine.

On speed-density systems, the computer calculates the amount of air in each cylinder by using manifold pressure and engine RPM. The amount of air in each cylinder is the major factor in determining the amount of fuel needed. Other sensors provide information to modify the fuel requirements. The formula used to determine the injector pulse width (PW) in milliseconds (ms) is:

Injector pulse width = MAP/BARO × RPM/maximum RPM

The formula is modified by values from other sensors, including:

- Throttle position (TP)
- Engine coolant temperature (ECT)
- Intake air temperature (IAT)
- Oxygen sensor voltage (O2S)
- Adaptive memory

A fuel injector delivers atomized fuel into the airstream where it is instantly vaporized. All throttle-body (TB) fuel-injection systems and many multipoint (port) injection systems use the speed-density method of fuel calculation.

MASS AIRFLOW FUEL-INJECTION SYSTEMS

The formula used by fuel-injection systems that use a mass airflow (MAF) sensor to calculate the injection base pulse width is:

Injector pulse width = airflow/RPM

The formula is modified by other sensor values such as:

- Throttle position
- Engine coolant temperature
- Barometric pressure
- Adaptive memory

NOTE: Many four-cylinder engines do not use a MAF sensor because, due to the time interval between intake events, some reverse airflow can occur in the intake manifold. The MAF sensor would "read" this flow of air as being additional air entering the engine, giving the PCM incorrect airflow information. Therefore, most four-cylinder engines use the speed-density method of fuel control.

THROTTLE-BODY INJECTION

The computer controls injector pulses in one of two ways:

- Synchronized
- Nonsynchronized

If the system uses a synchronized mode, the injector pulses once for each distributor reference pulse. In some vehicles, when dual injectors are used in a synchronized system, the injectors pulse alternately. In a nonsynchronized system, the injectors are pulsed once during a given period (which varies according to calibration) completely independent of distributor reference pulses.

The injector always opens the same distance, and the fuel pressure is maintained at a controlled value by the pressure regulator. The regulators used on throttle-body injection systems are not connected to a vacuum like many port fuel-injection systems. The strength of the spring inside the regulator determines at what pressure the valve is unseated, sending the fuel back to the tank and lowering the pressure. **SEE FIGURE 78–4.** The amount of fuel delivered by the injector depends on the amount of time (on-time) that the nozzle is open. This is the injector pulse width—the on-time in milliseconds that the nozzle is open.

The PCM commands a variety of pulse widths to supply the amount of fuel that an engine needs at any specific moment.

- A long pulse width delivers more fuel.
- A short pulse width delivers less fuel.

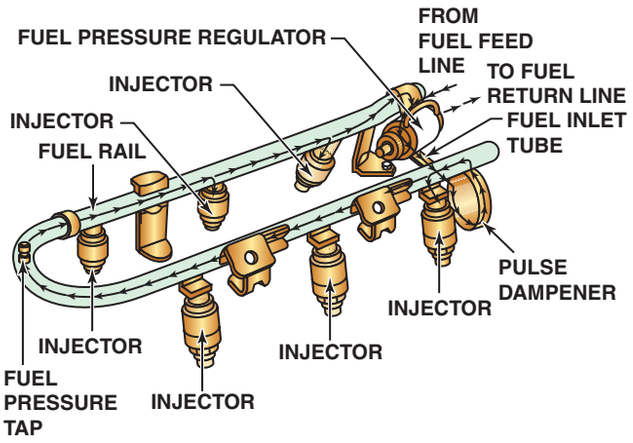

FIGURE 78–5 The injectors receive fuel and are supported by the fuel rail.

FREQUENTLY ASKED QUESTION

How Do the Sensors Affect the Pulse Width?

The base pulse width of a fuel-injection system is primarily determined by the value of the MAF or MAP sensor and engine speed (RPM). However, the PCM relies on the input from many other sensors to modify the base pulse width as needed. For example,

- **TP Sensor.** This sensor causes the PCM to command up to 500% (5 times) the base pulse width if the accelerator pedal is depressed rapidly to the floor. It can also reduce the pulse width by about 70% if the throttle is rapidly closed.
- **ECT.** The value of this sensor determines the temperature of the engine coolant, helps determine the base pulse width, and can account for up to 60% of the determining factors.
- **BARO.** The BARO sensor compensates for altitude and adds up to about 10% under high-pressure conditions and subtracts as much as 50% from the base pulse width at high altitudes.
- **IAT.** The intake air temperature is used to modify the base pulse width based on the temperature of the air entering the engine. It is usually capable of adding as much as 20% if very cold air is entering the engine or reduce the pulse width by up to 20% if very hot air is entering the engine.
- **O2S.** This is one of the main modifiers to the base pulse width and can add or subtract up to about 20% to 25% or more, depending on the oxygen sensor activity.

PORT-FUEL INJECTION

The advantages of port fuel-injection design also are related to characteristics of intake manifolds:

- Fuel distribution is equal to all cylinders because each cylinder has its own injector. ● **SEE FIGURE 78–5.**
- The fuel is injected almost directly into the combustion chamber, so there is no chance for it to condense on the walls of a cold intake manifold.

FREQUENTLY ASKED QUESTION

How Can It Be Determined If the Injection System Is Sequential?

Look at the color of the wires at the injectors. If a sequentially fired injector is used, then one wire color (the pulse wire) will be a different color for each injector. The other wire is usually the same color because all injectors receive voltage from some source. If a group- or batch-fired injection system is being used, then the wire colors will be the same for the injectors that are group fired. For example, a V-6 group-fired engine will have three injectors with a pink and blue wire (power and pulse) and the other three will have pink and green wires.

- Because the manifold does not have to carry fuel to properly position a TBI unit, it can be shaped and sized to tune the intake airflow to achieve specific engine performance characteristics.

An EFI injector is simply a specialized solenoid. ● **SEE FIGURE 78–6.** It has an armature winding to create a magnetic field, and a needle (pintle), a disc, or a ball valve. A spring holds the needle, disc, or ball closed against the valve seat, and when energized, the armature winding pulls open the valve when it receives a current pulse from the powertrain control module (PCM). When the solenoid is energized, it unseats the valve to inject fuel.

Electronic fuel-injection systems use a solenoid-operated injector to spray atomized fuel in timed pulses into the manifold or near the intake valve. ● **SEE FIGURE 78–7.** Injectors may be sequenced and fired in one of several ways, but their pulse width is determined and controlled by the engine computer.

Port systems have an injector for each cylinder, but they do not all fire the injectors in the same way. Domestic systems use one of three ways to trigger the injectors:

- Grouped double-fire
- Simultaneous double-fire
- Sequential

GROUPED DOUBLE-FIRE This system divides the injectors into two equalized groups. The groups fire alternately; each group fires once each crankshaft revolution, or twice per four-stroke cycle. The fuel injected remains near the intake valve and enters the engine when the valve opens. This method of pulsing injectors in groups is sometimes called **gang fired.**

SIMULTANEOUS DOUBLE-FIRE This design fires all of the injectors at the same time once every engine revolution: two pulses per four-stroke cycle. Many port fuel-injection systems on four-cylinder engines use this pattern of injector firing. It is easier for engineers to program this system and it can make relatively quick adjustments in the air–fuel ratio, but it still requires the intake charge to wait in the manifold for varying lengths of time.

SEQUENTIAL Sequential firing of the injectors according to engine firing order is the most accurate and desirable method of regulating port fuel injection. However, it is also the most complex and expensive to design and manufacture. In this system, the injectors are timed and pulsed individually, much like the spark plugs are sequentially operated in firing order of the engine. This system is often called **sequential fuel injection** or **SFI.** Each cylinder receives one charge every two crankshaft revolutions, just before the intake valve opens.

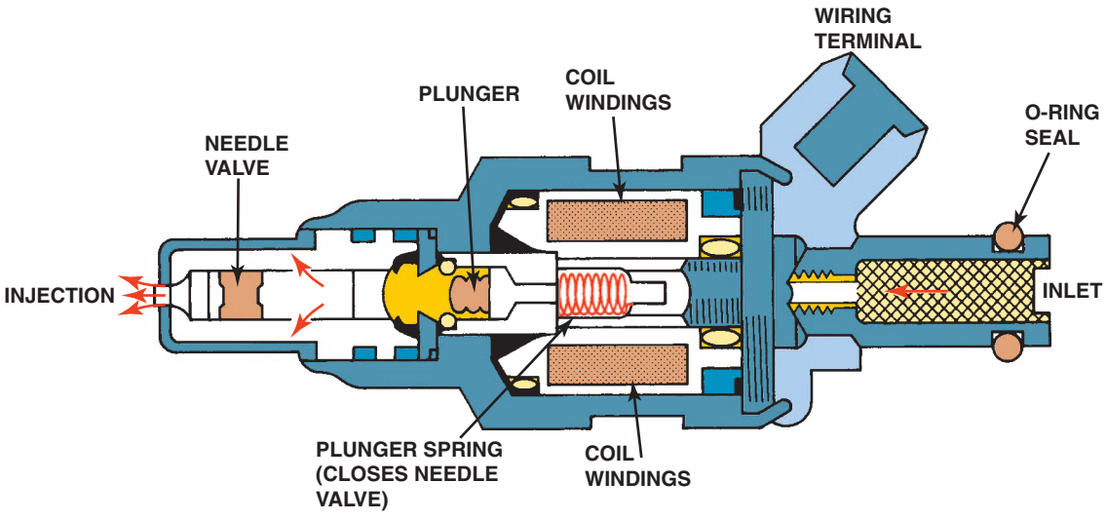

FIGURE 78–6 Cross-section of a typical port fuel-injection nozzle assembly. These injectors are serviced as an assembly only; no part replacement or service is possible except for replacement of external O-ring seals.

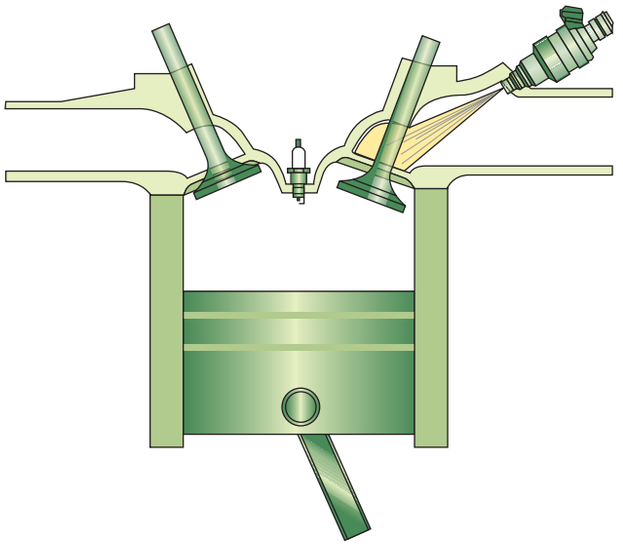

FIGURE 78–7 Port fuel injectors spray atomized fuel into the intake manifold about 3 inches (75 mm) from the intake valve.

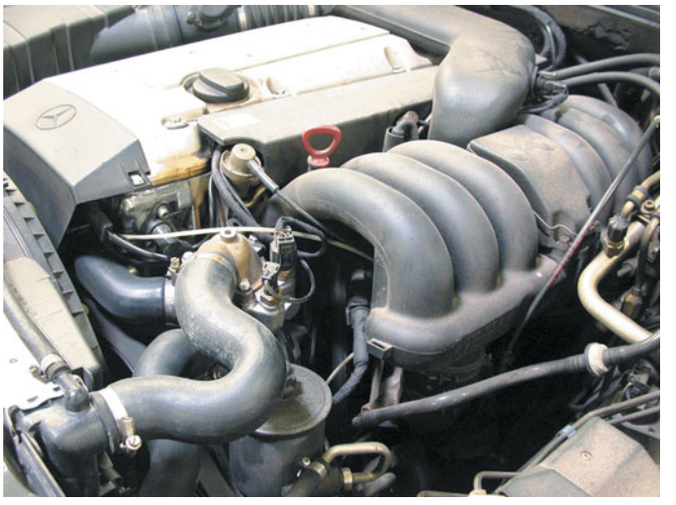

FIGURE 78–8 A port fuel-injected engine that is equipped with long, tuned intake manifold runners.

This means that the mixture is never static in the intake manifold and mixture adjustments can be made almost instantaneously between the firing of one injector and the next. A camshaft position sensor (CMP) signal or a special distributor reference pulse informs the PCM when the No. 1 cylinder is on its compression stroke. If the sensor fails or the reference pulse is interrupted, some injection systems shut down, while others revert to pulsing the injectors simultaneously.

The major advantage of using port injection instead of the simpler throttle-body injection is that the intake manifolds on port fuel-injected engines only contain air, not a mixture of air and fuel. This allows the engine design engineer the opportunity to design long, "tuned" intake-manifold runners that help the engine produce increased torque at low engine speeds. ● **SEE FIGURE 78–8.**

NOTE: Some port fuel-injection systems used on engines with four or more valves per cylinder may use two injectors per cylinder. One injector is used all the time, and the second injector is operated by the computer when high engine speed and high-load conditions are detected by the computer. Typically, the second injector injects fuel into the high-speed intake ports of the manifold. This system permits good low-speed power and throttle responses as well as superior high-speed power.

FUEL-PRESSURE REGULATOR

The pressure regulator and fuel pump work together to maintain the required pressure drop at the injector tips. The fuel-pressure regulator typically consists of a spring-loaded, diaphragm-operated valve in a metal housing.

Fuel-pressure regulators on fuel-return-type fuel-injection systems are installed on the return (downstream) side of the injectors at the end of the fuel rail, or are built into or mounted upon the throttle-body housing. Downstream regulation minimizes fuel-pressure pulsations caused by pressure drop across the injectors as the nozzles open. It also ensures positive fuel pressure at the injectors at all times and holds residual pressure in the lines when the engine is off. On mechanical returnless systems, the regulator is located back at the tank with the fuel filter.

In order for excess fuel (about 80% to 90% of the fuel delivered) to return to the tank, fuel pressure must overcome spring pressure on the spring-loaded diaphragm to uncover the return line to the

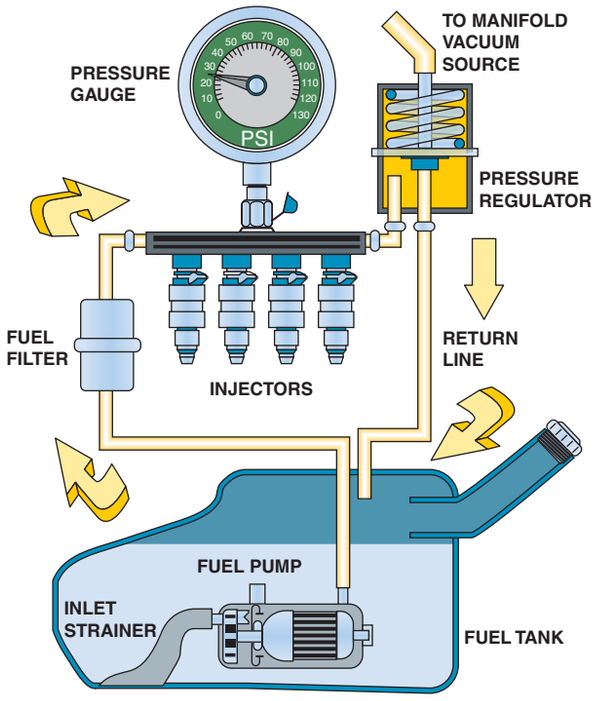

FIGURE 78–9 A typical port fuel-injected system showing a vacuum-controlled fuel-pressure regulator.

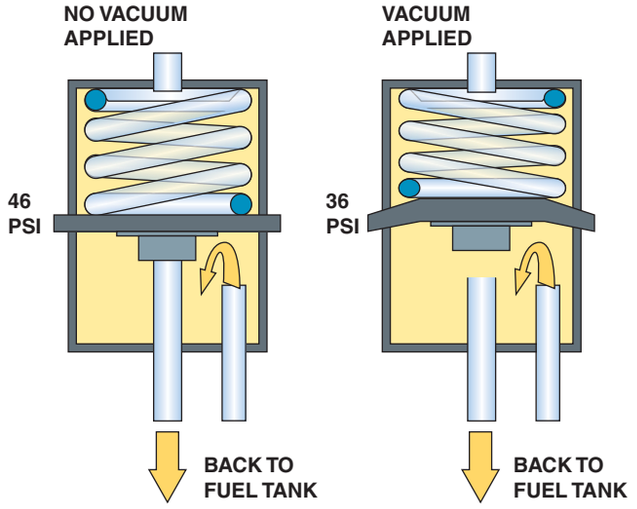

FIGURE 78–10 A typical fuel-pressure regulator that has a spring that exerts 46 pounds of force against the fuel. If 20 inches of vacuum are applied above the spring, the vacuum reduces the force exerted by the spring on the fuel, allowing the fuel to return to the tank at a lower pressure.

tank. This happens when system pressure exceeds operating requirements. With TBI, the regulator is close to the injector tip, so the regulator senses essentially the same air pressure as the injector.

The pressure regulator used in a port fuel-injection system has an intake manifold vacuum line connection on the regulator vacuum chamber. This allows fuel pressure to be modulated by a combination of spring pressure and manifold vacuum acting on the diaphragm. ● **SEE FIGURES 78–9 AND 78–10.**

In both TBI and port fuel-injection systems, the regulator shuts off the return line when the fuel pump is not running. This maintains pressure at the injectors for easy restarting after hot soak as well as reducing vapor lock.

NOTE: Some General Motors throttle-body units do not hold pressure and are called nonchecking.

Port fuel-injection systems generally operate with pressures at the injector of about 30 to 55 PSI (207 to 379 kPa), while TBI systems work with injector pressures of about 10 to 20 PSI (69 to 138 kPa). The difference in system pressures results from the difference in how the systems operate. Since injectors in a TBI system inject the fuel into the airflow at the manifold inlet (above the throttle), there is more time for atomization in the manifold before the air–fuel charge reaches the intake valve. This allows TBI injectors to work at lower pressures than injectors used in a port system.

TECH TIP

Don't Forget the Regulator

Some fuel-pressure regulators contain a 10-micron filter. If this filter becomes clogged, a lack of fuel flow would result. ● **SEE FIGURE 78–11.**

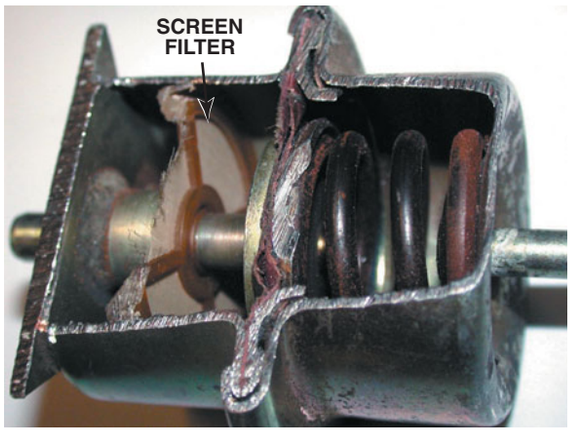

FIGURE 78–11 A lack of fuel flow could be due to a restricted fuel-pressure regulator. Notice the fine screen filter. If this filter were to become clogged, higher than normal fuel pressure would occur.

VACUUM-BIASED FUEL-PRESSURE REGULATOR

The primary reason why many port fuel-injected systems use a vacuum-controlled fuel-pressure regulator is to ensure that there is a constant pressure drop across the injectors. In a throttle-body fuel-injection system, the injector squirts into the atmospheric pressure regardless of the load on the engine. In a port fuel-injected engine, however, the pressure inside the intake manifold changes as the load on the engine increases.

Engine Operating Condition	Intake Manifold Vacuum	Fuel Pressure
Idle or cruise	High	Lower
Heavy load	Low	Higher

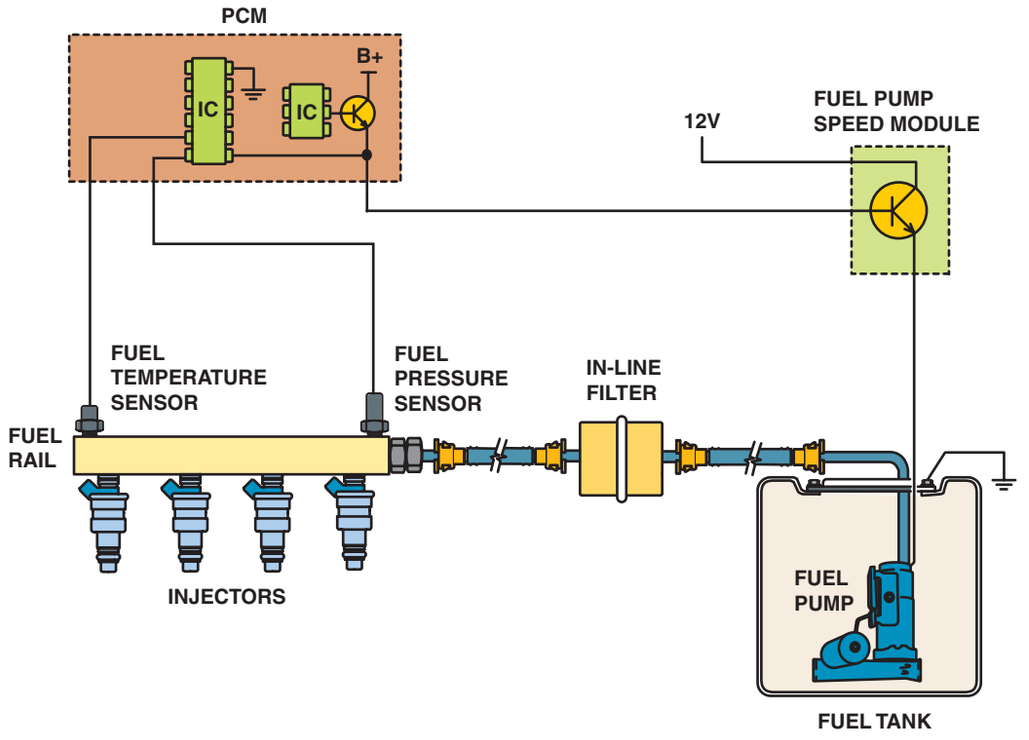

FIGURE 78–12 The fuel-pressure sensor and fuel-temperature sensor are often constructed together in one assembly to help give the PCM the needed data to control the fuel-pump speed.

The computer can best calculate injector pulse width based on all sensors if the pressure drop across the injector is the same under all operating conditions. A vacuum-controlled fuel-pressure regulator allows the equal pressure drop by reducing the force exerted by the regulator spring at high vacuum (low-load condition), yet allowing the full force of the regulator spring to be exerted when the vacuum is low (high-engine-load condition).

ELECTRONIC RETURNLESS FUEL SYSTEM

This system is unique because it does not use a mechanical valve to regulate rail pressure. Fuel pressure at the rail is sensed by a pressure transducer, which sends a low-level signal to a controller. The controller contains logic to calculate a signal to the pump power driver. The power driver contains a high-current transistor that controls the pump speed using pulse width modulation (PWM). This system is called the **electronic returnless fuel system (ERFS).** ● **SEE FIGURE 78–12.** This transducer can be differentially referenced to manifold pressure for closed-loop feedback, correcting and maintaining the output of the pump to a desired rail setting. This system is capable of continuously varying rail pressure as a result of engine vacuum, engine fuel demand, and fuel temperature (as sensed by an external temperature transducer, if necessary). A **pressure vent valve (PVV)** is employed at the tank to relieve overpressure due to thermal expansion of fuel. In addition, a supply-side bleed, by means of an in-tank reservoir using a supply-side jet pump, is necessary for proper pump operation.

MECHANICAL RETURNLESS FUEL SYSTEM

The first production returnless systems employed the **mechanical returnless fuel system (MRFS)** approach. This system has a bypass regulator to control rail pressure that is located in close proximity to the fuel tank. Fuel is sent by the in-tank pump to a chassis-mounted inline filter with excess fuel returning to the tank through a short return line. ● **SEE FIGURE 78–13.** The inline filter may be mounted directly to the tank, thereby eliminating the shortened return line. Supply pressure is regulated on the downstream side of the inline filter to accommodate changing restrictions throughout the filter's service life. This system is limited to constant rail pressure (*CRP) system calibrations, whereas with ERFS, the pressure transducer can be referenced to atmospheric pressure for CRP systems or differentially referenced to intake manifold pressure for constant differential injector pressure (**CIP) systems.

NOTE: *CRP is referenced to atmospheric pressure, has lower operating pressure, and is desirable for calibrations using speed/air density sensing. **CIP is referenced to manifold pressure, varies rail pressure, and is desirable in engines that use mass airflow sensing.

DEMAND DELIVERY SYSTEM (DDS)

Given the experience with both ERFS and MRFS, a need was recognized to develop new returnless technologies that could combine the speed control and constant injector pressure attributes of ERFS

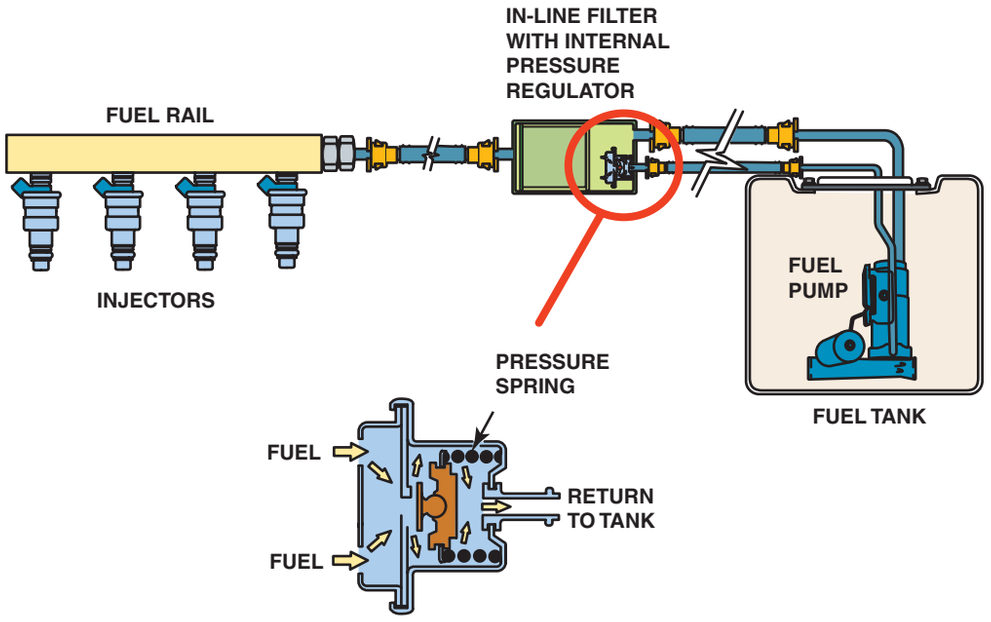

FIGURE 78–13 A mechanical returnless fuel system. The bypass regulator in the fuel filter controls fuel line pressure.

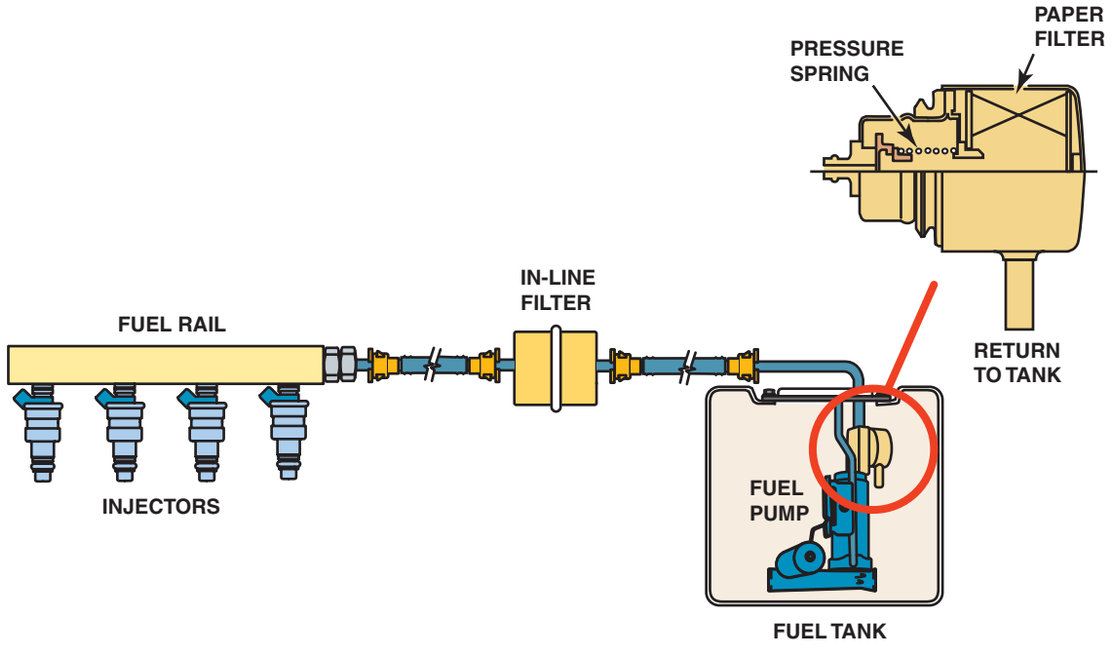

FIGURE 78–14 A demand delivery system uses a fuel pressure regulator attached to the fuel pump assembly.

together with the cost savings, simplicity, and reliability of MRFS. This new technology also needed to address pulsation dampening/hammering and fuel transient response. Therefore, the **demand delivery system (DDS)** technology was developed.

A different form of demand pressure regulator has been applied to the fuel rail. It mounts at the head or port entry and regulates the pressure downstream at the injectors by admitting the precise quantity of fuel into the rail as consumed by the engine. Having demand regulation at the rail improves pressure response to flow transients and provides rail pulsation dampening. A fuel pump and a low-cost, high-performance bypass regulator are used within the appropriate fuel sender. ● **SEE FIGURE 78–14.** They supply a pressure somewhat higher than the required rail set pressure to accommodate dynamic line and filter pressure losses. Electronic pump speed control is accomplished using a smart regulator as an integral flow sensor. A **pressure control valve (PCV)** may also be used and can readily reconfigure an existing design fuel sender into a returnless sender.

? **FREQUENTLY ASKED QUESTION**

Why Are Some Fuel Rails Rectangular Shaped?

A port fuel-injection system uses a pipe or tubes to deliver fuel from the fuel line to the intended fuel injectors. This pipe or tube is called the **fuel rail.** Some vehicle manufacturers construct the fuel rail in a rectangular cross-section. ● **SEE FIGURE 78–15.** The sides of the fuel rail are able to move in and out slightly, thereby acting as a fuel pulsator evening out the pressure pulses created by the opening and closing of the injectors to reduce underhood noise. A round cross-section fuel rail is not able to deform and, as a result, some manufacturers have had to use a separate dampener.

FIGURE 78–15 A rectangular-shaped fuel rail is used to help dampen fuel system pulsations and noise caused by the injectors opening and closing.

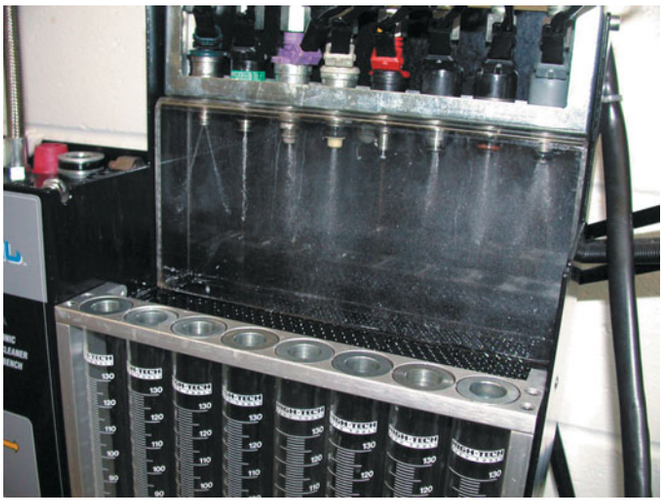

FIGURE 78–17 Each of the eight injectors shown are producing a correct spray pattern for the applications. While all throttle-body injectors spray a conical pattern, most port fuel injections do not.

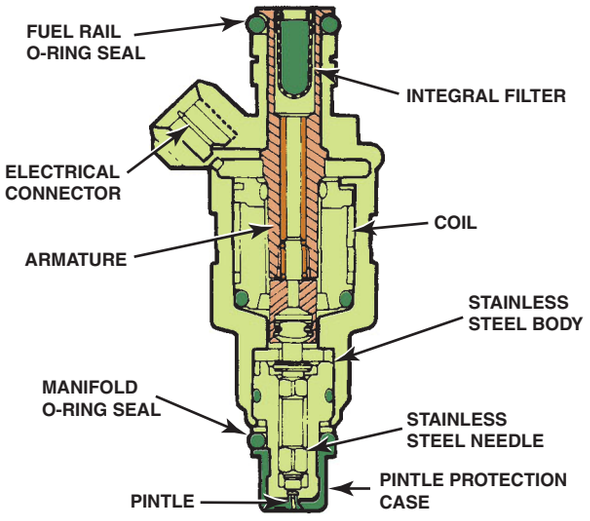

FIGURE 78–16 A multiport fuel injector. Notice that the fuel flows straight through and does not come in contact with the coil windings.

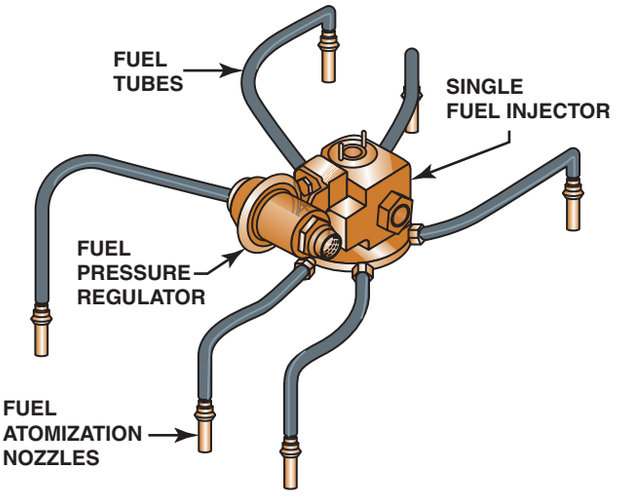

FIGURE 78–18 A central port fuel-injection system.

FUEL INJECTORS

EFI systems use a 12 volt solenoid-operated injectors. ● **SEE FIGURE 78–16.** This electromagnetic device contains an armature and a spring-loaded needle valve or ball valve assembly. When the computer energizes the solenoid, voltage is applied to the solenoid coil until the current reaches a specified level. This permits a quick pull-in of the armature during turn-on. The armature is pulled off of its seat against spring force, allowing fuel to flow through the inlet filter screen to the spray nozzle, where it is sprayed in a pattern that varies with application. ● **SEE FIGURE 78–17.** The injector opens the same amount each time it is energized, so the amount of fuel injected depends on the length of time the injector remains open. By angling the director hole plates, the injector sprays fuel more directly at the intake valves, which further atomizes and vaporizes the fuel before it enters the combustion chamber. PFI injectors typically are a top-feed design in which fuel enters the top of the injector and passes through its entire length to keep it cool before being injected.

Ford introduced two basic designs of deposit-resistant injectors on some engines. The design, manufactured by Bosch, uses a four-hole director/metering plate similar to that used by the Rochester Multec injectors. The design manufactured by Nippondenso uses an internal upstream orifice in the adjusting tube. It also has a re-designed pintle/seat containing a wider tip opening that tolerates deposit buildup without affecting injector performance.

CENTRAL PORT INJECTION

A cross between port fuel injection and throttle-body injection, CPI was introduced in the early 1990s by General Motors. The CPI assembly consists of a single fuel injector, a pressure regulator, and six poppet nozzle assemblies with nozzle tubes. ● **SEE FIGURE 78–18.** The central sequential fuel injection (CSFI) system has six injectors in place of just one used on the CPI unit.

When the injector is energized, its armature lifts off of the six fuel tube seats and pressurized fuel flows through the nozzle tubes to each poppet nozzle. The increased pressure causes each poppet nozzle ball to also lift from its seat, allowing fuel to flow from the nozzle. This

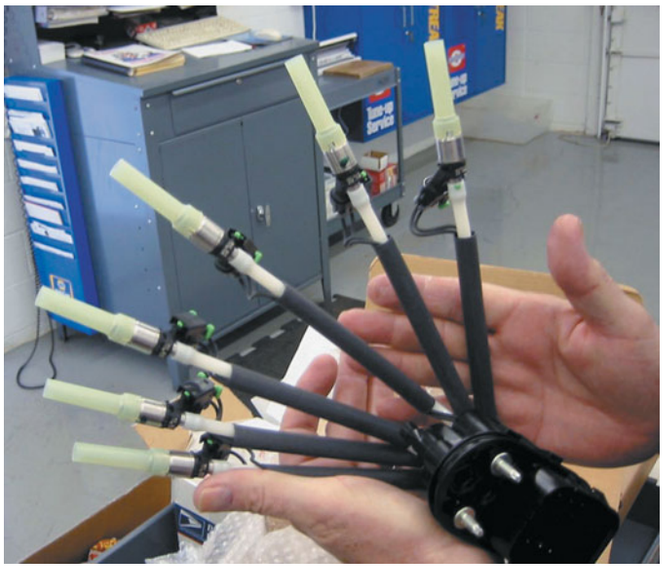

FIGURE 78–19 A factory replacement unit for a CSFI unit that has individual injectors at the ends that go into the intake manifold instead of poppet valves.

FREQUENTLY ASKED QUESTION

How Can the Proper injector Size Be Determined?

Most people want to increase the output of fuel to increase engine performance. Injector sizing can sometimes be a challenge, especially if the size of injector is not known. In most cases, manufacturers publish the rating of injectors, in pounds of fuel per hour (lb/hr). The rate is figured with the injector held open at 3 bars (43.5 PSI). An important consideration is that larger flow injectors have a higher minimum flow rating. Here is a formula to calculate injector sizing when changing the mechanical characteristics of an engine.

Flow rate = hp × BSFC/# of cylinders × maximum duty cycle (% of on-time of the injectors)

- **hp** is the projected horsepower. Be realistic!
- **BSFC** is brake-specific fuel consumption in pounds per horsepower-hour. Calculated values are used for this, 0.4 to 0.8 lb. In most cases, start on the low side for naturally aspirated engines and the high side for engines with forced induction.
- **# of cylinders** is actually the number of injectors being used.
- **Maximum duty cycle** is considered at 0.8 (80%). Above this, the injector may overheat, lose consistency, or not work at all.

For example:

5.7 liter V-8 = 240 hp × 0.65/8 cylinders × 8 = 24.37 lb/hr injectors required

hybrid injection system combines the single injector of a TBI system with the equalized fuel distribution of a PFI system. It eliminates the individual fuel rail while allowing more efficient manifold tuning than is otherwise possible with a TBI system. Newer versions use six individual solenoids to fire one for each cylinder. ● **SEE FIGURE 78–19.**

FREQUENTLY ASKED QUESTION

What Is Battery Voltage Correction?

Battery voltage correction is a program built into the PCM that causes the injector pulse width to increase if there is a drop in electrical system voltage. Lower battery voltage would cause the fuel injectors to open slower than normal and the fuel pump to run slower. Both of these conditions can cause the engine to run leaner than normal if the battery voltage is low. Because a lean air–fuel mixture can cause the engine to overheat, the PCM compensates for the lower voltage by adding a percentage to the injector pulse width. This richer condition will help prevent serious engine damage. The idle speed is also increased to turn the alternator faster if low battery voltage is detected.

FUEL-INJECTION MODES OF OPERATION

All fuel-injection systems are designed to supply the correct amount of fuel under a wide range of engine operating conditions. These modes of operation include:

Starting (cranking)	Acceleration enrichment
Clear flood	Deceleration enleanment
Idle (run)	Fuel shutoff

STARTING MODE When the ignition is turned to the start position, the engine cranks and the PCM energizes the fuel pump relay. The PCM also pulses the injectors on, basing the pulse width on engine speed and engine coolant temperature. The colder the engine is, the greater the pulse width. Cranking mode air–fuel ratio varies from about 1.5:1 at −40°F (−40°C) to 14.7:1 at 200°F (93°C).

CLEAR FLOOD MODE If the engine becomes flooded with too much fuel, the driver can depress the accelerator pedal to greater than 80% to enter the clear flood mode. When the PCM detects that the engine speed is low (usually below 600 RPM) and the throttle-position (TP) sensor voltage is high (WOT), the injector pulse width is greatly reduced or even shut off entirely, depending on the vehicle.

OPEN-LOOP MODE Open-loop operation occurs during warm-up before the oxygen sensor can supply accurate information to the PCM. The PCM determines injector pulse width based on values from the MAF, MAP, TP, ECT, and IAT sensors.

CLOSED-LOOP MODE Closed-loop operation is used to modify the base injector pulse width as determined by feedback from the oxygen sensor to achieve proper fuel control.

ACCELERATION ENRICHMENT MODE During acceleration, the throttle-position (TP) voltage increases, indicating that a richer air–fuel mixture is required. The PCM then supplies a longer injector pulse width and may even supply extra pulses to supply the needed fuel for acceleration.

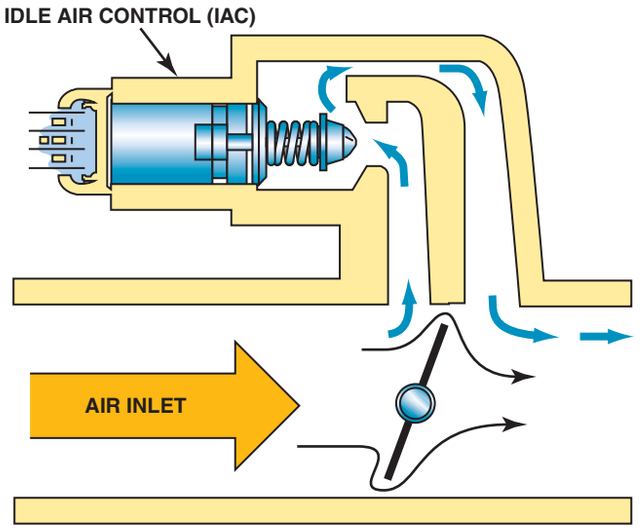

FIGURE 78–20 The small arrows indicate the air bypassing the throttle plate in the closed throttle position. This air is called minimum air. The air flowing through the IAC (blue arrows) is the airflow that determines the idle speed.

DECELERATION ENLEANMENT MODE When the engine decelerates, a leaner air–fuel mixture is required to help reduce emissions and to prevent deceleration backfire. If the deceleration is rapid, the injector may be shut off entirely for a short time and then pulsed on enough to keep the engine running.

FUEL SHUTOFF MODE Besides shutting off fuel entirely during periods of rapid deceleration, PCM also shuts off the injector when the ignition is turned off to prevent the engine from continuing to run.

IDLE CONTROL

Port fuel-injection systems generally use an auxiliary air bypass to control idle speed. ● **SEE FIGURE 78–20.** This air bypass or regulator provides needed additional airflow, and thus more fuel. The engine needs more power when cold to maintain its normal idle speed to overcome the increased friction from cold lubricating oil. It does this by opening an intake air passage to let more air into the engine just as depressing the accelerator pedal would open the throttle valve, allowing more air into the engine. The system is calibrated to maintain engine idle speed at a specified value regardless of engine temperature.

Most PFI systems use an idle air control (IAC) motor to regulate idle bypass air. The IAC is computer-controlled, and is either a solenoid-operated valve or a stepper motor that regulates the airflow around the throttle. The idle air control valve is also called an **electronic air control (EAC)** valve.

When the engine stops, most IAC units will retract outward to get ready for the next engine start. When the engine starts, the engine speed is high to provide for proper operation when the engine is cold. Then, as the engine gets warmer, the computer reduces engine idle speed gradually by reducing the number of counts or steps commanded by the IAC.

? FREQUENTLY ASKED QUESTION

Why Does the Idle Air Control Valve Use Milliamperes?

Some Chrysler vehicles, such as the Dodge minivan, use linear solenoid idle air control valves (LSIAC). The PCM uses regulated current flow through the solenoid to control idle speed and the scan tool display is in milliamperes (mA).

Closed position = 180 to 200 mA
Idle = 300 to 450 mA
Light cruise = 500 to 700 mA
Fully open = 900 to 950 mA

When the engine is warm and restarted, the idle speed should momentarily increase, then decrease to normal idle speed. This increase and then decrease in engine speed is often called an engine **flare.** If the engine speed does not flare, then the IAC may not be working (it may be stuck in one position).

STEPPER MOTOR OPERATION

A digital output is used to control stepper motors. Stepper motors are direct-current motors that move in fixed steps or increments from de-energized (no voltage) to fully energized (full voltage). A stepper motor often has as many as 120 steps of motion.

A common use for stepper motors is as an idle air control (IAC) valve, which controls engine idle speeds and prevents stalls due to changes in engine load. When used as an IAC, the stepper motor is usually a reversible DC motor that moves in increments, or steps. The motor moves a shaft back and forth to operate a conical valve. When the conical valve is moved back, more air bypasses the throttle plates and enters the engine, increasing idle speed. As the conical valve moves inward, the idle speed decreases.

When using a stepper motor that is controlled by the PCM, it is very easy for the PCM to keep track of the position of the stepper motor. By counting the number of steps that have been sent to the stepper motor, the PCM can determine the relative position of the stepper motor. While the PCM does not actually receive a feedback signal from the stepper motor, it does know how many steps forward or backward the motor should have moved.

A typical stepper motor uses a permanent magnet and two electromagnets. Each of the two electromagnetic windings is controlled by the computer. The computer pulses the windings and changes the polarity of the windings to cause the armature of the stepper motor to rotate 90 degrees at a time. Each 90-degree pulse is recorded by the computer as a "count" or "step"; therefore, the name given to this type of motor. ● **SEE FIGURE 78–21.**

Idle airflow in a TBI system travels through a passage around the throttle and is controlled by a stepper motor. In some applications, an externally mounted permanent magnet motor called the **idle speed control (ISC) motor** mechanically advances the throttle linkage to advance the throttle opening.

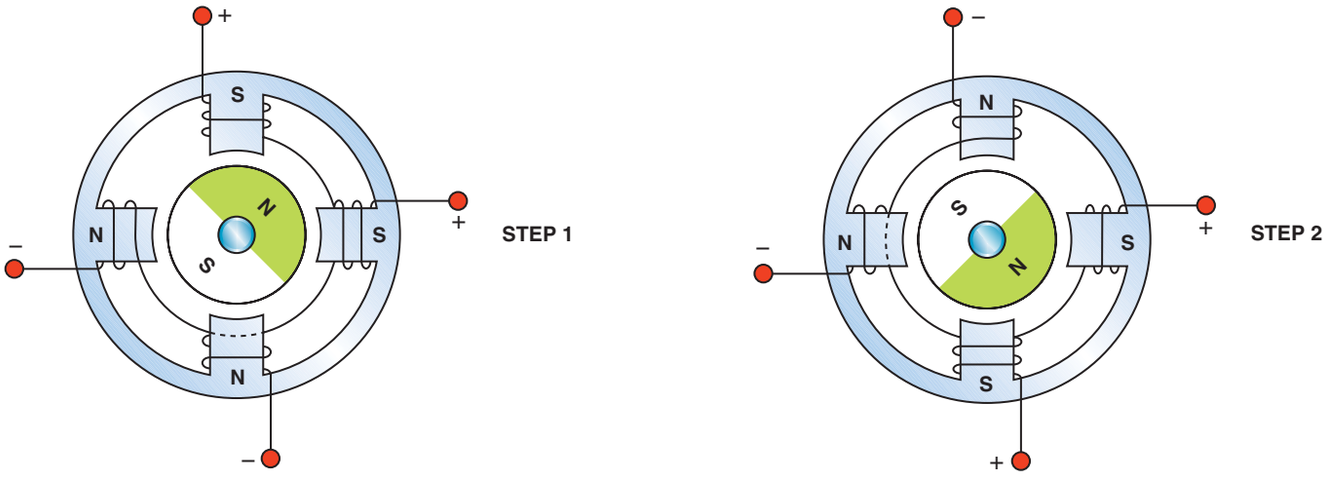

FIGURE 78–21 Most stepper motors use four wires, which are pulsed by the computer to rotate the armature in steps.

DIRECT FUEL INJECTION

Several vehicle manufacturers such as Audi, Mitsubishi, Mercedes, BMW, Toyota/Lexus, Mazda, Ford, and General Motors are using **gasoline direct injection (GDI)** systems, which General Motors refers to as a **Spark Ignition Direct Injection (SIDI)** system. A direct-injection system sprays high-pressure fuel, up to 2,900 PSI, into the combustion chamber as the piston approaches the top of the compression stroke. With the combination of high-pressure swirl injectors and modified combustion chamber, almost instantaneous vaporization of the fuel occurs. This combined with a higher compression ratio allows a direct-injected engine to operate using a leaner-than-normal air–fuel ratio, which results in improved fuel economy with higher power output and reduced exhaust emissions. ● **SEE FIGURE 79–1.**

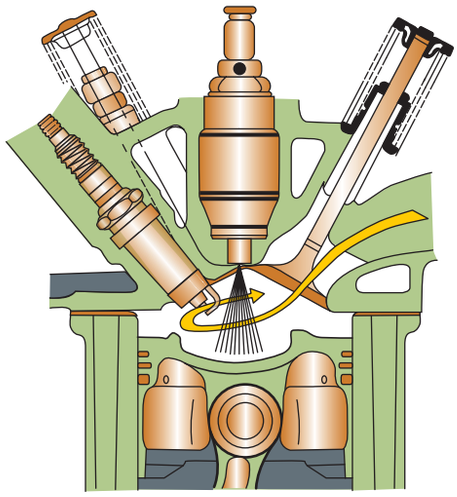

FIGURE 79–1 A gasoline direct-injection system injects fuel under high pressure directly into the combustion chamber.

ADVANTAGES OF GASOLINE DIRECT INJECTION

The use of direct injection compared with port fuel-injection has many advantages including:

- Improved fuel economy due to reduced pumping losses and heat loss
- Allows a higher compression ratio for higher engine efficiency
- Allows the use of lower-octane gasoline
- The volumetric efficiency is higher
- Less need for extra fuel for acceleration
- Improved cold starting and throttle response
- Allows the use of higher percentage of EGR to reduce exhaust emissions
- Up to 25% improvement in fuel economy
- 12% to 15% reduction in exhaust emissions

DISADVANTAGES OF GASOLINE DIRECT INJECTION

- Higher cost due to high-pressure pump and injectors
- More components compared with port fuel-injection
- Due to the high compression, a NO_x storage catalyst is sometimes required to meet emission standards, especially in Europe (● **SEE FIGURE 79–2).**
- Uses up to six operating modes depending on engine load and speed, which requires more calculations to be performed by the powertrain control module (PCM).

DIRECT-INJECTION FUEL DELIVERY SYSTEM

LOW-PRESSURE SUPPLY PUMP

The fuel pump in the fuel tank supplies fuel to the high-pressure fuel pump at a pressure of approximately 60 PSI. The fuel filter is located in the fuel tank and is part of the fuel pump assembly. It is not usually serviceable as a separate component. The engine control module (ECM) controls the output of the high-pressure pump, which has a range between 500 PSI (3,440 kPa) and 2,900 PSI (15,200 kPa) during engine operation. ● **SEE FIGURE 79–3.**

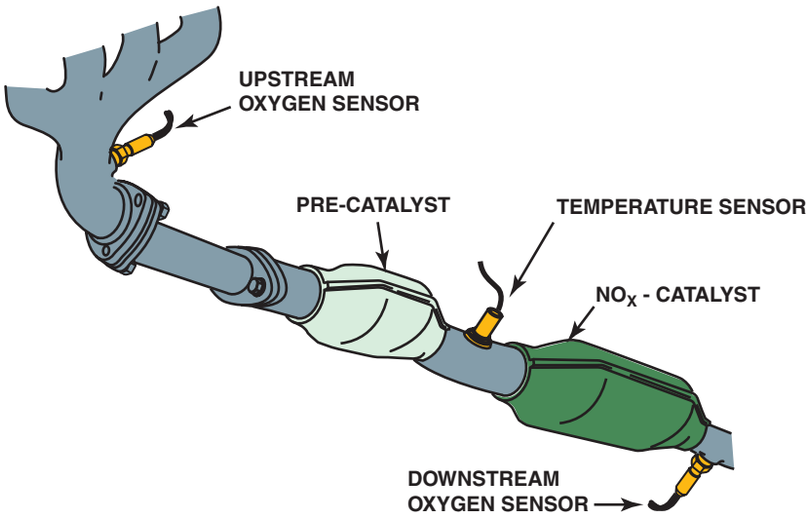

FIGURE 79–2 An engine equipped with a gasoline direct injection (GDI) sometimes requires a NO_x catalyst to meet exhaust emission standards.

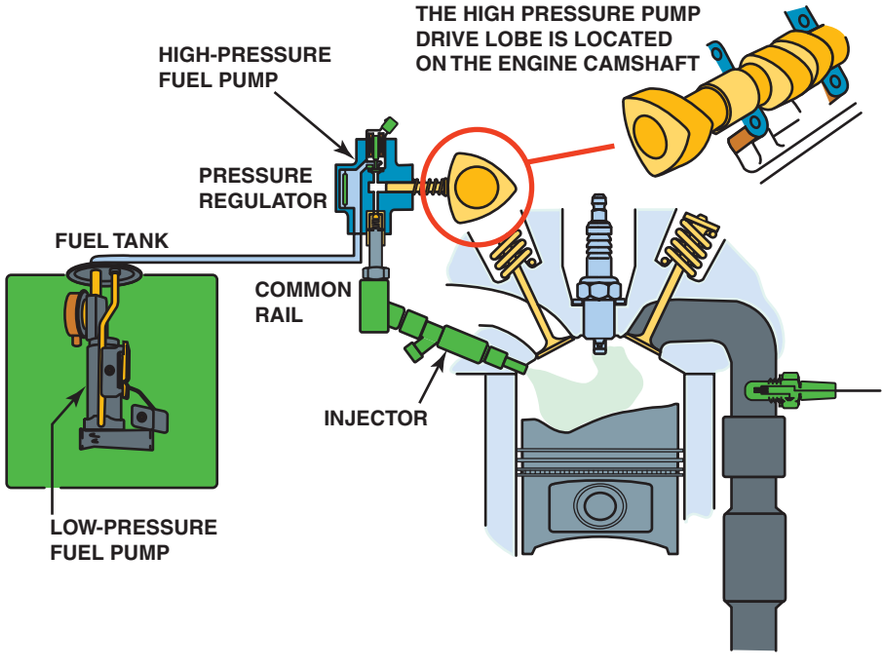

FIGURE 79–3 A typical direct-injection system uses two pumps—one low-pressure electric pump in the fuel tank and the other a high-pressure pump driven by the camshaft. The high pressure fuel system operates at a pressure as low as 500 PSI during light load conditions and as high as 2,900 PSI under heavy loads.

HIGH-PRESSURE PUMP In a General Motors system, the engine control module (ECM) controls the output of the high-pressure pump, which has a range between 500 PSI (3,440 kPa) and 2,900 PSI (15,200 kPa) during engine operation. The high-pressure fuel pump connects to the pump in the fuel tank through the low-pressure fuel line. The pump consists of a single-barrel piston pump, which is driven by the engine camshaft. The pump plunger rides on a three-lobed cam on the camshaft. The high-pressure pump is cooled and lubricated by the fuel itself. ● **SEE FIGURE 79–4.**

FUEL RAIL The fuel rail stores the fuel from the high-pressure pump and stores high pressure fuel for use to each injector. All injectors get the same pressure fuel from the fuel rail.

FUEL PRESSURE REGULATOR An electric pressure-control valve is installed between the pump inlet and outlet valves. The fuel rail pressure sensor connects to the PCM with three wires:

- 5-volt reference
- ground
- signal

The sensor signal provides an analog signal to the PCM that varies in voltage as fuel rail pressure changes. Low pressure results in a low-voltage signal and high pressure results in a high-voltage signal.

The PCM uses internal drivers to control the power feed and ground for the pressure control valve. When both PCM drivers are deactivated, the inlet valve is held open by spring pressure. This

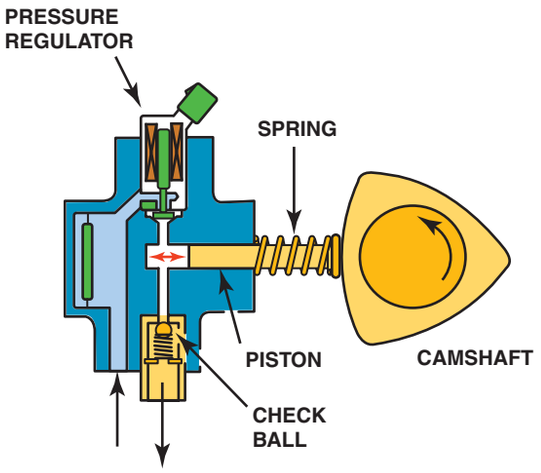

FIGURE 79–4 A typical camshaft-driven high-pressure pump used to increase fuel pressure to 2,000 PSI or higher.

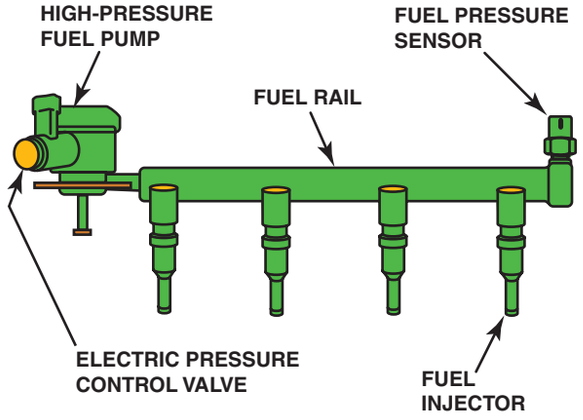

FIGURE 79–5 A gasoline direct-injection (GDI) fuel rail and pump assembly with the electric pressure control valve.

causes the high pressure fuel pump to default to low-pressure mode. The fuel from the high-pressure fuel pump flows through a line to the fuel rail and injectors. The actual operating pressure can vary from as low as 900 PSI (6,200 kPa) at idle to over 2,000 PSI (13,800 kPa) during high speed or heavy load conditions. ● **SEE FIGURE 79–5.**

GASOLINE DIRECT-INJECTION FUEL INJECTORS

Each high-pressure fuel injector assembly is an electrically magnetic injector mounted in the cylinder head. In the GDI system, the PCM controls each fuel injector with 50 to 90 volts (usually 60–70 volts), depending on the system, which is created by a boost capacitor in the PCM. During the high-voltage boost phase, the capacitor is discharged through an injector, allowing for initial injector opening. The injector is then held open with 12 volts. The high-pressure fuel injector has a small slit or six precision-machined holes that generate the desired spray pattern. The injector also has an extended tip to allow for cooling from a water jacket in the cylinder head.

● **SEE CHART 79–1** for an overview of the differences between a port fuel-injection system and a gasoline direct-injection system.

MODES OF OPERATION

The two basic modes of operation include:

1. **Stratified mode.** In this mode of operation, the air–fuel mixture is richer around the spark plug than it is in the rest of the cylinder.
2. **Homogeneous mode.** In this mode of operation, the air–fuel mixture is the same throughout the cylinder.

There are variations of these modes that can be used to fine-tune the air–fuel mixture inside the cylinder. For example, Bosch, a supplier to many vehicle manufacturers, uses six modes of operation including:

- **Homogeneous mode.** In this mode, the injector is pulsed one time to create an even air–fuel mixture in the cylinder. The injection occurs during the intake stroke. This mode is used during high-speed and/or high-torque conditions.
- **Homogeneous lean mode.** Similar to the homogeneous mode except that the overall air–fuel mixture is slightly lean for better fuel economy. The injection occurs during the intake stroke. This mode is used under steady, light-load conditions.
- **Stratified mode.** In this mode of operation, the injection occurs just before the spark occurs resulting in lean combustion, reducing fuel consumption.
- **Homogeneous stratified mode.** In this mode, there are two injections of fuel:
  - The first injection is during the intake stroke.
  - The second injection is during the compression stroke.

  As a result of these double injections, the rich air–fuel mixture around the spark plug is ignited first. Then, the rich mixture

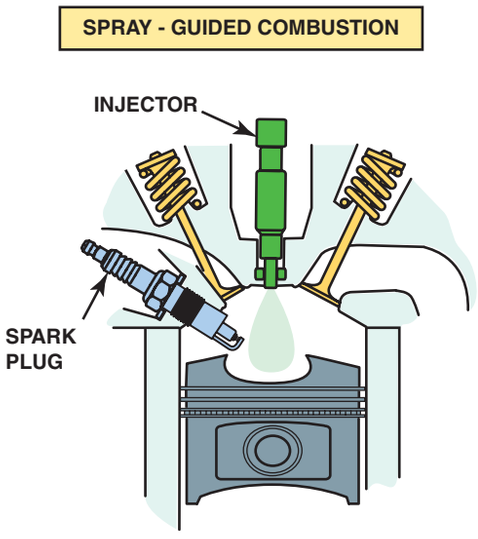

FIGURE 79–6 In this design, the fuel injector is at the top of the cylinder and sprays fuel into the cavity of the piston.

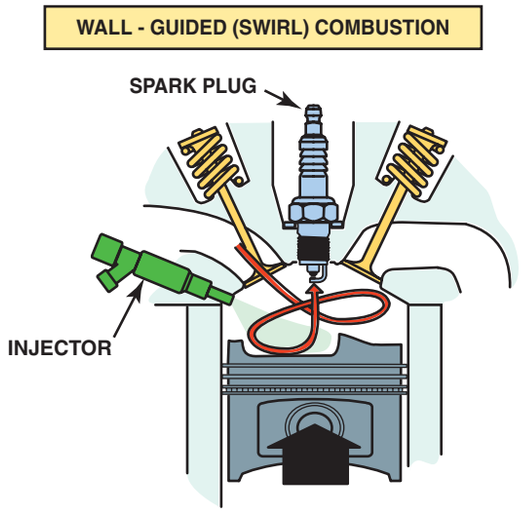

FIGURE 79–7 The side injector combines with the shape of the piston to create a swirl as the piston moves up on the compression stroke.

ignites the leaner mixture. The advantages of this mode include lower exhaust emissions than the stratified mode and less fuel consumption than the homogeneous lean mode.

- **Homogeneous knock protection mode.** The purpose of this mode is to reduce the possibility of spark knock from occurring under heavy loads at low engine speeds. There are two injections of fuel:
  - The first injection occurs on the intake stroke.
  - The second injection occurs during the compression stroke with the overall mixture being stoichiometric.

  As a result of this mode, the PCM does not need to retard ignition timing as much to operate knock-free.
- **Stratified catalyst heating mode.** In this mode, there are two injections:
  - The first injection is on the compression stroke just before combustion.
  - The second injection occurs after combustion occurs to heat the exhaust. This mode is used to quickly warm the catalytic converter and to burn the sulfur from the NO_x catalyst.

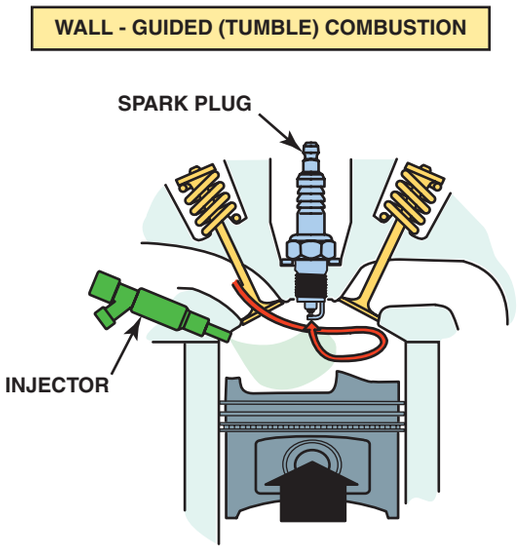

FIGURE 79–8 The piston creates a tumbling force as the piston moves upward.

PISTON TOP DESIGNS

Gasoline direct injection (GDI) systems use a variety of shapes of piston and injector locations depending on make and model of engine. Three of the most commonly used designs include:

- **Spray-guided combustion.** In this design, the injector is placed in the center of the combustion chamber and injects fuel into the dished out portion of the piston. The shape of the piston helps guide and direct the mist of fuel in the combustion chamber. ● **SEE FIGURE 79–6.**
- **Swirl combustion.** This design uses the shape of the piston and the position of the injector at the side of the combustion chamber to create turbulence and swirl of the air–fuel mixture. ● **SEE FIGURE 79–7.**
- **Tumble combustion.** Depending on when the fuel is injected into the combustion chamber, helps determine how the air–fuel is moved or tumbled. ● **SEE FIGURE 79–8.**

LEXUS PORT- AND DIRECT-INJECTION SYSTEMS

OVERVIEW Many Lexus vehicles use gasoline direct injection (GDI) and in some engines, they also use a conventional port fuel-injection system. The Lexus D-4S system combines direct-injection injectors located in the combustion chamber with port fuel-injectors in the intake manifold near the intake valve. The two injection systems work together to supply the fuel needed by the engine. ● **SEE FIGURE 79–9** for how the two systems are used throughout the various stages of engine operation.

COLD-START WARM-UP To help reduce exhaust emissions after a cold start, the fuel system uses a stratified change mode. This results in a richer air–fuel mixture near the spark plug and allows for the

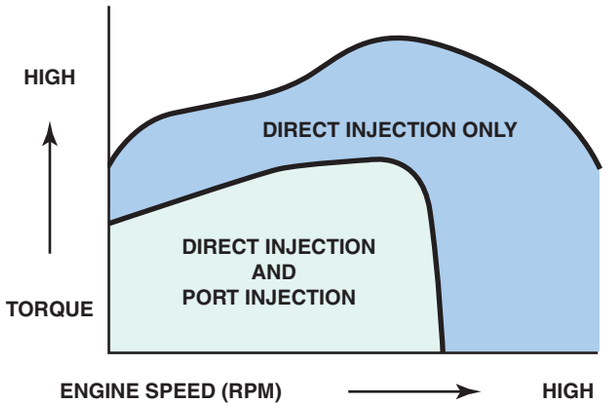

FIGURE 79–9 Notice that there are conditions when the port fuel-injector located in the intake manifold, and the gasoline direct injector, located in the cylinder both operate to provide the proper air–fuel mixture.

spark to be retarded to increase the temperature of the exhaust. As a result of the increased exhaust temperature, the catalytic converter rapidly reaches operating temperature, which reduces exhaust emissions.

ENGINE START SYSTEM

An engine equipped with gasoline direct injection could use the system to start the engine. This is most useful during idle stop mode when the engine is stopped while the vehicle is at a traffic light to save fuel. The steps used in the Mitsubishi start-stop system, called the *smart idle stop system (SISS)*, allow the engine to be started without a starter motor and include the following steps:

STEP 1 The engine is stopped. The normal stopping position of an engine when it stops is 70 degrees before top dead center, plus or minus 20 degrees. This is because the engine stops with one cylinder on the compression stroke and the PCM can determine the cylinder position, using the crankshaft and camshaft position sensors.

STEP 2 When a command is made to start the engine by the PCM, fuel is injected into the cylinder that is on the compression stroke and ignited by the spark plug.

STEP 3 The piston on the compression stroke is forced downward forcing the crankshaft to rotate counterclockwise or in the opposite direction to normal operation.

STEP 4 The rotation of the crankshaft then forces the companion cylinder toward the top of the cylinder.

STEP 5 Fuel is injected and the spark plug is fired, forcing the piston down, causing the crankshaft to rotate in the normal (clockwise) direction. Normal combustion events continue allowing the engine to keep running.

GASOLINE DIRECT-INJECTION SERVICE

NOISE ISSUES Gasoline direct injection (GDI) systems operate at high pressure and the injectors can often be heard with the engine running and the hood open. This noise can be a customer concern because the clicking sound is similar to noisy valves. If a noise issue is the customer concern, check the following:

- Check a similar vehicle to determine if the sound is louder or more noticeable than normal.
- Check that nothing under the hood is touching the fuel rail. If another line or hose is in contact with the fuel rail, the sound of the injectors clicking can be transmitted throughout the engine, making the sound more noticeable.
- Check for any technical service bulletins (TSBs) that may include new clips or sound insulators to help reduce the noise.

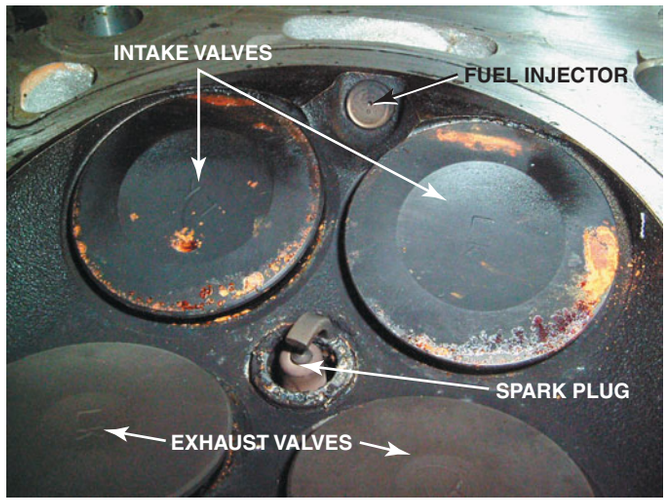

FIGURE 79–10 There may become a driveability issue because the gasoline direct-injection injector is exposed to combustion carbon and fuel residue.

CARBON ISSUES Carbon is often an issue in engines equipped with gasoline direct-injection systems. Carbon can affect engine operation by accumulating in two places:

- **On the injector itself.** Because the injector tip is in the combustion chamber, fuel residue can accumulate on the injector, reducing its ability to provide the proper spray pattern and amount of fuel. Some injector designs are more likely to be affected by carbon than others. For example, if the injector uses small holes, these tend to become clogged more often than an injector that uses a single slit opening where the fuel being sprayed out tends to blast away any carbon. ● **SEE FIGURE 79–10.**
- **The backside of the intake valve.** This is a common place for fuel residue and carbon to accumulate on engines equipped with gasoline direct injection. The accumulation of carbon on the intake valve can become so severe that the engine will start and idle, but lack power to accelerate the vehicle. The carbon deposits restrict the airflow into the cylinder enough to decrease engine power.

NOTE: Lexus engines that use both port and gasoline direct-injection injectors do not show intake valve deposits. It is thought that the fuel being sprayed onto the intake valve from the port injector helps keep the intake valve clean.

CARBON CLEANING. Most experts recommend the use of Techron®, a fuel system dispersant, to help keep carbon from accumulating. The use of a dispersant every six months or every 6,000 miles has proven to help prevent injector and intake valve deposits.

If the lack of power is discovered and there are no stored diagnostic trouble codes, a conventional carbon cleaning procedure will likely restore power if the intake valves are coated.

ELECTRONIC THROTTLE CONTROL SYSTEM

OBJECTIVES: After studying Chapter 80, the reader will be able to: • Prepare for ASE test content area "E" (Computerized Engine Controls Diagnosis and Repair). • Describe the purpose and function of an electronic throttle control (ETC) system. • Explain how an electronic throttle control system works. • List the parts of a typical electronic throttle control system. • Describe how to diagnose faults in an electronic throttle control system.

KEY TERMS: Accelerator pedal position (APP) sensor 893 • Coast-down stall 898 • Default position 894 • Drive-by-wire 893 • Electronic throttle control (ETC) 893 • Fail safe position 894 • Neutral position 894 • Servomotor 894 • Throttle position (TP) sensor 893

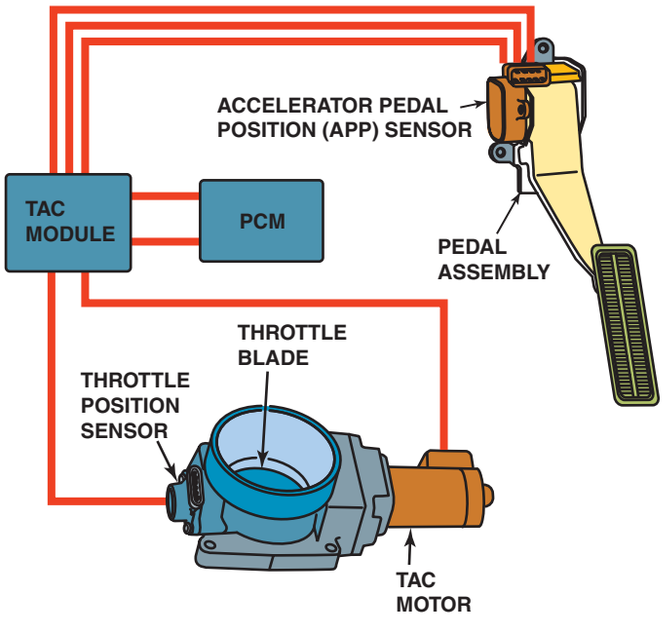

FIGURE 80–1 The throttle pedal is connected to the accelerator pedal position (APP) sensor. The electronic throttle body includes a throttle position sensor to provide throttle angle feedback to the vehicle computer. Some systems use a Throttle Actuator Control (TAC) module to operate the throttle blade (plate).

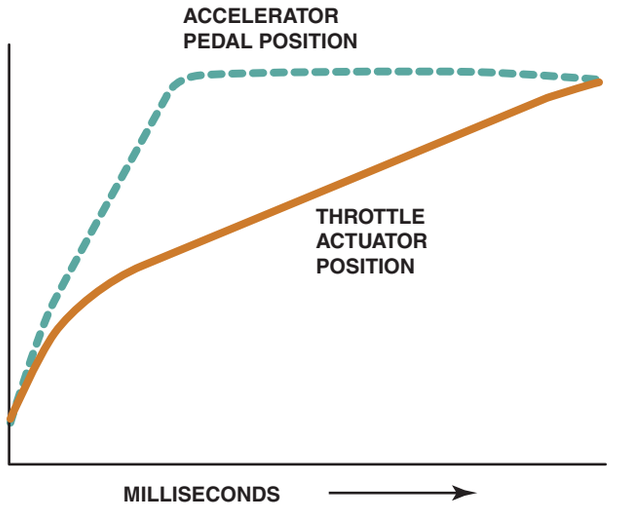

FIGURE 80–2 The opening of the throttle plate can be delayed as long as 30 milliseconds (0.030 sec.) to allow time for the amount of fuel needed to catch up to the opening of the throttle plate.

ELECTRONIC THROTTLE CONTROL (ETC) SYSTEM

ADVANTAGES OF ETC The absence of any mechanical linkage between the throttle pedal and the throttle body requires the use of an electric actuator motor. The electronic throttle system has the following advantages over the conventional cable:

- Eliminates the mechanical throttle cable, thereby reducing the number of moving parts.
- Eliminates the need for cruise control actuators and controllers.
- Helps reduce engine power for traction control (TC) and electronic stability control (ESC) systems.
- Used to delay rapid applications of torque to the transmission/transaxle to help improve driveability and to smooth shifts.
- Helps reduce pumping losses by using the electronic throttle to open at highway speeds with greater fuel economy. The electronic throttle control (ETC) opens the throttle to maintain engine and vehicle speed as the powertrain control module (PCM) leans the air–fuel ratio, retards ignition timing, and introduces additional exhaust gas recirculation (EGR) to reducing pumping losses.
- Used to provide smooth engine operation, especially during rapid acceleration.
- Eliminates the need for an idle air control valve.

The electronic throttle can be called **drive-by-wire,** but most vehicle manufacturers use the term **electronic throttle control (ETC)** to describe the system that opens the throttle valve electrically.

PARTS INVOLVED The typical ETC system includes the following components:

1. **Accelerator pedal position (APP)** sensor, also called accelerator pedal sensor (APS)
2. The electronic throttle actuator (servomotor), which is part of the electronic throttle body
3. A **throttle position (TP) sensor**
4. An electronic control unit, which is usually the powertrain control module (PCM)

● **SEE FIGURE 80–1.**

NORMAL OPERATION OF THE ETC SYSTEM

Driving a vehicle equipped with an electronic throttle control (ETC) system is about the same as driving a vehicle with a conventional mechanical throttle cable and throttle valve. However, the driver may notice some differences, which are to be considered normal. These normal conditions include:

- The engine may not increase above idle speed when depressing the accelerator pedal when the gear selector is in PARK.
- If the engine speed does increase when the accelerator is depressed with the transmission in PARK or NEUTRAL, the engine speed will likely be limited to less than 2000 RPM.
- While accelerating rapidly, there is often a slight delay before the engine responds. ● **SEE FIGURE 80–2.**
- While at cruise speed, the accelerator pedal may or may not cause the engine speed to increase if the accelerator pedal is moved slightly.

ACCELERATOR PEDAL POSITION SENSOR

CABLE-OPERATED SYSTEM Honda Accords until 2008 model year used a cable attached to the accelerator pedal to operate the APP sensor located under the hood. A similar arrangement

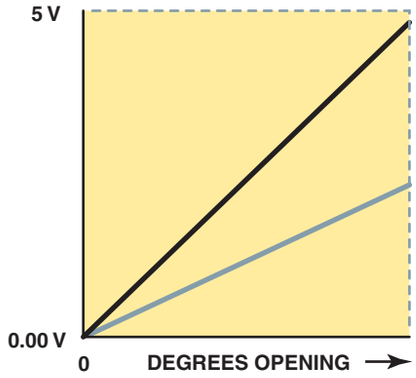

FIGURE 80–3 A typical accelerator pedal position (APP) sensor, showing two different output voltage signals that are used by the PCM to determine accelerator pedal position. Two (or three in some applications) are used as a double check because this is a safety-related sensor.

was used in Dodge RAM trucks in 2003. In both of these applications, the throttle cable was simply moving the APP sensor and not moving the throttle plate. The throttle plate is controlled by the PCM and moved by the electronic throttle control motor.

TWO SENSORS The accelerator pedal position sensor uses two and sometimes three separate sensors, which act together to give accurate accelerator pedal position information to the controller, but also are used to check that the sensor is working properly. They function just like a throttle position sensor, and two are needed for proper system function. One APP sensor output signal increases as the pedal is depressed and the other signal decreases. The controller compares the signals with a look-up table to determine the pedal position. Using two or three signals improves redundancy should one sensor fail, and allows the PCM to quickly detect a malfunction. When three sensors are used, the third signal can either decrease or increase with pedal position, but its voltage range will still be different from the other two. ● **SEE FIGURE 80–3.**

? FREQUENTLY ASKED QUESTION

What Is the "Spring Test"?

The spring test is a self-test performed by the PCM whenever the engine is started. The PCM operates the throttle to check if it can react to the command and return to the default (home) position. This self-test is used by the PCM to determine that the spring and motor are working correctly and may be noticed by some vehicle owners by the following factors:

- A slight delay in the operation of the starter motor. The PCM performs this test when the ignition switch is turned to the "on" position. While it takes just a short time to perform the test, it can be sensed by the driver that there could be a fault in the ignition switch or starter motor circuits.
- A slight "clicking" sound may also be heard coming from under the hood when the ignition is turned on. This is normal and is related to the self-test on the throttle as it opens and closes.

? FREQUENTLY ASKED QUESTION

Why Not Use a Stepper Motor for ETC?

A stepper motor is a type of motor that has multiple windings and is pulsed by a computer to rotate a certain number of degrees when pulsed. The disadvantage is that a stepper motor is too slow to react compared with a conventional DC electric motor and is the reason a stepper motor is not used in electronic throttle control systems.

THROTTLE BODY ASSEMBLY

The throttle body assembly contains the following components:

- Throttle plate
- Electric actuator DC motor
- Dual throttle position (TP) sensors
- Gears used to multiply the torque of the DC motor
- Springs used to hold the throttle plate in the default location

THROTTLE PLATE AND SPRING The throttle plate is held slightly open by a concentric clock spring. The spring applies a force that will close the throttle plate if power is lost to the actuator motor. The spring is also used to open the throttle plate slightly from the fully closed position.

ELECTRONIC THROTTLE BODY MOTOR The actuator is a DC electric motor and is often called a **servomotor.** The throttle plate is held in a **default position** by a spring inside the throttle body assembly. This partially open position, also called the **neutral position** or the **fail safe position,** is about 16% to 20% open. This default position varies depending on the vehicle and usually results in an engine speed of 1200 to 1500 RPM.

- The throttle plate is driven closed to achieve speeds lower than the default position, such as idle speed.
- The throttle plate is driven open to achieve speeds higher than the default position, such as during acceleration. ● **SEE FIGURE 80–4.**

The throttle plate motor is driven by a bidirectional pulse-width modulated (PWM) signal from the PCM or electronic throttle control module using an H-bridge circuit. ● **SEE FIGURE 80–5a, b.**

The H-bridge circuit is controlled by the powertrain control module (PCM) by:

- Reversing the polarity of power and ground brushes to the DC motor
- Pulse-width modulating (PWM) the current through the motor

The PCM monitors the position of the throttle from the two throttle position (TP) sensors. The PCM then commands the throttle plate to the desired position. ● **SEE FIGURE 80–6.**

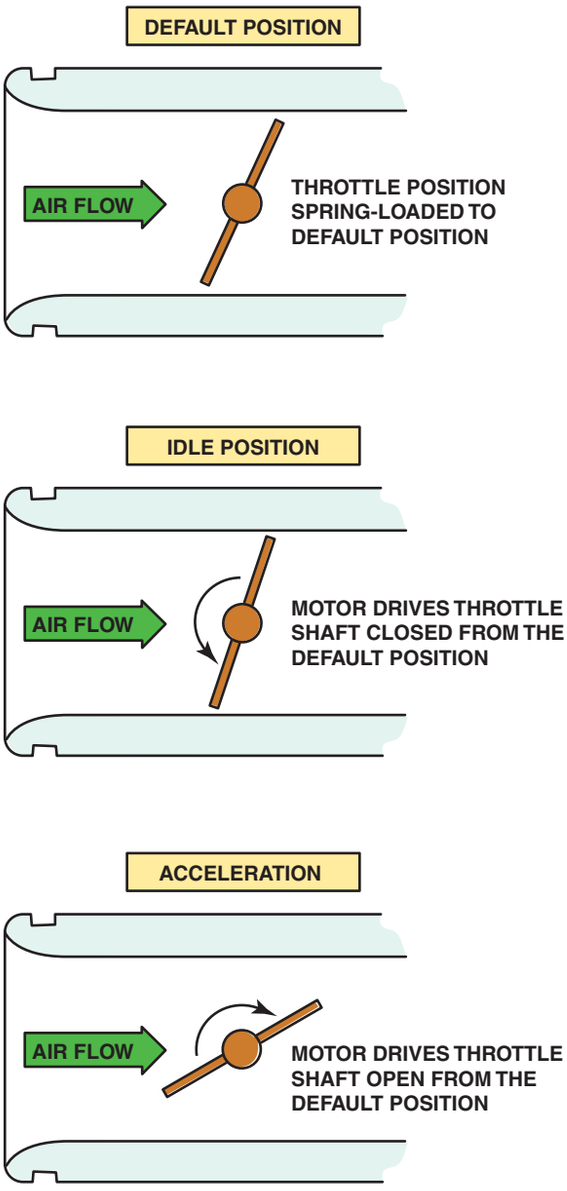

FIGURE 80–4 The default position for the throttle plate is in slightly open position. The servomotor then is used to close it for idle and open it during acceleration.

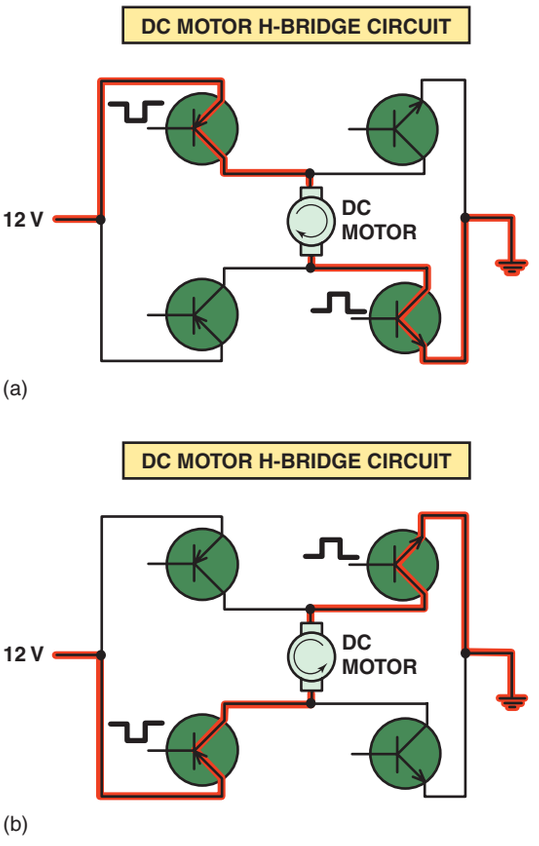

FIGURE 80–5 (a) An H-bridge circuit is used to control the direction of the DC electric motor of the electronic throttle control unit. (b) To reverse the direction of operation, the polarity of the current through the motor is reversed.

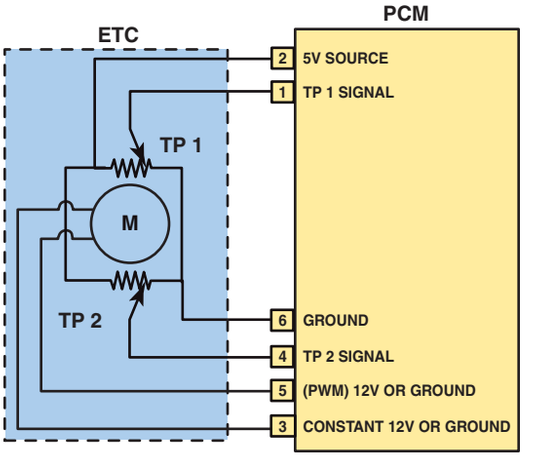

FIGURE 80–6 Schematic of a typical electronic throttle control (ETC) system. Note that terminal #5 is always pulse-width modulated and that terminal #3 is always constant, but both power and ground are switched to change the direction of the motor.

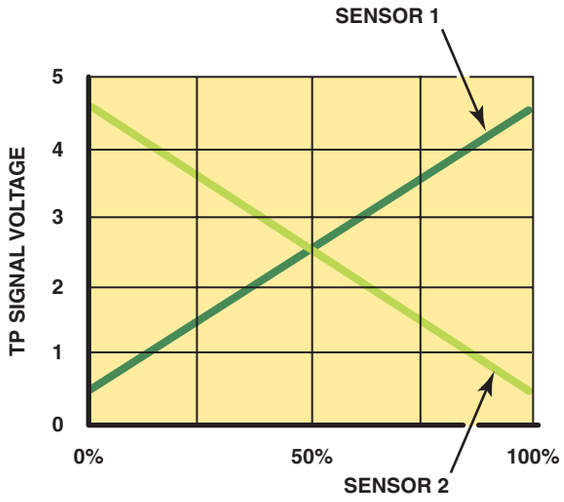
THROTTLE POSITION (TP) SENSOR

Two throttle position (TP) sensors are used in the throttle body assembly to provide throttle position signals to the PCM. Two sensors are used as a fail-safe measure and for diagnosis. There are two types of TP sensors used in electronic throttle control (ETC) systems: potentiometers and Hall-effect.

THREE-WIRE POTENTIOMETER SENSORS These sensors use a 5-volt reference from the PCM and produce an analog (variable) voltage signal that is proportional to the throttle plate position. The two sensors produce opposite signals as the throttle plate opens:

- One sensor starts at low voltage (about 0.5 V) and increases as the throttle plate is opened.
- The second sensor starts at a higher voltage (about 4.5 V) and produces a lower voltage as the throttle plate is opened. ● **SEE FIGURE 80–7.**

HALL-EFFECT TP SENSORS Some vehicle manufacturers, Honda for example, use a non-contact Hall-effect throttle position sensor. Because there is not physical contact, this type of sensor is less likely to fail due to wear.



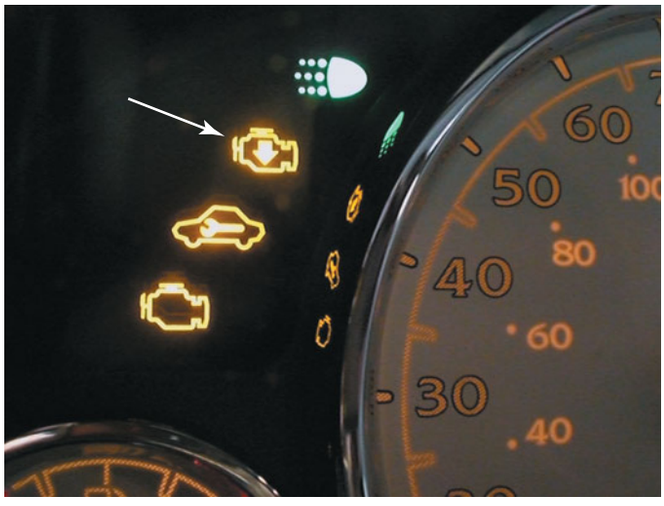


FIGURE 80–7 The two TP sensors used on the throttle body of an electronic throttle body assembly produce opposite voltage signals as the throttle is opened. The total voltage of both combined at any throttle plate position is 5 volts.

? FREQUENTLY ASKED QUESTION

How Do You Calibrate a New APP Sensor?

Whenever an accelerator pedal position (APP) sensor is replaced, it should be calibrated before it will work correctly. Always check service information for the exact procedure to follow after APP sensor replacement. Here is a typical example of the procedure:

STEP 1 Make sure accelerator pedal is fully released.
STEP 2 Turn the ignition switch on (engine off) and wait at least 2 seconds.
STEP 3 Turn the ignition switch off and wait at least 10 seconds.
STEP 4 Turn the ignition switch on (engine on) and wait at least 2 seconds.
STEP 5 Turn the ignition switch off and wait at least 10 seconds.

DIAGNOSIS OF ELECTRONIC THROTTLE CONTROL SYSTEMS

FAULT MODE Electronic throttle control (ETC) systems can have faults like any other automatic system. Due to the redundant sensors in accelerator pedal position (APP) sensors and throttle position (TP) sensor, many faults result in a *"limp home"* situation instead of a total failure. The limp home mode is also called the *"fail-safe mode"* and indicates the following actions performed by the powertrain control module (PCM).

- Engine speed is limited to the default speed (about 1200 to 1600 RPM).
- There is slow or no response when the accelerator pedal is depressed.
- The cruise control system is disabled.
- A diagnostic trouble code (DTC) is set.
- An ETC warning lamp on the dash will light. The warning lamp may be labeled differently, depending on the vehicle manufacturer. For example:
  - General Motors vehicle–Reduced power lamp (● **SEE FIGURE 80–8**)
  - Ford–Wrench symbol (amber or green) (● **SEE FIGURE 80–9**)
  - Chrysler–Red lightning bolt symbol (● **SEE FIGURE 80–10**)
- The engine will run and can be driven slowly. This limp-in mode operation allows the vehicle to be driven off of the road and to a safe location.

The ETC may enter the limp-in mode if any of the following has occurred:

- Low battery voltage has been detected
- PCM failure
- One TP and the MAP sensor have failed
- Both TP sensors have failed
- The ETC actuator motor has failed
- The ETC throttle spring has failed

REAL WORLD FIX

The High Idle Toyota

The owner of a Toyota Camry complained that the engine would idle at over 1200 RPM compared with a normal 600 to 700 RPM. The vehicle would also not accelerate. Using a scan tool, a check for diagnostic trouble codes showed one code: P2101–"TAC motor circuit low."

Checking service information led to the inspection of the electronic throttle control throttle body assembly. With the ignition key out of the ignition and the inlet air duct off the throttle body, the technician used a screwdriver to push gently to see if the throttle plate worked.

Normal operation–The throttle plate should move and then spring back quickly to the default position.

Abnormal operation–If the throttle plate stays where it is moved or does not return to the default position, there is a fault with the throttle body assembly.

● **SEE FIGURE 80–11.**

Solution: The technician replaced the throttle body assembly with an updated version and proper engine operation was restored. The technician disassembled the old throttle body and found it was corroded inside due to moisture entering the unit through the vent hose.

● **SEE FIGURE 80–12.**

VACUUM LEAKS The electronic throttle control (ETC) system is able to compensate for many vacuum leaks. A vacuum leak at the intake manifold for example will allow air into the engine that is not measured by the mass airflow sensor. The ETC system will simply move the throttle as needed to achieve the proper idle speed to compensate for the leak.

DIAGNOSTIC PROCEDURE If a fault occurs in the ETC system, check service information for the specified procedure to follow for the vehicle being checked. Most vehicle service information includes the following steps:

STEP 1 Verify the customer concern.

STEP 2 Use a factory scan tool or an aftermarket scan tool with original equipment capability and check for diagnostic trouble codes (DTCs).

STEP 3 If there are stored diagnostic trouble codes, follow service information instructions for diagnosing the system.

STEP 4 If there are no stored diagnostic trouble codes, check scan tool data for possible fault areas in the system.

SCAN TOOL DATA Scan data related to the electronic throttle control system can be confusing. Typical data and the meaning include:

- **APP indicated angle.** The scan tool will display a percentage ranging from 0% to 100%. When the throttle is released, the indicated angle should be 0%. When the throttle is depressed to wide open, the reading should indicate 100%.
- **TP desired angle.** The scan tool will display a percentage ranging from 0% to 100%. This represents the desired throttle angle as commanded by the driver of the vehicle.
- **TP indicated angle.** The TP indicated angle is the angle of the measured throttle opening and it should agree with the TP desired angle.
- **TP sensors 1 and 2.** The scan tool will display "agree" or "disagree." If the PCM or throttle actuator control (TAC) module receives a voltage signal from one of the TP sensors that is not in the proper relationship to the other TP sensor, the scan tool will display disagree.

ETC THROTTLE FOLLOWER TEST

On some vehicles, such as many Chrysler vehicles, the operation of the electronic throttle control can be tested using a factory or factory-level scan tool. To perform this test, use the "throttle follower test" procedure as shown on the scan tool. An assistant is needed to check that the throttle plate is moving as the accelerator pedal is depressed. This test cannot be done normally because the PCM does not normally allow the throttle plate to be moved unless the engine is running.

SERVICING ELECTRONIC THROTTLE SYSTEMS

ETC-RELATED PERFORMANCE ISSUES The only service that an electronic throttle control system may require is a cleaning of the throttle body. Throttle body cleaning is a routine service procedure on port fuel-injected engines and is still needed when the throttle is being opened by an electric motor rather than a throttle cable tied to a mechanical accelerator pedal. The throttle body may need cleaning if one or more of the following symptoms are present:

- Lower than normal idle speed
- Rough idle
- Engine stalls when coming to a stop (called a **coast-down stall**)

If any of the above conditions exists, a throttle body cleaning will often correct these faults.

CAUTION: Some vehicle manufacturers add a nonstick coating to the throttle assembly and warn that cleaning could remove this protective coating. Always follow the vehicle manufacturer's recommended procedures.

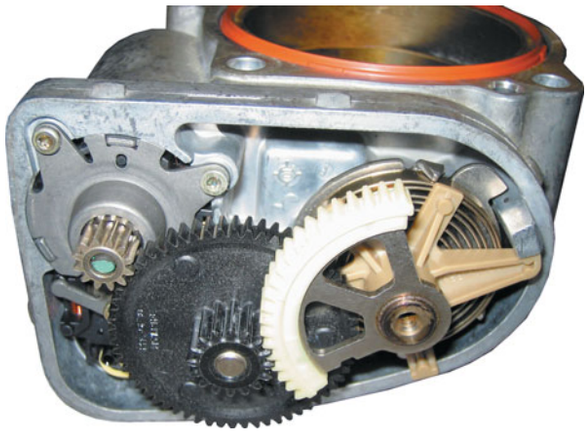

FIGURE 80–13 Notice the small motor gear on the left drives a larger plastic gear (black), which then drives the small gear in mesh with the section of a gear attached to the throttle plate. This results in a huge torque increase from the small motor and helps explain why it could be dangerous to insert a finger into the throttle body assembly.

THROTTLE BODY CLEANING PROCEDURE Before attempting to clean a throttle body on an engine equipped with an electronic throttle control system, be sure that the ignition key is out of the vehicle and the ready light is off if working on a Toyota/Lexus hybrid electric vehicle to avoid the possibility of personal injury.

WARNING

The electric motor that operates the throttle plate is strong enough to cut off a finger. ● **SEE FIGURE 80–13.**

To clean the throttle, perform the following steps:

STEP 1 With the ignition off and the key removed from the ignition, remove the air inlet hose from the throttle body.

STEP 2 Spray throttle body cleaner onto a shop cloth.

STEP 3 Open the throttle body and use the shop cloth to remove the varnish and carbon deposits from the throttle body housing and throttle plate.

CAUTION: Do not spray cleaner into the throttle body assembly. The liquid cleaner could flow into and damage the throttle position (TP) sensors.

STEP 4 Reinstall the inlet hose being sure that there are no air leaks between the hose and the throttle body assembly.

STEP 5 Start the engine and allow the PCM to learn the correct idle. If the idle is not correct, check service information for the specified procedures to follow to perform a throttle relearn.

THROTTLE BODY RELEARN PROCEDURE When installing a new throttle body or powertrain control module (PCM) or sometimes after cleaning the throttle body, the throttle position has to be learned by the PCM. After the following conditions have been met, a typical throttle body relearn procedure for a General Motors vehicle includes:

- Accelerator pedal released
- Battery voltage higher than 8 volts

- Vehicle speed must be zero
- Engine coolant temperature (ECT) higher than 40°F (5°C) and lower than 212°F (100°C)
- Intake air temperature (IAT) higher than 40°F (5°C)
- No throttle diagnostic trouble codes set

If all of the above conditions are met, perform the following steps:

STEP 1 Turn the ignition on (engine off) for 30 seconds.

STEP 2 Turn the ignition off and wait 30 seconds.

Start the engine and the idle learn procedure should cause the engine to idle at the correct speed.

FUEL-INJECTION SYSTEM DIAGNOSIS AND SERVICE

OBJECTIVES: **After studying Chapter 81, the reader will be able to:** • Prepare for ASE Engine Performance (A8) certification test content area "C" (Fuel, Air Induction, and Exhaust Systems Diagnosis and Repair). • Explain how to test the fuel injection system using a scan tool. • Explain how to check a fuel-pressure regulator. • Describe how to test fuel injectors. • Explain how to diagnose electronic fuel-injection problems. • Describe how to service the fuel-injection system.

KEY TERMS: Graphing multimeter (GMM) 900 • IAC counts 902 • Idle air control (IAC) 908 • Noid light 903 • Peak-and-hold injector 908 • Pressure transducer 900 • Saturation 907

PORT FUEL-INJECTION PRESSURE REGULATOR DIAGNOSIS

Most port-fuel-injected engines use a vacuum hose connected to the fuel-pressure regulator. At idle, the pressure inside the intake manifold is low (high vacuum). Manifold vacuum is applied above the diaphragm inside the fuel-pressure regulator. This reduces the pressure exerted on the diaphragm and results in a lower, about 10 PSI (69 kPa), fuel pressure applied to the injectors. To test a vacuum-controlled fuel-pressure regulator, follow these steps:

1. Connect a fuel-pressure gauge to monitor the fuel pressure.
2. Locate the fuel-pressure regulator and disconnect the vacuum hose from the regulator.

   NOTE: If gasoline drips out of the vacuum hose when removed from the fuel-pressure regulator, the regulator is defective and will require replacement.

3. With the engine running at idle speed, reconnect the vacuum hose to the fuel-pressure regulator while watching the fuel-pressure gauge. The fuel pressure should drop (about 10 PSI or 69 kPa) when the hose is reattached to the regulator.
4. Using a hand-operated vacuum pump, apply vacuum (20 in. Hg) to the regulator. The regulator should hold vacuum. If the vacuum drops, replace the fuel-pressure regulator. ● **SEE FIGURE 81–1.**

NOTE: Some vehicles do not use a vacuum-regulated fuel-pressure regulator. Many of these vehicles use a regulator located inside the fuel tank that supplies a constant fuel pressure to the fuel injectors.

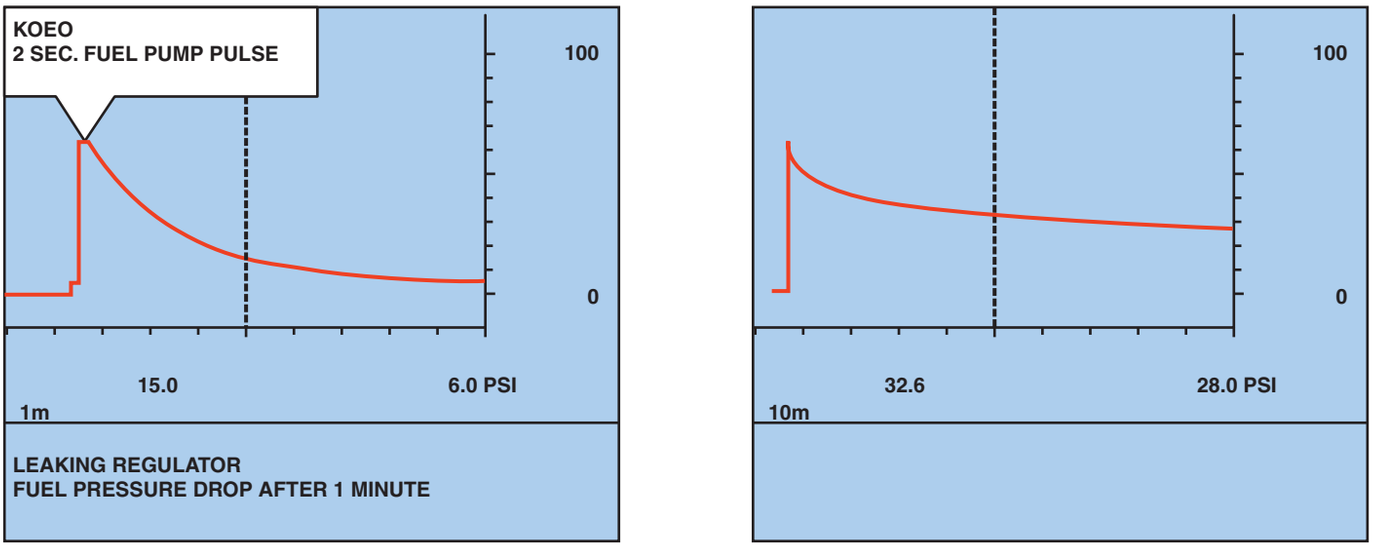

FIGURE 81–1 If the vacuum hose is removed from the fuel-pressure regulator when the engine is running, the fuel pressure should increase. If it does not increase, then the fuel pump is not capable of supplying adequate pressure or the fuel-pressure regulator is defective. If gasoline is visible in the vacuum hose, the regulator is leaking and should be replaced.

Pressure Transducer Fuel Pressure Test

Using a **pressure transducer** and a **graphing multimeter (GMM)** or digital storage oscilloscope (DSO) allows the service technician to view the fuel pressure over time. ● **SEE FIGURE 81–2(a).** Note that the fuel pressure dropped from 15 PSI down to 6 PSI on a TBI-equipped vehicle after just one minute. A normal pressure holding capability is shown in ● **FIGURE 81–2(b)** when the pressure dropped only about 10% after 10 minutes on a port-fuel injection system.

FIGURE 81–2 (a) A fuel-pressure graph after key on, engine off (KOEO) on a TBI system. (b) Pressure drop after 10 minutes on a normal port fuel-injection system.

FIGURE 81–3 A clogged PCV system caused the engine oil fumes to be drawn into the air cleaner assembly. This is what the technician discovered during a visual inspection on this TBI system.

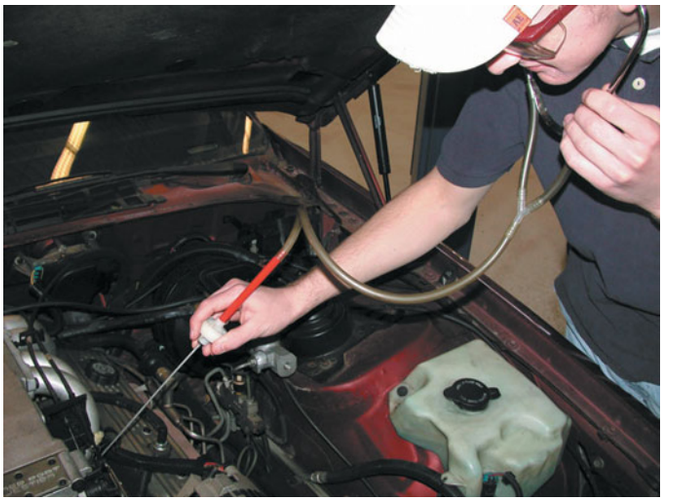

FIGURE 81–4 All fuel injectors should make the same sound with the engine running at idle speed. A lack of sound indicates a possible electrically open injector or a break in the wiring. A defective computer could also be the cause of a lack of clicking (pulsing) of the injectors.

DIAGNOSING ELECTRONIC FUEL-INJECTION PROBLEMS USING VISUAL INSPECTION

All fuel-injection systems require the proper amount of clean fuel delivered to the system at the proper pressure and the correct amount of filtered air. The following items should be carefully inspected before proceeding to more detailed tests.

- Check the air filter and replace as needed.
- Check the air induction system for obstructions.
- Check the conditions of all vacuum hoses. Replace any hose that is split, soft (mushy), or brittle.
- Check the positive crankcase ventilation (PCV) valve for proper operation or replacement as needed. ● **SEE FIGURE 81–3.**

NOTE: The use of an incorrect PCV valve can cause a rough idle or stalling.

TECH TIP

Stethoscope Fuel-Injection Test

A commonly used test for injector operation is to listen to the injector using a stethoscope with the engine operating at idle speed. ● **SEE FIGURE 81–4.** All injectors should produce the same clicking sound. If any injector makes a clunking or rattling sound, it should be tested further or replaced. With the engine still running, place the end of the stethoscope probe to the return line from the fuel-pressure regulator. ● **SEE FIGURE 81–5.** Fuel should be heard flowing back to the fuel tank if the fuel-pump pressure is higher than the fuel-regulator pressure. If no sound of fuel is heard, then either the fuel pump or the fuel-pressure regulator is at fault.

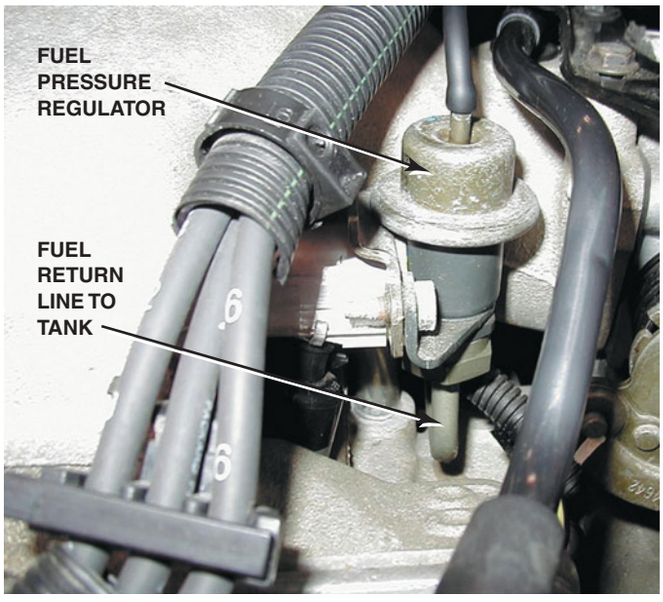

FIGURE 81–5 Fuel should be heard returning to the fuel tank at the fuel return line if the fuel-pump and fuel-pressure regulator are functioning correctly.

FIGURE 81–6 Using a scan tool to check for IAC counts or percentage as part of a diagnostic routine.

TECH TIP

Quick and Easy Leaking Injector Test

Leaking injectors may be found by disabling the ignition, unhooking all injectors, and checking exhaust for hydrocarbons (HC) using a gas analyzer while cranking the engine (maximum HC = 300 PPM). This test does not identity which injector is leaking but it does confirm that one or more injector is leaking.

TECH TIP

No Spark, No Squirt

Most electronic fuel-injection computer systems use the ignition primary (pickup coil or crank sensor) pulse as the trigger for when to inject (squirt) fuel from the injectors (nozzles). If this signal were not present, no fuel would be injected. Because this pulse is also necessary to trigger the module to create a spark from the coil, it can be said that "no spark" could also mean "no squirt." Therefore, if the cause of a no-start condition is observed to be a lack of fuel injection, do not start testing or replacing fuel-system components until the ignition system is checked for proper operation.

- Check all fuel-injection electrical connections for corrosion or damage.
- Check for gasoline at the vacuum port of the fuel-pressure regulator if the vehicle is so equipped. Gasoline in the vacuum hose at the fuel-pressure regulator indicates that the regulator is defective and requires replacement.

SCAN TOOL VACUUM LEAK DIAGNOSIS

If a vacuum (air) leak occurs on an engine equipped with a speed-density-type of fuel injection, the extra air would cause the following to occur:

- The idle speed increases due to the extra air just as if the throttle pedal was depressed.
- The MAP sensor reacts to the increased air from the vacuum leak as an additional load on the engine.
- The computer increases the injector pulse width slightly longer due to the signal from the MAP sensor.
- The air–fuel mixture remains unchanged.
- The idle air control (IAC) counts will decrease, thereby attempting to reduce the engine speed to the target idle speed stored in the computer memory. ● **SEE FIGURE 81–6.**

Therefore, one of the best indicators of a vacuum leak on a speed-density fuel-injection system is to look at the IAC counts or percentage. Normal **IAC counts** or percentage is usually 15 to 25. A reading of less than 5 indicates a vacuum leak.

If a vacuum leak occurs on an engine equipped with a mass airflow-type fuel-injection system, the extra air causes the following to occur:

- The engine will operate leaner-than-normal because the extra air has not been measured by the MAF sensor.
- The idle speed will likely be lower due to the leaner-than-normal air–fuel mixture.
- The idle air control (IAC) counts or percentage will often increase in an attempt to return the engine speed to the target speed stored in the computer.

PORT FUEL-INJECTION SYSTEM DIAGNOSIS

To determine if a port fuel-injection system—including the fuel pump, injectors, and fuel-pressure regulator–is operating correctly, take the following steps.

1. Attach a fuel-pressure gauge to the Schrader valve on the fuel rail. ● **SEE FIGURE 81–7.**

FIGURE 81–7 Checking the fuel pressure using a fuel-pressure gauge connected to the Schrader valve.

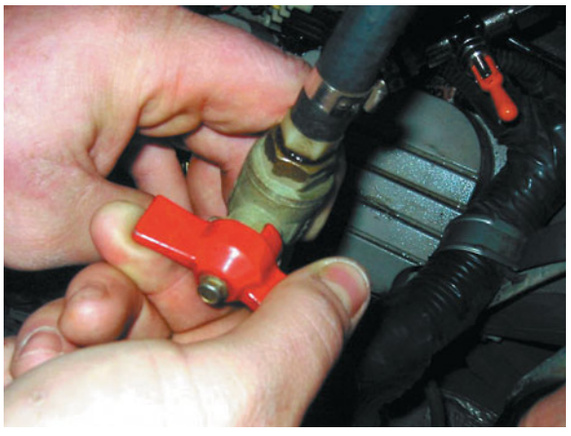

FIGURE 81–8 Shutoff valves must be used on vehicles equipped with plastic fuel lines to isolate the cause of a pressure drop in the fuel system.

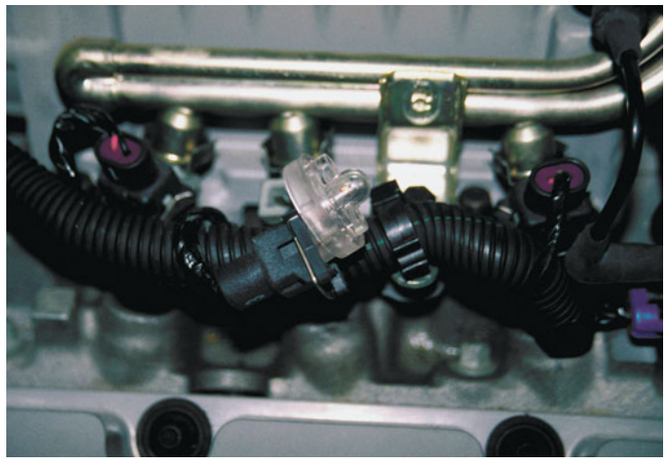

2. Turn the ignition key on or start the engine to build up the fuel-pump pressure (often about 35 to 45 PSI. Always check service information for the specified fuel pressure).
3. Wait 20 minutes and observe the fuel pressure retained in the fuel rail and note the PSI reading. The fuel pressure should not drop more than 20 PSI (140 kPa) in 20 minutes. If the drop is less than 20 PSI in 20 minutes, everything is okay; if the drop is *greater,* then there is a possible problem with:
   - The check valve in the fuel pump
   - Leaking injectors, lines, or fittings
   - A defective (leaking) fuel-pressure regulator

   To determine which unit is defective, perform the following:

- Reenergize the electric fuel pump.
- Clamp the fuel *supply* line, and wait 10 minutes (see Caution box). If the pressure drop does not occur, replace the fuel pump. If the pressure drop still occurs, continue with the next step.
- Repeat the pressure buildup of the electric pump and clamp the fuel return line. If the pressure drop time is now okay, replace the fuel-pressure regulator.
- If the pressure drop still occurs, one or more of the injectors is leaking. Remove the injectors with the fuel rail and hold over paper. Replace those injectors that drip one or more drops after 10 minutes with pressurized fuel.

(b)

FIGURE 81–9 (a) Noid lights are usually purchased as an assortment so that one is available for any type or size of injector wiring connector. (b) The connector is unplugged from the injector and a noid light is plugged into the harness side of the connector. The noid light should flash when the engine is being cranked if the power circuit and the pulsing to ground by the computer are functioning normally.

CAUTION: Do not clamp plastic fuel lines. Connect shutoff valves to the fuel system to shut off supply and return lines. ● **SEE FIGURE 81–8.**

TESTING FOR AN INJECTOR PULSE

One of the first checks that should be performed when diagnosing a no-start condition is whether the fuel injectors are being pulsed by the computer. Checking for proper pulsing of the injector is also important in diagnosing a weak or dead cylinder.

A **noid light** is designed to electrically replace the injector in the circuit and to flash if the injector circuit is working correctly. ● **SEE FIGURE 81–9.** To use a noid light, disconnect the electrical connector at the fuel injector and plug the noid light into the injector harness connections. Crank or start the engine. The noid light should flash regularly.

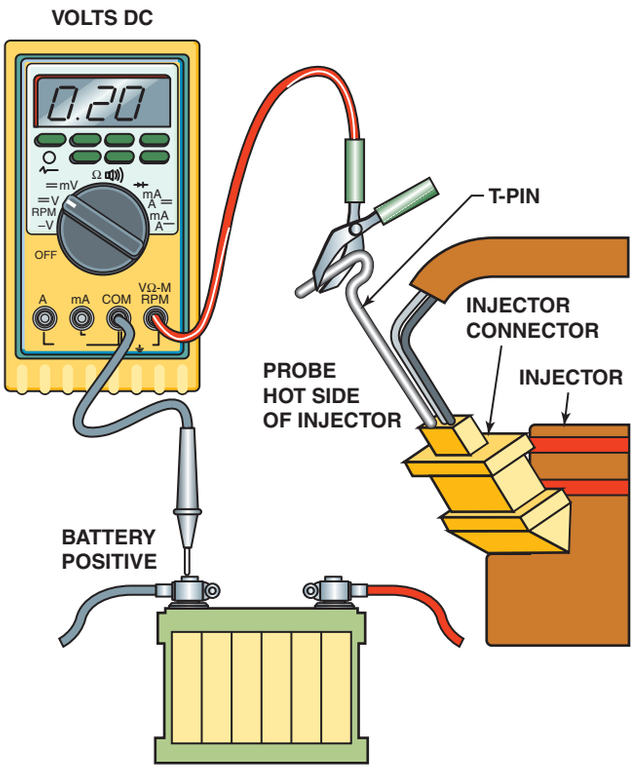

FIGURE 81–10 Use a DMM set to read DC volts to check the voltage drop of the positive circuit to the fuel injector. A reading of 0.5 volt or less is generally considered to be acceptable.

NOTE: The term *noid* is simply an abbreviation of the word *solenoid.* Injectors use a movable iron core and are therefore solenoids. Therefore, a noid light is a replacement for the solenoid (injector).

Possible noid light problems and causes include the following:

1. **The light is off and does not flash.** The problem is an open in either the power side or ground side (or both) of the injector circuit.
2. **The noid light flashes dimly.** A dim noid light indicates excessive resistance or low voltage available to the injector. Both the power and ground side must be checked.
3. **The noid light is on and does not flash.** If the noid light is on, then both a power and a ground are present. Because the light does not flash (blink) when the engine is being cranked or started, then a short-to-ground fault exists either in the computer itself or in the wiring between the injector and the computer.

CAUTION: A noid lamp must be used with caution. The computer may show a good noid light operation and have low supply voltage. ● **SEE FIGURE 81–10.**

CHECKING FUEL-INJECTOR RESISTANCE

Each port fuel injector must deliver an equal amount of fuel or the engine will idle roughly or perform poorly.

The electrical balance test involves measuring the injector coil-winding resistance. For best engine operation, all injectors should have the same electrical resistance. To measure the resistance, carefully release the locking feature of the connector and remove the connector from the injector.

	TBI High-Pressure 5.0L (1981–1985)	1.5–3.5 Ω

NOTE: Some engines require specific procedures to gain access to the injectors. Always follow the manufacturers' recommended procedures.

With an ohmmeter, measure the resistance across the injector terminals. Be sure to use the low-ohms feature of the digital ohmmeter to read in tenths (0.1) of an ohm. ● **SEE FIGURES 81–11 AND 81–12.** Check service information for the resistance specification of the injectors. Measure the resistance of all of the injectors. Replace any injector that does not fall within the resistance range of the specification. The resistance of the injectors should be measured twice—once when the engine (and injectors) are cold and once after the engine has reached normal operating temperature. If any injector resistance is not equal to specifications, make certain that the terminals of the injector are electrically sound, and perform other tests to confirm an injector problem before replacement.

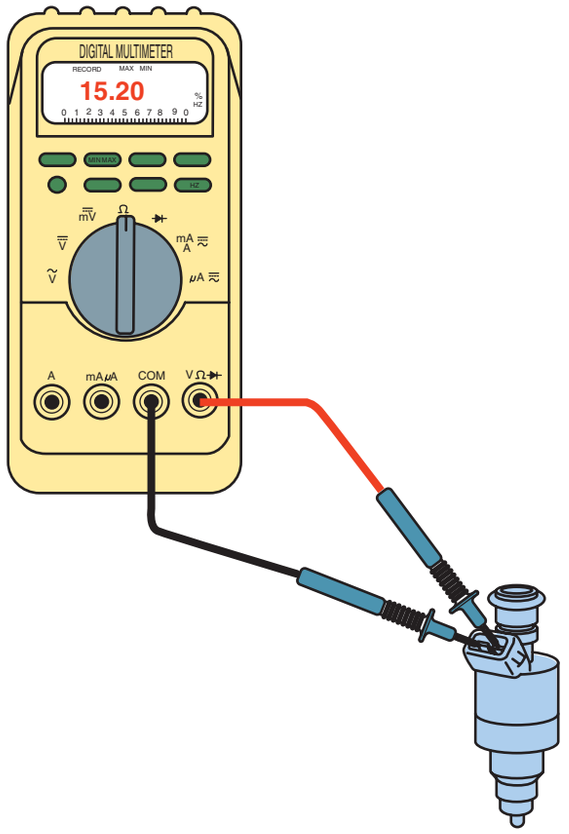

FIGURE 81–11 An ohmmeter is connected to the injector electrical terminals to read injector coil resistance.

FIGURE 81–12 To measure fuel-injector resistance, a technician constructed a short wiring harness with a double banana plug that fits into the V and COM terminals of the meter and an injector connector at the other end. This setup makes checking resistance of fuel injectors quick and easy.

MEASURING RESISTANCE OF GROUPED INJECTORS

Many vehicles are equipped with a port fuel-injection system that "fires" two or more injectors at a time. For example, a V-6 may group all three injectors on one bank to pulse on at the same time. Then the other three injectors will be pulsed on. This sequence alternates. To measure the resistance of these injectors, it is often easiest to measure each group of three that is wired in parallel. The resistance of three injectors wired in parallel is one-third of the resistance of each individual injector. For example,

Injector resistance = 12 ohms (Ω)

Three injectors in parallel = 4 ohms (Ω)

A V-6 has two groups of three injectors. Therefore, both groups should measure the same resistance. If both groups measure 4 ohms, then it is likely that all six injectors are okay. However, if one group measures only 2.9 ohms and the other group measures 4 ohms, then it is likely that one or more fuel injectors are defective (shorted). This means that the technician now has reasonable cause to remove the intake manifold to get access to each injector for further testing. ● **SEE FIGURE 81–13.**

TECH TIP

Equal Resistance Test

All fuel injectors should measure the specified resistance. However the specification often indicates the temperature of the injectors be at room temperature and of course will vary according to the temperature. Rather than waiting for all of the injectors to achieve room temperature, measure the resistance and check that they are all within 0.4 ohm of each other. To determine the difference, record the resistance of each injector and then subtract the lowest resistance reading from the highest resistance reading to get the difference. If more than 0.4 ohm then further testing will be needed to verify defective injector(s).

MEASURING RESISTANCE OF INDIVIDUAL INJECTORS

While there are many ways to check injectors, the first test is to measure the resistance of the coil inside and compare it to factory specifications. ● **SEE FIGURE 81–14.** If the injectors are not accessible, check service information for the location of the electrical connector for the injectors. Unplug the connector and measure the resistance of each injector at the injector side of the connector. Use service information to determine the wire colors for the power side and the pulse side of each injector.

PRESSURE-DROP BALANCE TEST

The pressure balance test involves using an electrical timing device to pulse the fuel injectors on for a given amount of time, usually 500 ms or 0.5 second, and observing the drop in pressure that accompanies the pulse. If the *fuel flow* through each injector is equal, the drop in pressure in the system will be equal. Most manufacturers

(b)

FIGURE 81–13 (a) The meter is connected to read one group of three 12-ohm injectors. The result should be 4 ohms and this reading is a little low indicating that at least one injector is shorted (low resistance). (b) This meter is connected to the other group of three injectors and indicates that most, if not all three, injectors are shorted. The technician replaced all six injectors and the engine ran great.

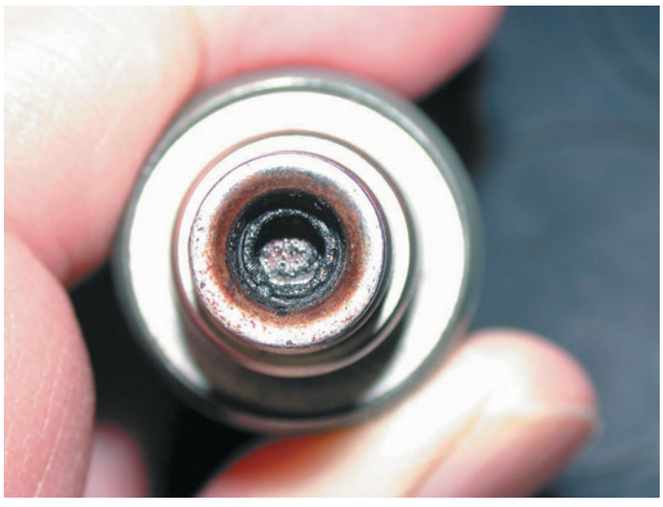

FIGURE 81–14 If an injector has the specified resistance, this does not mean that it is okay. This injector had the specified resistance yet it did not deliver the correct amount of fuel because it was clogged.

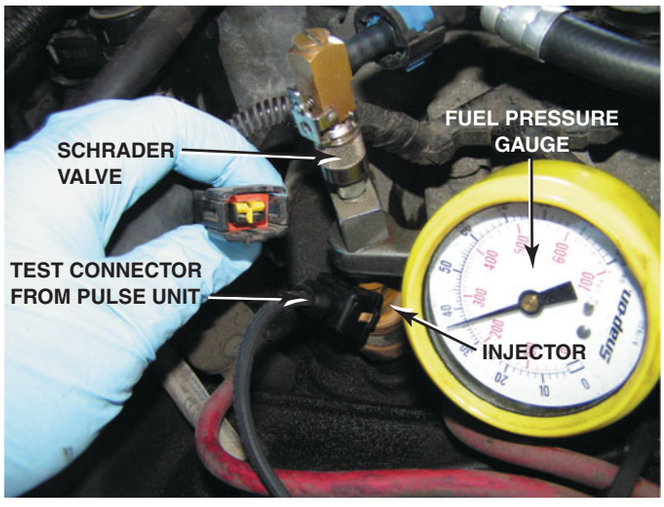

FIGURE 81–15 After connecting a pressure gauge, unplug the electrical connector from an injector and attach the test lead from the pulse unit to the injector.

recommend that the pressures be within about 1.5 PSI (10 kPa) of each other for satisfactory engine performance. This test method not only tests the electrical functioning of the injector (for definite time and current pulse), but also tests for mechanical defects that could affect fuel flow amounts.

The purpose of running this injector balance test is to determine which injector is restricted, inoperative, or delivering fuel differently than the other injectors. Replacing a complete set of injectors can be expensive. The basic tools needed are:

- Accurate pressure gauge with pressure relief
- Injector pulser with time control
- Necessary injector connection adapters
- Safe receptacle for catching and disposing of any fuel released

STEP 1 Attach the pressure gauge to the fuel delivery rail on the supply side. Make sure the connections are safe and leakproof.

STEP 2 Attach the injector pulser to the first injector to be tested.

STEP 3 Turn the ignition key to the on position to prime the fuel rail. Note the static fuel-pressure reading.

STEP 4 Activate the pulser for the timed firing pulses.

STEP 5 Note and record the new static rail pressure after the injector has been pulsed. ● **SEE FIGURE 81–15.**

STEP 6 Reenergize the fuel pump and repeat this procedure for all of the engine injectors.

STEP 7 Compare the two pressure readings and compute the pressure drop for each injector. Compare the pressure drops of the injectors to each other. Any variation in pressure drops will indicate an uneven fuel delivery rate between the injectors.

For example:

Injector	1	2	3	4	5	6
Initial pressure	40	40	40	40	40	40
Second pressure	30	30	35	30	20	30
Pressure drop	10	10	5	10	20	10
Possible problem	OK	OK	Restriction	OK	Leak	OK

FIGURE 81–16 An injector tester being used to check the voltage drop through the injector while the tester is sending current through the injectors. This test is used to check the coil inside the injector. This same tester can be used to check for equal pressure drop of each injector by pulsing the injector on for 500 ms.

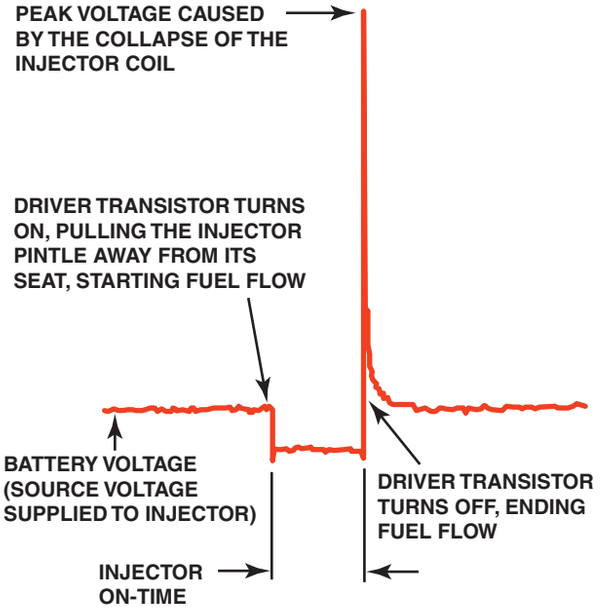

FIGURE 81–18 The injector on-time is called the pulse width. (*Courtesy of Fluke Corporation*)

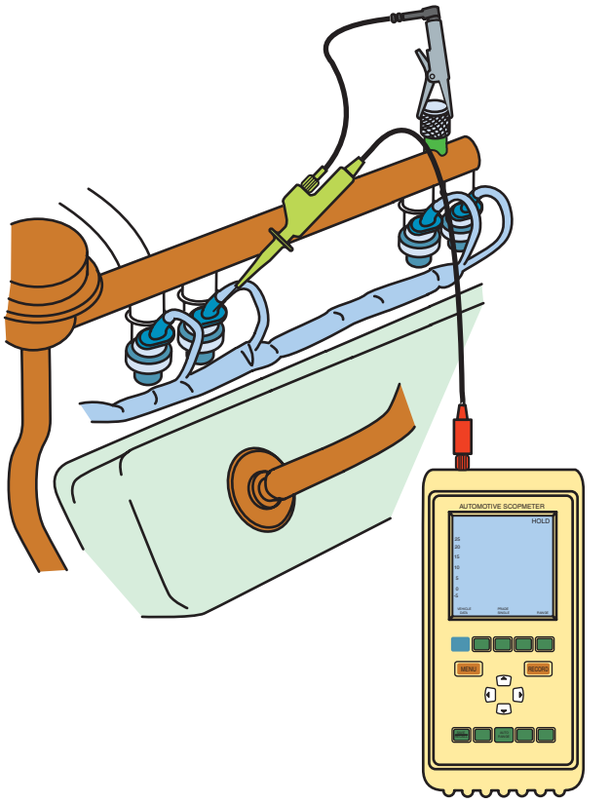

FIGURE 81–17 A digital storage oscilloscope can be easily connected to an injector by carefully back probing the electrical connector.

INJECTOR VOLTAGE-DROP TESTS

Another test of injectors involves pulsing the injector and measuring the voltage drop across the windings as current is flowing. A typical voltage-drop tester is shown in ● **FIGURE 81–16.** The tester, which is recommended for use by General Motors Corporation, pulses the injector while a digital multimeter is connected to the unit, which will display the voltage drop as the current flows through the winding.

CAUTION: Do not test an injector using a pulse-type tester more than one time without starting the engine to help avoid a hydrostatic lock caused by the flow of fuel into the cylinder during the pulse test.

Record the highest voltage drop observed on the meter display during the test. Repeat the voltage-drop test for all of the injectors. The voltage drop across each injector should be within 0.1 volt of each other. If an injector has a higher-than-normal voltage drop, the injector windings have higher-than-normal resistance.

SCOPE-TESTING FUEL INJECTORS

A scope (analog or digital storage) can be connected into each injector circuit. There are three types of injector drive circuits and each type of circuit has its own characteristic pattern. ● **SEE FIGURE 81–17** for an example of how to connect a scope to read a fuel-injector waveform.

SATURATED SWITCH TYPE In a saturated switch-type injector-driven circuit, voltage (usually a full 12 volts) is applied to the injector. The ground for the injector is provided by the vehicle computer. When the ground connection is completed, current flows through the injector windings. Due to the resistance and inductive reactance of the coil itself, it requires a fraction of a second (about 3 milliseconds or 0.003 seconds) for the coil to reach **saturation** or maximum current flow. Most saturated switch-type fuel injectors have 12 to 16 ohms of resistance. This resistance, as well as the computer switching circuit, control and limit the current flow through the injector. A voltage spike occurs when the computer shuts off (opens the injector ground-side circuit) the injectors. ● **SEE FIGURE 81–18.**

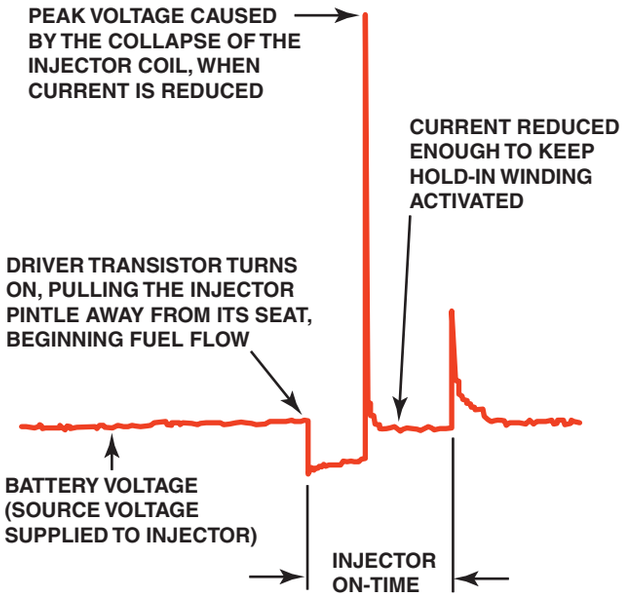

FIGURE 81–19 A typical peak-and-hold fuel-injector waveform. Most fuel injectors that measure less than 6 ohms will usually display a similar waveform.

PEAK-AND-HOLD TYPE A **peak-and-hold** type is typically used for TBI and some port low-resistance injectors. Full battery voltage is applied to the injector and the ground side is controlled through the computer. The computer provides a high initial current flow (about 4 amperes) to flow through the injector windings to open the injector core. Then the computer reduces the current to a lower level (about 1 ampere). The hold current is enough to keep the injector open, yet conserves energy and reduces the heat buildup that would occur if the full current flow remains on as long as the injector is commanded on. Typical peak-and-hold-type injector resistance ranges from 2 to 4 ohms.

The scope pattern of a typical peak-and-hold-type injector shows the initial closing of the ground circuit, then a voltage spike as the current flow is reduced. Another voltage spike occurs when the lower level current is turned off (opened) by the computer. ● **SEE FIGURE 81–19.**

PULSE-WIDTH MODULATED TYPE A pulse-width modulated type of injector drive circuit uses lower-resistance coil injectors. Battery voltage is available at the positive terminal of the injector and the computer provides a variable-duration connection to ground on the negative side of the injector. The computer can vary the time intervals that the injector is grounded for very precise fuel control.

Each time the injector circuit is turned off (ground circuit opened), a small voltage spike occurs. It is normal to see multiple voltage spikes on a scope connected to a pulse-width modulated type of fuel injector.

IDLE AIR SPEED CONTROL DIAGNOSIS

On an engine equipped with fuel injection (TBI or port injection), the idle speed is controlled by increasing or decreasing the amount of air bypassing the throttle plate. Again, an electronic stepper motor or pulse-width modulated solenoid is used to maintain the correct idle speed. This control is often called the **idle air control (IAC).** ● **SEE FIGURES 81–21 THROUGH 81–23.**

When the engine stops, most IAC units will retract outward to get ready for the next engine start. When the engine starts, the engine speed is high to provide for proper operation when the engine is cold. Then, as the engine gets warmer, the computer reduces engine idle speed gradually by reducing the number of counts or steps commanded by the IAC.

When the engine is warm and restarted, the idle speed should momentarily increase, then decrease to normal idle speed. This increase and then decrease in engine speed is often called an engine-flare. If the engine speed does not flare, then the IAC may not be working (it may be stuck in one position).

FREQUENTLY ASKED QUESTION

If Three of Six Injectors Are Defective, Should I Also Replace the Other Three?

This is a good question. Many service technicians "recommend" that the three good injectors also be replaced along with the other three that tested as being defective. The reasons given by these technicians include:

- All six injectors have been operating under the same fuel, engine, and weather conditions.
- The labor required to replace all six is just about the same as replacing only the three defective injectors.
- Replacing all six at the same time helps ensure that all of the injectors are flowing the same amount of fuel so that the engine is operating most efficiently.

With these ideas in mind, the customer should be informed and offered the choice. Complete sets of injectors such as those in ● **FIGURE 81–20** can be purchased at a reasonable cost.

FUEL-INJECTION SERVICE

After many years of fuel-injection service, some service technicians still misunderstand the process of proper fuel-system handling. Much has been said over the years with regard to when and how

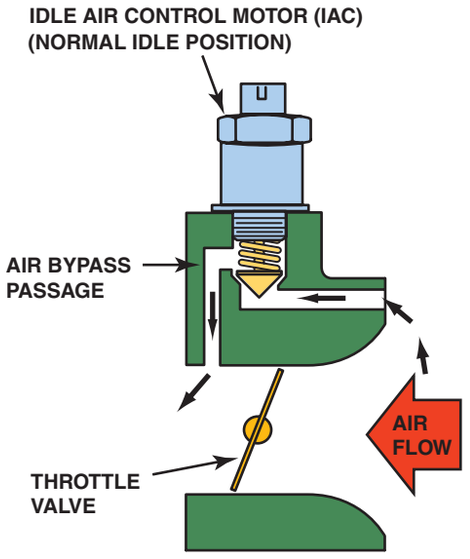

FIGURE 81–21 An IAC controls idle speed by controlling the amount of air that passes around the throttle plate. More airflow results in a higher idle speed.

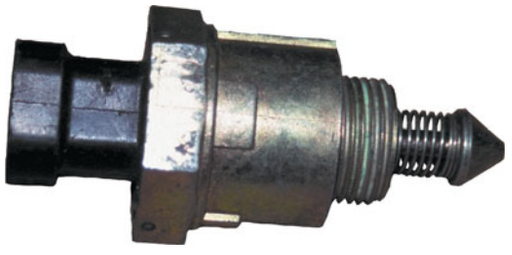

FIGURE 81–22 A typical IAC.

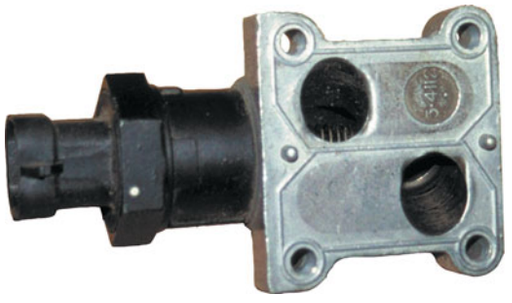

FIGURE 81–23 Some IAC units are purchased with the housing as shown. Carbon buildup in these passages can cause a rough or unstable idling or stalling.

FIGURE 81–24 (a) Nothing looks unusual when the hood is first opened. (b) When the cover is removed from the top of the engine, a mouse or some other animal nest is visible. The animal had already eaten through a couple of injector wires. At least the cause of the intermittent misfire was discovered.

REAL WORLD FIX

There Is No Substitute for a Thorough Visual Inspection

An intermittent "check engine" light and a random-misfire diagnostic trouble code (DTC) P0300 was being diagnosed. A scan tool did not provide any help because all systems seemed to be functioning normally. Finally, the technician removed the engine cover and discovered a mouse nest. ● **SEE FIGURE 81–24.**

to perform injector cleaning. Some manufacturers have suggested methods of cleaning while others have issued bulletins to prohibit any cleaning at all.

All engines using fuel injection do require some type of fuel-system maintenance. Normal wear and tear with underhood temperatures and changes in gasoline quality contribute to the buildup of olefin wax, dirt, water, and many other additives. Unique to each engine is an idle air-control design that also may contribute different levels of carbon deposits.

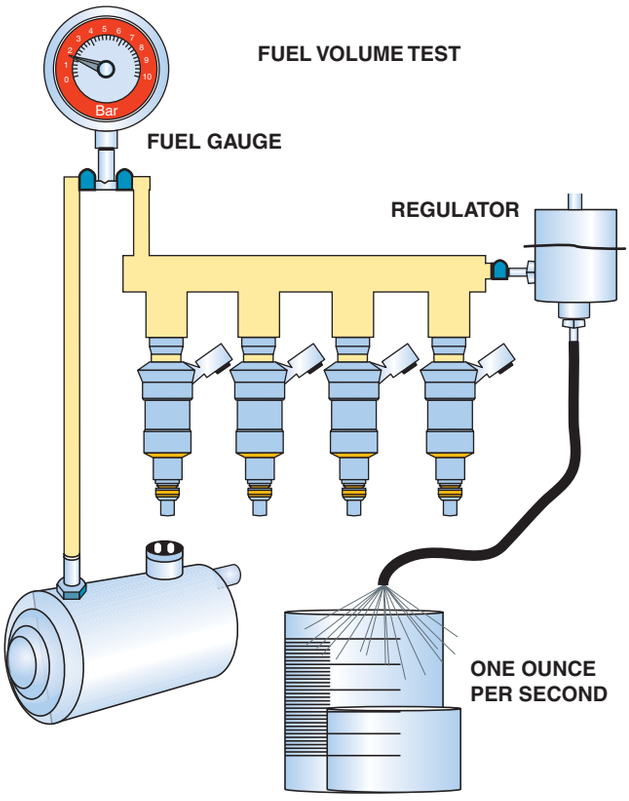

FIGURE 81–25 Checking fuel-pump volume using a hose from the outlet of the fuel-pressure regulator into a calibrated container.

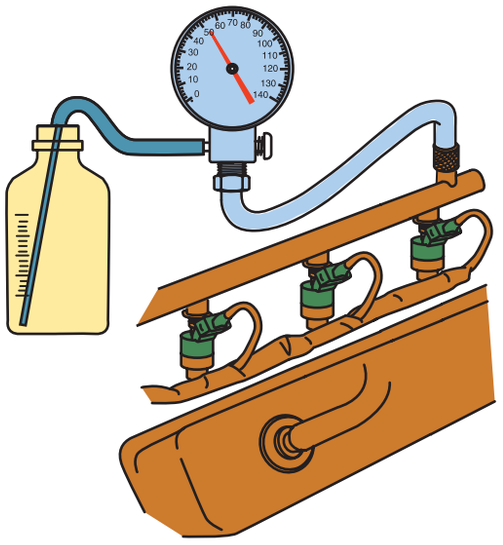

FIGURE 81–26 Testing fuel-pump volume using a fuel-pressure gauge with a bleed hose inserted into a suitable container. The engine is running during this test.

Fuel-injection system service should include the following operations:

1. **Check fuel-pump operating pressure and volume.** The missing link here is volume. Most working technicians assume that if the pressure is correct, the volume is also okay. Hook up a fuel-pressure tester to the fuel rail inlet to quickly test the fuel pressure with the engine running. At the same time, test the volume of the pump by sending fuel into the holding tank. (One ounce per second is the usual specification.) ● **SEE FIGURE 81–25.** A two-line system tester is the recommended procedure to use and is attached to the fuel inlet and the return on the fuel rail. The vehicle onboard system is looped and returns fuel to the tank.
2. **Test the fuel-pressure regulator for operation and leakage.** At this time, the fuel-pressure regulator would be tested for operational pressure and proper regulation, including leakage. Below are some points to consider:
   - Good pressure does not mean proper volume. For example, a clogged filter may test okay on pressure but the restriction may not allow proper volume under load. ● **SEE FIGURE 81–26.**
   - It is a good idea to use the vehicle's own gasoline to service the system versus a can of shop gasoline that has been sitting around for some time.
   - Pressure regulators do fail and a lot more do not properly shut off fuel, causing higher-than-normal pump wear and shorter service life.
3. **Flush the entire fuel rail and upper fuel-injector screens including the fuel-pressure regulator.** Raise the input pressure to a point above regulator setting to allow a constant flow of fuel through the inlet pressure side of the system, through the fuel rail, and out the open fuel-pressure regulator. In most cases the applied pressure is 75 to 90 PSI (517 to 620 kPa), but will be maintained by the presence of a regulator. At this point, cleaning chemical is added to the fuel at a 5:1 mixture and allowed to flow through the system for 15 to 30 minutes. ● **SEE FIGURE 81–27.** Results are best on a hot engine with the fuel supply looped and the engine not running. Below are some points to consider:
   - This flush is the fix most vehicles need first. The difference is that the deposits are removed to a remote tank and filter versus attempting to soften the deposits and blow them through the upper screens.
   - Most injectors use a 10-micron final filter screen. A 25% restriction in the upper screen would increase the injector on-time approximately 25%.
   - **Clean the fuel injectors.** Start the engine and adjust the output pressure closer to regulator pressure or lower than in the previous steps. Lower pressure will cause the pulse width to open up somewhat longer and allow the injectors to be cleaned. Slow speed (idle) position will take a longer time frame and operating temperature will be reached. Clean injectors are the objective, but the chemical should also decarbon the engine valves, pistons, and oxygen sensor.
4. **Decarbon the engine assembly.** On most vehicles, the injector spray will help the decarboning process. On others, you may need to enhance the operation with external addition of a mixture through the PCV hose, throttle plates, or idle air controls.
5. **Clean the throttle plate and idle air control passages.** Doing this service alone on most late-model engines will show a manifold vacuum increase of up to 2 in. Hg. Stop the engine and clean the areas as needed, then use a handheld fuel injector connected in parallel with the pressure hose, along with a pulser to allow cleaning of the throttle plates with the same chemical as injectors are running on. ● **SEE FIGURE 81–28.** This works well as air is drawn into IAC passages on a running engine and will clean the passages without IAC removal.
6. **Relearn the onboard computer.** Some vehicles may have been running in such a poor state of operation that the onboard computer may need to be relearned. Consult service information for the suggested relearn procedures for each particular vehicle.

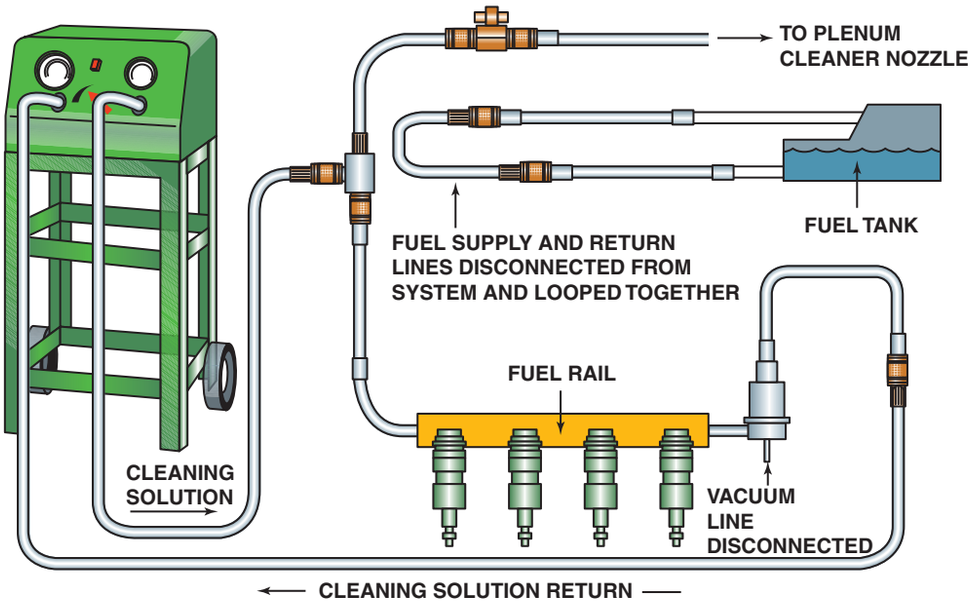

FIGURE 81–27 A typical two-line cleaning machine hookup, showing an extension hose that can be used to squirt a cleaning solution into the throttle body while the engine is running on the cleaning solution and gasoline mixture. Typical two-line cleaning machines include Carbon Clean, Auto Care, Injector Test, DeCarbon, or Motor-Vac.

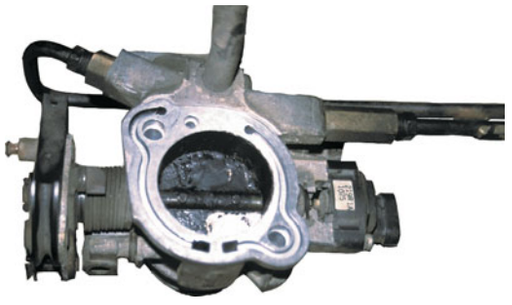

FIGURE 81–28 To thoroughly clean a throttle body, it is sometimes best to remove it from the vehicle.

TECH TIP

Check the Injectors at the "Bends and the Ends"

Injectors that are most likely to become restricted due to clogging of the filter basket screen are the injectors at the ends of the rail especially on returnless systems where dirt can accumulate. Also the injectors that are located at the bends of the fuel rail are also subject to possible clogging due to the dirt being deposited where the fuel makes a turn in the rail.

This service usually takes approximately one hour for the vehicle to run out of fuel and the entire service to be performed. The good thing is that the technician may do other services while this is being performed. Some technicians may install a set of plugs or change the fuel filter while the engine is flushing. This service should restore the fuel system to original operations.

TECH TIP

Be Sure to Clean the Fuel Rail

Whenever you service the fuel injectors, or if you suspect that there may be a fuel-injector problem, remove the entire fuel rail assembly and check the passages for contamination. Always thoroughly clean the rail when replacing fuel injectors.

Fuel-Injection Symptom Chart

Symptom	Possible Causes
Hard cold starts	• Low fuel pressure • Leaking fuel injectors • Contaminated fuel • Low-volatility fuel • Dirty throttle plate
Garage stalls	• Low fuel pressure • Insufficient fuel volume • Restricted fuel injector • Contaminated fuel • Low-volatility fuel
Poor cold performance	• Low fuel pressure • Insufficient fuel volume • Contaminated fuel • Low-volatility fuel
Tip-in hesitation (hesitation just as the accelerator pedal is depressed)	• Low fuel pressure • Insufficient fuel volume • Intake valve deposits • Contaminated fuel • Low-volatility fuel

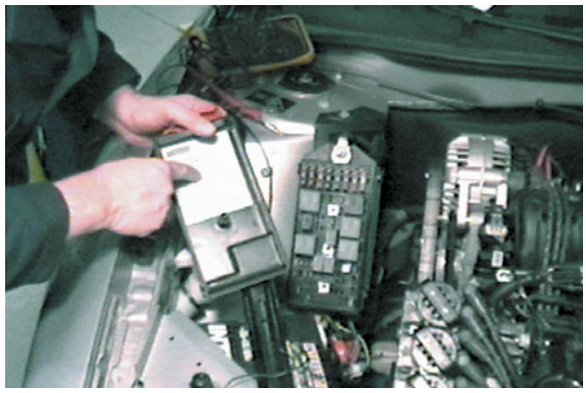
FUEL-SYSTEM SCAN TOOL DIAGNOSTICS

FUEL TRIM VALUES Diagnosing a faulty fuel system can be a difficult task. However, it can be made easier by utilizing the information available via the serial data stream. By observing the long-term fuel trim and the short-term fuel trim, we can determine how the fuel system is performing. Short-term fuel trim and long-term fuel trim can help us to zero in on specific areas of trouble. Readings should be taken at idle and at 3000 RPM. Use the following chart as a guide.

Condition	Long-Term Fuel Trim at Idle	Long-Term Fuel Trim at 3000 RPM
System normal	0% ± 10%	0% ± 10%
Vacuum leak	HIGH	OK
Fuel flow problem	OK	HIGH
Low fuel pressure	HIGH	HIGH
High fuel pressure	*OK or LOW	*OK or LOW

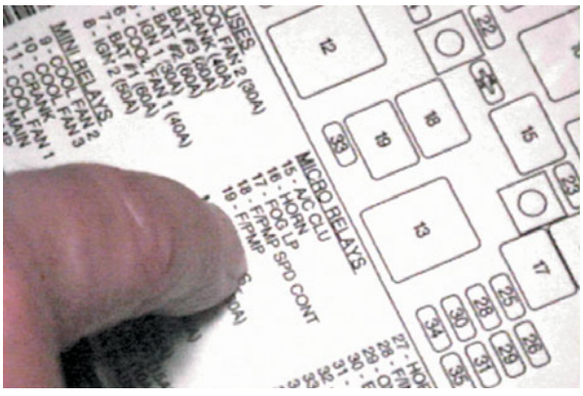
*High fuel pressure will affect trim at idle, at 3000 RPM, or both.

IAC COUNTS A scan tool can be used to check the counts or steps needed to control the idle speed. With the engine at normal operating temperature, the following IAC position as displayed on a scan tool will help with fuel system diagnosis.



Normal—Normal idle air control counts should be 25–35 counts or percentage.

Lower-than-normal—If the IAC counts or percentage is less than 5 then there could be a vacuum leak (speed density system) or false air on some mass air flow engines.



Higher-than-normal—If the counts or percentage is higher than 50, then this could be due to an excessive drag on the engine or a dirty throttle body or throttle plate.

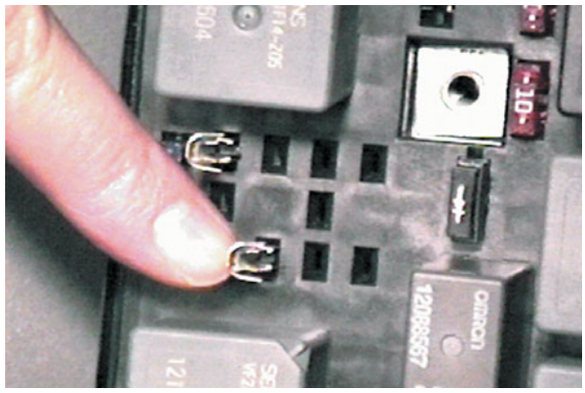
1 The tools needed to diagnose a circuit containing a relay include a digital multimeter (DMM), a fused jumper wire, and an assortment of wiring terminals.

2 Start the diagnosis by locating the relay center. It is under the hood on this General Motors vehicle, so access is easy. Not all vehicles are this easy.

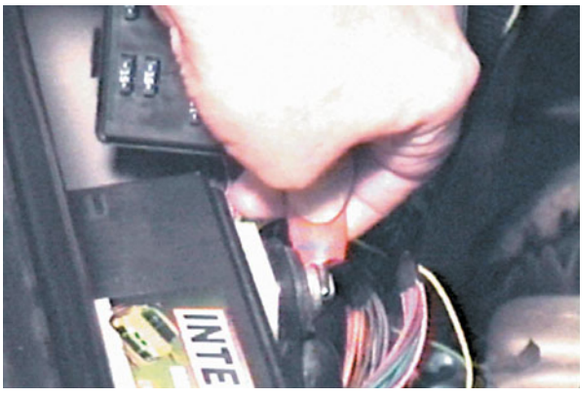
3 The chart under the cover for the relay center indicates the location of the relay that controls the electric fuel pump.

4 Locate the fuel-pump relay and remove by using a puller if necessary. Try to avoid rocking or twisting the relay to prevent causing damage to the relay terminals or the relay itself.

5 Terminals 85 and 86 represent the coil inside the relay. Terminal 30 is the power terminal, 87a is the normally closed contact, and 87 is the normally open contact.

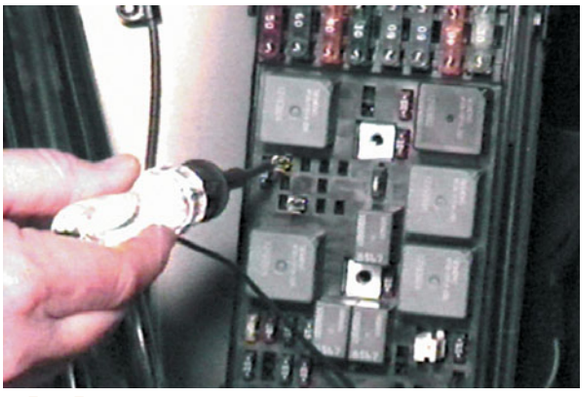


6 The terminals are also labeled on most relays.



CONTINUED ▶

7 To help make good electrical contact with the terminals without doing any harm, select the proper-size terminal from the terminal assortment.



8 Insert the terminals into the relay socket in 30 and 87.

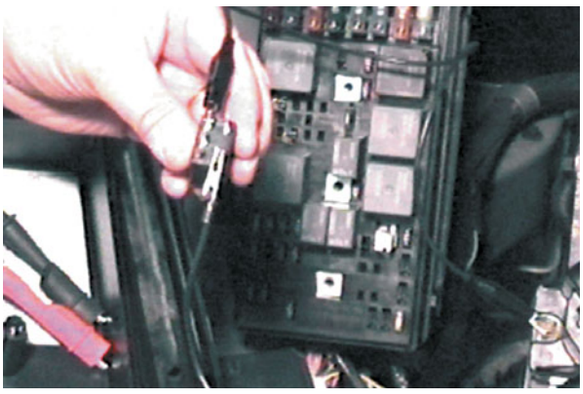
9 To check for voltage at terminal 30, use a test light or a voltmeter. Start by connecting the alligator clip of the test light to the positive (+) terminal of the battery.

10 Touch the test light to the negative (−) terminal of the battery or a good engine ground to check the test light.

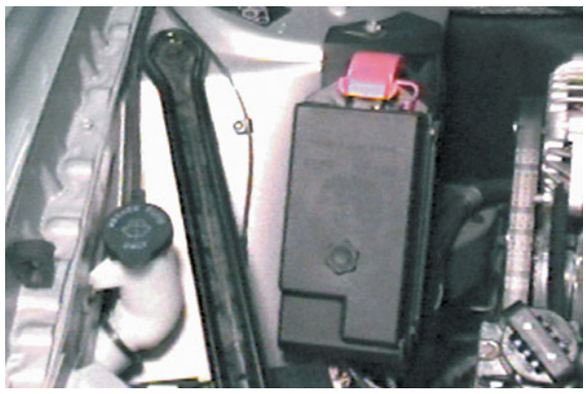
11 Connect the ground lead of the test light to a good ground and check for voltage at terminal 30 of the relay. The ignition may have to be in the on (run) position.

12 To check to see if the electric fuel pump can be operated from the relay contacts, use a fused jumper wire and touch the relay contacts that correspond to terminals 30 and 87 of the relay.

13 Connect the leads of the meter to contacts 30 and 87 of the relay socket. The reading of 4.7 amperes is okay because the specification is 4 to 8 amperes.

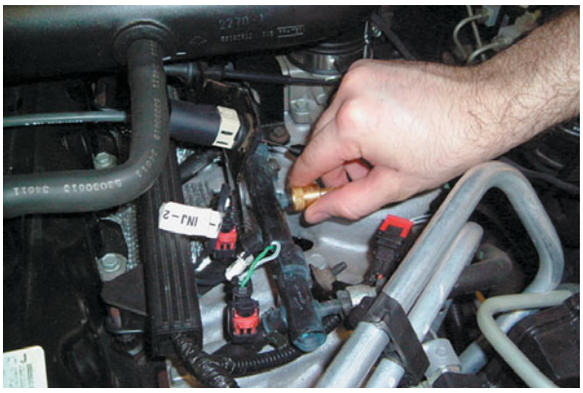


14 Set the meter to read ohms (Ω) and measure the resistance of the relay coil. The usual reading for most relays is between 60 and 100 ohms.

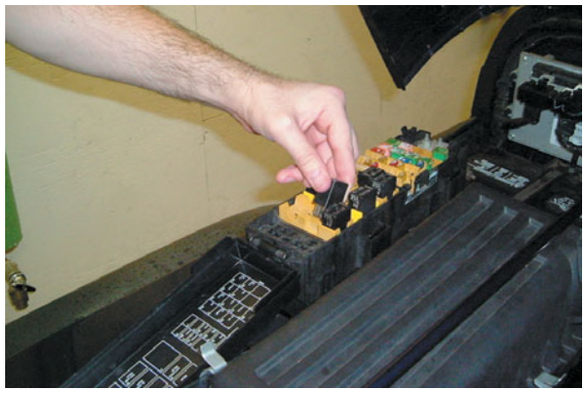


15 Measure between terminal 30 and 87a. Terminal 87a is the normally closed contact, and there should be little, if any, resistance between these two terminals, as shown.

16 To test the normally open contacts, connect one meter lead to terminal 30 and the other lead to terminal 87. The ohmmeter should show an open circuit by displaying OL.



17 Connect a fused jumper wire to supply 12 volts to terminal 86 and a ground to terminal 85 of the relay. If the relay clicks, then the relay coil is able to move the armature (movable arm) of the relay.

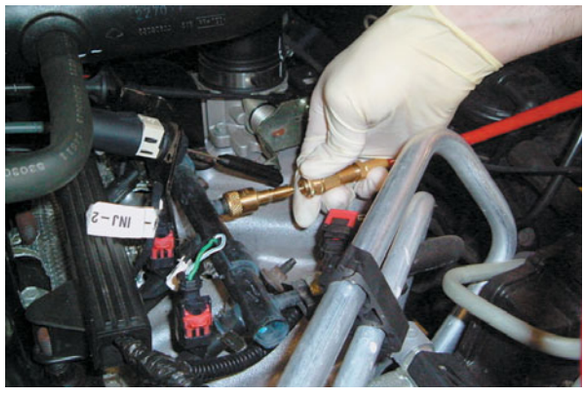


18 After testing, be sure to reinstall the relay and the relay cover.

FUEL INJECTOR CLEANING

1 Start the fuel injector cleaning process by bringing the vehicle's engine up to operating temperature. Shut off the engine, remove the cap from the fuel rail test port, and install the appropriate adapter.

2 The vehicle's fuel pump is disabled by removing its relay or fuse. In some cases, it may be necessary to disconnect the fuel pump at the tank if the relay or fuse powers more than just the pump.

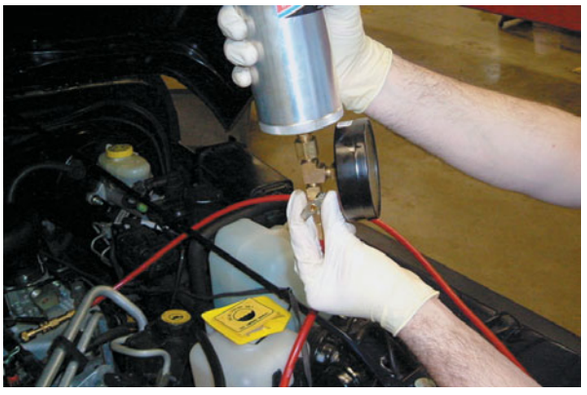


3 Turn the outlet valve of the canister to the OFF or CLOSED position.

4 Remove the fuel injector cleaning canister's top and regulator assembly. Note that there is an O-ring seal located here that must be in place for the canister's top to seal properly.

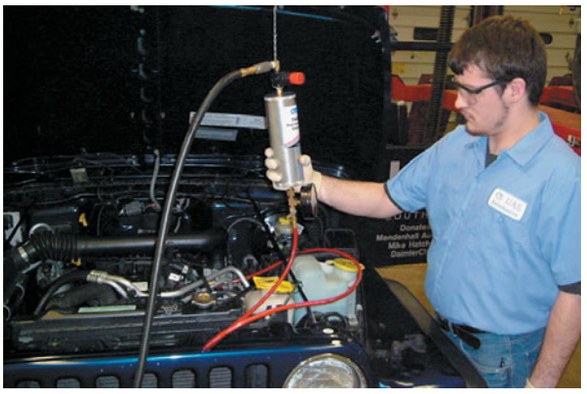
5 Pour the injection system cleaning fluid into the open canister. Rubber gloves are highly recommended for this step as the fluid is toxic.

6 Replace the canister's top (making sure it is tight) and connect its hose to the fuel rail adapter. Be sure that the hose is routed away from exhaust manifolds and other hazards.



7 Hang the canister from the vehicle's hood and adjust the air pressure regulator to full OPEN position (CCW).

8 Connect shop air to the canister and adjust the air pressure regulator to the desired setting. Canister pressure can be read directly from the gauge.



9 Canister pressure should be adjusted to 5 PSI below system fuel pressure. An alternative for return-type systems is to block the fuel return line to the tank.

10 Open the outlet valve on the canister.

11 Start the vehicle's engine and let run at 1000–1500 RPM. The engine is now running on fuel injector cleaning fluid provided by the canister.

12 Continue the process until the canister is empty and the engine stalls. Remove the cleaning equipment, enable the vehicle's fuel pump, and run the engine to check for leaks.

EMISSION STANDARDS IN THE UNITED STATES

In the United States, emissions standards are managed by the Environmental Protection Agency (EPA) as well as some U.S. state governments. Some of the strictest standards in the world are formulated in California by the California Air Resources Board (CARB).

TIER 1 AND TIER 2

Federal emission standards are set by the **Clean Air Act Amendments (CAAA)** of 1990 grouped by tier. All vehicles sold in the United States must meet Tier 1 standards that went into effect in 1994 and are the least stringent. Additional Tier 2 standards have been optional since 2001, and was fully phased in by 2009. The current Tier 1 standards are different between automobiles and light trucks (SUVs, pickup trucks, and minivans), but Tier 2 standards will be the same for both types of vehicles.

There are several ratings that can be given to vehicles, and a certain percentage of a manufacturer's vehicles must meet different levels in order for the company to sell its products in affected regions. Beyond Tier 1, and in order by stringency, are the following levels:

- **TLEV Transitional Low-Emission Vehicle.** More stringent for HC than Tier 1.
- **LEV** (also known as **LEV I): Low-Emission Vehicle.** An intermediate California standard about twice as stringent as Tier 1 for HC and NO_x.
- **ULEV** (also known as **ULEV I): Ultra-Low-Emission Vehicle.** A stronger California standard emphasizing very low HC emissions.
- **ULEV II: Ultra-Low-Emission Vehicle.** A cleaner-than-average vehicle certified under the Phase II LEV standard. Hydrocarbon and carbon monoxide emissions levels are nearly 50% lower than those of a LEV II-certified vehicle. ● **SEE FIGURE 82–1.**
- **SULEV: Super-Ultra-Low-Emission Vehicle.** A California standard even tighter than ULEV, including much lower HC and NO_x emissions; roughly equivalent to Tier 2 Bin 2 vehicles.
- **ZEV: Zero-Emission Vehicle.** A California standard prohibiting any tailpipe emissions. The ZEV category is largely restricted to electric vehicles and hydrogen-fueled vehicles. In these cases, any emissions that are created are produced at another site, such as a power plant or hydrogen reforming center, unless such sites run on renewable energy.

NOTE: A battery-powered electric vehicle charged from the power grid will still be up to 10 times cleaner than even the cleanest gasoline vehicles over their respective lifetimes.

- **PZEV: Partial Zero-Emission Vehicle.** Compliant with the SULEV standard; additionally has near-zero evaporative emissions and a 15-year/150,000-mile warranty on its emission control equipment.

Tier 2 standards are even more stringent. Tier 2 variations are appended with "II," such as LEV II or SULEV II. Other categories have also been created:

- **ILEV: Inherently Low-Emission Vehicle.** A vehicle certified to meet the transitional low-emission vehicle standards established by the California Air Resources Board (CARB)
- **AT-PZEV: Advanced Technology Partial Zero-Emission Vehicle.** If a vehicle meets the PZEV standards and is using high-technology features, such as an electric motor or high-pressure gaseous fuel tanks for compressed natural gas, it qualifies as an AT-PZEV. Hybrid electric vehicles such as the Toyota Prius can qualify, as can internal combustion engine vehicles that run on natural gas (CNG), such as the Honda Civic GX. These vehicles are classified as "partial" ZEV because they receive partial credit for the number of ZEV vehicles that automakers would otherwise be required to sell in California.
- **NLEV: National Low-Emission Vehicle.** All vehicles nationwide must meet this standard, which started in 2001.

FEDERAL EPA BIN NUMBER

The higher the tier number, the newer the regulation; the lower the bin number, the cleaner the vehicle. The Toyota Prius is a very clean Bin 3, while the Hummer H2 is a dirty Bin 11. ● **SEE CHARTS 82–1, 82–2, AND 82–3.**

SMOG EMISSION INFORMATION

New vehicles are equipped with a sticker that shows the relative level of smog-causing emissions created by the vehicle compared to others on the market. Smog-causing emissions include unburned hydrocarbons (HC) and oxides of nitrogen (NO_x). ● **SEE FIGURE 82–2.**

CALIFORNIA STANDARDS

The pre-2004 California Air Resources Board (CARB) standards as a whole were known as LEV I. Within that, there were four possible ratings: Tier 1, TLEV, LEV, and ULEV. The newest CARB rating system (since January 1, 2004) is known as LEV II. Within that rating system there are three primary ratings: LEV, ULEV, and SULEV. States other than California are given the option to use the federal EPA standards, or they can adopt California's standards.

EUROPEAN STANDARDS

Europe has its own set of standards that vehicles must meet, which includes the following tiers:

- Euro III (1999–2005)
- Euro IV (2005–2008)

Vehicle emission standards and technological advancements have successfully reduced pollution from cars and trucks by about 90% since the 1970s. Unfortunately, there currently are more vehicles on the road and they are being driven more miles each year, partially offsetting the environmental benefits of individual vehicle emissions reductions.

EXHAUST ANALYSIS TESTING

The Clean Air Act Amendments require enhanced Inspection and Maintenance (I/M) programs in areas of the country that have the worst air quality and the Northeast Ozone Transport region. The states must submit to the EPA a **State Implementation Plan (SIP)** for their programs. Each enhanced I/M program is required to include as a minimum the following items:

- Computerized emission analyzers
- Visual inspection of emission control items
- Minimum waiver limit (to be increased based on the inflation index)

FIGURE 82–3 Photo of a sign taken at an emissions test facility.

- Remote on-road testing of one-half of 1% of the vehicle population
- Registration denial for vehicles not passing an I/M test
- Denial of waiver for vehicles that are under warranty or that have been tampered with
- Annual inspections
- OBD-II systems check for 1996 and newer vehicles

FEDERAL TEST PROCEDURE (FTP) The **Federal Test Procedure (FTP)** is the test used to certify all new vehicles before they can be sold. Once a vehicle meets these standards, it is certified by the EPA for sale in the United States. The FTP test procedure is a loaded-mode test lasting for a total duration of 505 seconds and is designed to simulate an urban driving trip. A cold start-up representing a morning start and a hot start after a soak period is part of the test. In addition to this drive cycle, a vehicle must undergo evaporative testing. Evaporative emissions are determined using the **Sealed Housing for Evaporative Determination (SHED)** test, which measures the evaporative emissions from the vehicle after a heat-up period representing a vehicle sitting in the sun. In addition, the vehicle is driven and then tested during the hot soak period.

NOTE: A SHED is constructed entirely of stainless steel. The walls, floors, and ceiling, plus the door, are all constructed of stainless steel because it does not absorb hydrocarbons, which could offset test results.

The FTP is a much more stringent test of vehicle emissions than is any test type that uses equipment that measures percentages of exhaust gases. The federal emission standards for each model year vehicle are the same for that model regardless of what size engine the vehicle is equipped with. This is why larger V-8 engines often are equipped with more emission control devices than smaller four- and six-cylinder engines.

I/M TEST PROGRAMS There are a variety of I/M testing programs that have been implemented by the various states. These programs may be centralized testing programs or decentralized testing programs. Each state is free to develop a testing program suitable to their needs as long as they can demonstrate to the EPA that their plan will achieve the attainment levels set by the EPA. This approach has led to a variety of different testing programs. ● **SEE FIGURE 82–3.**

FIGURE 82–4 A vehicle being tested during an enhanced emission test.

VISUAL TAMPERING CHECKS Visual tampering checks may be part of an I/M testing program and usually include checking for the following items:

- Catalytic converter
- Fuel tank inlet restrictor
- Exhaust gas recirculation (EGR)
- Evaporative emission system
- Air-injection reaction system (AIR)
- Positive crankcase ventilation (PCV)

If any of these systems are missing, not connected, or tampered with, the vehicle will fail the emissions test and will have to be repaired/replaced by the vehicle owner before the vehicle can pass the emission test. Any cost associated with repairing or replacing these components may not be used toward the waiver amount required for the vehicle to receive a waiver.

ONE-SPEED AND TWO-SPEED IDLE TEST The one-speed and two-speed idle test measures the exhaust emissions from the tailpipe of the vehicle at idle and/or at 2500 RPM. This uses stand-alone exhaust gas sampling equipment that measures the emissions in percentages. Each state chooses the standards that the vehicle has to meet in order to pass the test. The advantage to using this type of testing is that the equipment is relatively cheap and allows states to have decentralized testing programs because many facilities can afford the necessary equipment required to perform this test.

LOADED MODE TEST The loaded mode test uses a dynamometer that places a "single weight" load on the vehicle. The load applied to the vehicle varies with the speed of the vehicle. Typically, a four-cylinder vehicle speed would be 24 mph, a six-cylinder vehicle speed would be 30 mph, and an eight-cylinder vehicle speed would be 34 mph. Conventional stand-alone sampling equipment is used to measure HC and CO emissions. This type of test is classified as a Basic I/M test by the EPA. ● **SEE FIGURE 82–4.**

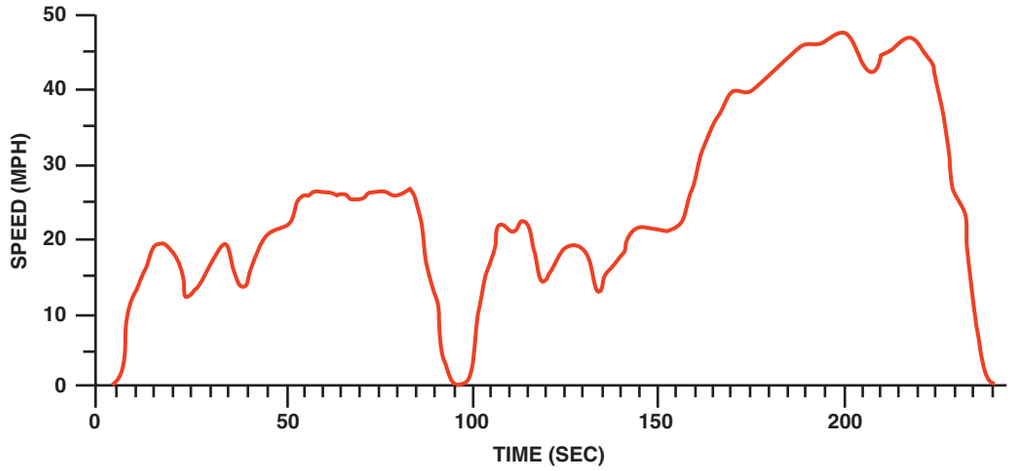

FIGURE 82–5 Trace showing the Inspection/Maintenance 240 test. The test duplicates an urban test loop around Los Angeles, California. The first "hump" in the curve represents the vehicle being accelerated to about 20 mph, then driving up a small hill to about 30 mph and coming to a stop at 94 seconds. Then, the vehicle accelerates while climbing a hill and speeding up to about 50 mph during this second phase of the test.

ACCELERATION SIMULATION MODE (ASM) The **ASM-type** of test uses a dynamometer that applies a heavy load on the vehicle at a steady-state speed. The load applied to the vehicle is based on the acceleration rate on the second simulated hill of the FTP. This acceleration rate is 3.3 mph/sec/sec (read as 3.3 mph per second per second, which is the unit of acceleration). There are different ASM tests used by different states.

The **ASM 50/15** test places a load of 50% on the vehicle at a steady 15 mph. This load represents 50% of the horsepower required to simulate the FTP acceleration rate of 3.3 mph/sec. This type of test produces relatively high levels of NO_x emissions; therefore, it is useful in detecting vehicles that are emitting excessive NO_x.

The **ASM 25/25** test places a 25% load on the vehicle while it is driven at a steady 25 mph. This represents 25% of the load required to simulate the FTP acceleration rate of 3.3 mph/sec. Because this applies a smaller load on the vehicle at a higher speed, it will produce a higher level of HC and CO emissions than the ASM 50/15. NO_x emissions will tend to be lower with this type of test.

I/M 240 TEST The **I/M 240** test is the EPA's enhanced test. It is actually a portion of the 505-second FTP test used by the manufacturers to certify their new vehicles. The "240" stands for 240 seconds of drive time on a dynamometer. This is a loaded-mode transient test that uses constant volume sampling equipment to measure the exhaust emissions in mass just as is done during the FTP. The I/M 240 test simulates the first two hills of the FTP drive cycle. ● **FIGURE 82–5** shows the I/M 240 drive trace.

OBD-II TESTING In 1999, the EPA requested that states adopt OBD-II systems testing for 1996 and newer vehicles. The OBD-II system is designed to illuminate the MIL light and store trouble codes any time a malfunction exists that would cause the vehicle emissions to exceed 1 1/2 times the FTP limits. If the OBD-II system is working correctly, the system should be able to detect a vehicle failure that would cause emissions to increase to an unacceptable level. The EPA has determined that the OBD-II system should detect emission failures of a vehicle even before that vehicle would fail an emissions test of the type that most states are employing. Furthermore, the EPA has determined that, as the population of OBD-II-equipped vehicles increases and the population of older non-OBD-II-equipped vehicles decreases, tailpipe testing will no longer be necessary.

The OBD-II testing program consists of a computer that can scan the vehicle OBD-II system using the DLC connector. The technician first performs a visual check of the vehicle MIL light to determine if it is working correctly. Next, the computer is connected to the vehicle's DLC connector. The computer will scan the vehicle OBD-II system and determine if there are any codes stored that are commanding the MIL light on. In addition, it will scan the status of the readiness monitors and determine if they have all run and passed. If the readiness monitors have all run and passed, it indicates that the OBD-II system has tested all the components of the emission control system. An OBD-II vehicle would fail this OBD-II test if:

- The MIL light does not come on with the key on, engine off
- The MIL is commanded on
- A number (varies by state) of the readiness monitors have not been run

If none of these conditions are present, the vehicle will pass the emissions test.

REMOTE SENSING The EPA requires that, in high-enhanced areas, states perform on-the-road testing of vehicle emissions. The state must sample 0.5% of the vehicle population base in high-enhanced areas. This may be accomplished by using a remote sensing device. This type of sensing may be done through equipment that projects an infrared light through the exhaust stream of a passing vehicle. The reflected beam can then be analyzed to determine the pollutant levels coming from the vehicle. If a vehicle fails this type of test, the vehicle owner will receive notification in the mail that he or she must take the vehicle to a test facility to have the emissions tested.

RANDOM ROADSIDE TESTING Some states may implement random roadside testing that would usually involve visual checks of the emission control devices to detect tampering. Obviously, this method is not very popular as it can lead to traffic tie-ups and delays on the part of commuters.

Exhaust analysis is an excellent tool to use for the diagnosis of engine performance concerns. In areas of the country that require

FIGURE 82–6 A partial stream sampling exhaust probe being used to measure exhaust gases in parts per million (PPM) or percent (%).

exhaust testing to be able to get license plates, exhaust analysis must be able to:

- Establish a baseline for failure diagnosis and service.
- Identify areas of engine performance that are and are not functioning correctly.
- Determine that the service and repair of the vehicle have been accomplished and are complete.

EXHAUST ANALYSIS AND COMBUSTION EFFICIENCY

A popular method of engine analysis, as well as emission testing, involves the use of five-gas exhaust analysis equipment. ● **SEE FIGURE 82–6.** The five gases analyzed and their significance include:

HYDROCARBONS Hydrocarbons (HC) are unburned gasoline and are measured in parts per million (ppm). A correctly operating engine should burn (oxidize) almost all the gasoline; therefore, very little unburned gasoline should be present in the exhaust. Acceptable levels of HC are 50 PPM or less. High levels of HC could be due to excessive oil consumption caused by weak piston rings or worn valve guides. The most common cause of excessive HC emissions is a fault in the ignition system. Items that should be checked include:

- Spark plugs
- Spark plug wires
- Distributor cap and rotor (if the vehicle is so equipped)
- Ignition timing (if possible)
- Ignition coil

CARBON MONOXIDE Carbon monoxide (CO) is unstable and will easily combine with any oxygen to form stable carbon dioxide (CO_2). The fact that CO combines with oxygen is the reason that CO is a poisonous gas (in the lungs, it combines with oxygen to form CO_2 and deprives the brain of oxygen). CO levels of a properly operating engine should be less than 0.5%. High levels of CO can be caused by clogged or restricted crankcase ventilation devices such as the PCV valve, hose(s), and tubes. Other items that might cause excessive CO include:

- Clogged air filter
- Incorrect idle speed
- Too-high fuel-pump pressure
- Any other items that can cause a rich condition

CARBON DIOXIDE (CO_2) Carbon dioxide (CO_2) is the result of oxygen in the engine combining with the carbon of the gasoline. An acceptable level of CO_2 is between 12% and 15%. A high reading indicates an efficiently operating engine. If the CO_2 level is low, the mixture may be either too rich or too lean.

OXYGEN The next gas is oxygen (O_2). There is about 21% oxygen in the atmosphere, and most of this oxygen should be "used up" during the combustion process to oxidize all the hydrogen and carbon (hydrocarbons) in the gasoline. Levels of O_2 should be very low (about 0.5%). High levels of O_2, especially at idle, could be due to an exhaust system leak.

NOTE: Adding 10% alcohol to gasoline provides additional oxygen to the fuel and will result in lower levels of CO and higher levels of O_2 in the exhaust.

OXIDES OF NITROGEN (NO_X) An oxide of nitrogen (NO) is a colorless, tasteless, and odorless gas when it leaves the engine, but as soon as it reaches the atmosphere and mixes with more oxygen,

? FREQUENTLY ASKED QUESTION

What Does NMHC Mean?

NMHC means **non-methane hydrocarbon** and it is the standard by which exhaust emission testing for hydrocarbons is evaluated. Methane is natural gas and can come from animals, animal waste, and other natural sources. By not measuring methane gas, all background sources are eliminated, giving better results as to the true amount of unburned hydrocarbons that are present in the exhaust stream.

? FREQUENTLY ASKED QUESTION

How Can My Worn-Out, Old, High-Mileage Vehicle Pass an Exhaust Emission Test?

Age and mileage of a vehicle are generally not factors when it comes to passing an exhaust emission test. Regular maintenance is the most important factor for passing an enhanced Inspection and Maintenance (I/M) exhaust analysis test. Failure of the vehicle owner to replace broken accessory drive belts, leaking air pump tubes, defective spark plug wires, or a cracked exhaust manifold can lead to failure of other components such as the catalytic converter. Tests have shown that if the vehicle is properly cared for, even an engine that has 300,000 miles (483,000 km) can pass an exhaust emission test.

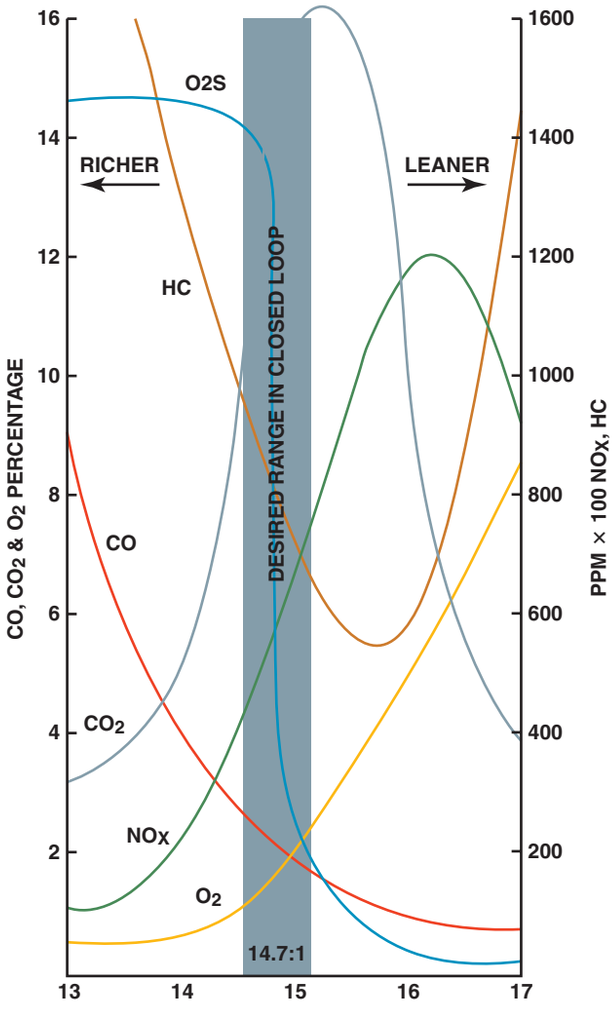

FIGURE 82–7 Exhaust emissions are very complex. When the air–fuel mixture becomes richer, some exhaust emissions are reduced, while others increase.

nitrogen oxides (NO_2) are formed. NO_2 is reddish-brown and has an acid and pungent smell. NO and NO_2 are grouped together and referred to as NO_X, where *x* represents any number of oxygen atoms. NO_X, the symbol used to represent all oxides of nitrogen, is the fifth gas commonly tested using a five-gas analyzer. The exhaust gas recirculation (EGR) system is the major controlling device limiting the formation of NO_X.

Acceptable exhaust emissions include:

	Without Catalytic Converter	With Catalytic Converter
HC	300 PPM or less	30 to 50 PPM or less
CO	3% or less	0.3% to 0.5% or less
O_2	0% to 2%	0% to 2%
CO_2	12% to 15% or higher	12% to 15% or higher
NO_X	Less than 100 PPM at idle and less than 1,000 PPM at WOT	Less than 100 PPM at idle and less than 1,000 PPM at WOT

SEE FIGURE 82–7.

TECH TIP

CO Equals O_2

If the exhaust is rich, CO emissions will be higher than normal. If the exhaust is lean, O_2 emissions will be higher than normal. Therefore, if the CO reading is the same as the O_2 reading, then the engine is operating correctly. For example, if both CO and O_2 are 0.5% and the engine develops a vacuum leak, the O_2 will rise. If a fuel-pressure regulator were to malfunction, the resulting richer air–fuel mixture would increase CO emissions. Therefore, if both the rich indicator (CO) and the lean indicator (O_2) are equal, the engine is operating correctly.

HC TOO HIGH

High hydrocarbon exhaust emissions are usually caused by an engine misfire. What burns the fuel in an engine? The ignition system ignites a spark at the spark plug to ignite the proper mixture inside the combustion chamber. If a spark plug does not ignite the mixture, the resulting unburned fuel is pushed out of the cylinder on the exhaust stroke by the piston through the exhaust valves and into the exhaust system. Therefore, if any of the following ignition components or adjustments are not correct, excessive HC emission is likely.

1. Defective or worn spark plugs
2. Defective or loose spark plug wires
3. Defective distributor cap and/or rotor
4. Incorrect ignition timing (either too far advanced or too far retarded)
5. A lean air–fuel mixture can also cause a misfire. This condition is referred to as a lean misfire. A lean air-fuel mixture can be caused by low fuel pump pressure, a clogged fuel filter or a restricted fuel injector.

NOTE: To make discussion easier in future reference to these items, this list of ignition components and check can be referred to as simply as "spark stuff."

CO TOO HIGH

Excessive carbon monoxide is an indication of too rich an air–fuel mixture. CO is the **rich indicator.** The higher the CO reading, the richer the air–fuel mixture. High concentrations of CO indicate that not enough oxygen was available for the amount of fuel. Common causes of high CO include:

- Too-high fuel-pump pressure
- Defective fuel-pressure regulator
- Clogged air filter or PCV valve

NOTE: One technician remembers "CO" as meaning "clogged oxygen" and always looks for restricted airflow into the engine whenever high CO levels are detected.

- Defective injectors

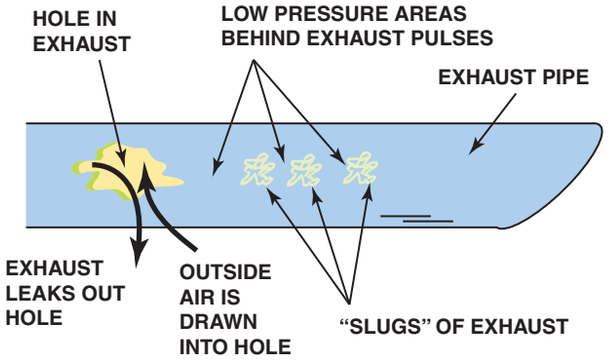

FIGURE 82–8 A hole in the exhaust system can cause outside air (containing oxygen) to be drawn into the exhaust system. This extra oxygen can be confusing to a service technician because the extra O_2 in the exhaust stream could be misinterpreted as a too-lean air–fuel mixture.

TECH TIP

How to Find a Leak in the Exhaust System

A hole in the exhaust system can dilute the exhaust gases with additional oxygen (O_2). ● **SEE FIGURE 82–8.**

This additional O_2 in the exhaust can lead the service technician to believe that the air–fuel mixture is too lean. To help identify an exhaust leak, perform an exhaust analysis at idle and at 2500 RPM (fast idle) and compare with the following:

- If the O_2 is high at idle and at 2500 RPM, the mixture is lean at both idle and at 2500 RPM.
- If the O_2 is low at idle and high at 2500 RPM, this usually means that the vehicle is equipped with a working AIR pump.
- If the O_2 is high at idle, but okay at 2500 RPM, a hole in the exhaust or a small vacuum leak that is "covered up" at higher speed is indicated.

MEASURING OXYGEN (O_2) AND CARBON DIOXIDE (CO_2)

Two gas exhaust analyzers (HC and CO) work well, but both HC and CO are consumed (converted) inside the catalytic converter. The amount of leftover oxygen coming out of the tailpipe is an indication of leanness. The higher the O_2 level, the leaner the exhaust. Oxygen therefore is the **lean indicator.** Acceptable levels of O_2 are 0% to 2%.

NOTE: A hole in the exhaust system can draw outside air (oxygen) into the exhaust system. Therefore, to be assured of an accurate reading, carefully check the exhaust system for leaks. Using a smoke machine is an easy method to locate leaks in the exhaust system.

Carbon dioxide (CO_2) is a measure of efficiency. The higher the level of CO_2 in the exhaust stream, the more efficiently the engine is operating. Levels of 12% to 15% are considered to be acceptable.

TECH TIP

Your Nose Knows

Using the nose, a technician can often identify a major problem without having to connect the vehicle to an exhaust analyzer. For example,

- The strong smell of exhaust is due to excessive unburned hydrocarbon (HC) emissions. Look for an ignition system fault that could prevent the proper burning of the fuel. A vacuum leak could also cause a lean misfire and cause excessive HC exhaust emissions.
- If your eyes start to burn or water, suspect excessive oxides of nitrogen (NO_x) emissions. The oxides of nitrogen combine with the moisture in the eyes to form a mild solution of nitric acid. The acid formation causes the eyes to burn and water. Excessive NO_x exhaust emissions can be caused by:
  - A vacuum leak causing higher-than-normal combustion chamber temperatures
  - Overadvanced ignition timing causing higher-than-normal combustion chamber temperatures
  - Lack of proper amount of exhaust gas recirculation (EGR) (This is usually noticed above idle on most vehicles.)
- Dizzy feeling or headache. This is commonly caused by excessive carbon monoxide (CO) exhaust emissions. Get into fresh air as soon as possible. A probable cause of high levels of CO is an excessively rich air–fuel mixture.

Because CO_2 levels peak at an air–fuel mixture of 14.7:1, a lower level of CO_2 indicates either a too-rich or a too-lean condition. The CO_2 measurement by itself does not indicate which condition is present. For example:

CO_2 = 8% (This means efficiency is low and the air–fuel mixture is not correct.)

Look at O_2 and CO levels.

A high O_2 indicates lean and a high CO indicates rich.

PHOTOCHEMICAL SMOG FORMATION

Oxides of nitrogen are formed by high temperature—over 2500°F (1370°C)—and/or pressures inside the combustion chamber. Oxides of nitrogen contribute to the formation of photochemical **smog** when sunlight reacts chemically with NO_x and unburned hydrocarbons (HC). Smog is a term derived by combining the words *smoke* and *fog*. Ground-level ozone is a constituent of smog. **Ozone** is an enriched oxygen molecule with three atoms of oxygen (O_3) instead of the normal two atoms of oxygen (O_2).

Ozone in the upper atmosphere is beneficial because it blocks out harmful ultraviolet rays that contribute to skin cancer. However, at ground level, this ozone (smog) is an irritant to the respiratory system.

TECH TIP

Check for Dog Food?

A commonly experienced problem in many parts of the country involves squirrels or other animals placing dog food into the air intake ducts of vehicles. Dog food is often found packed tight in the ducts against the air filter. An air intake restriction reduces engine power and vehicle performance.

REAL WORLD FIX

The Case of the Retarded Exhaust Camshaft

A Toyota equipped with a double overhead camshaft (DOHC) inline six-cylinder engine failed the state-mandated enhanced exhaust emission test for NO_x. The engine ran perfectly without spark knocking (ping), which is usually a major reason for excessive NO_x emissions. The technician checked the following:

- The ignition timing, which was found to be set to specifications (if too far advanced, can cause excessive NO_x)
- The cylinders, which were decarbonized using top engine cleaner
- The EGR valve, which was inspected and the EGR passages cleaned

After all the items were completed, the vehicle was returned to the inspection station where the vehicle again failed for excessive NO_x emissions (better, but still over the maximum allowable limit).

After additional hours of troubleshooting, the technician decided to go back to basics and start over again. A check of the vehicle history with the owner indicated that the only previous work performed on the engine was a replacement timing belt over a year before. The technician discovered that the exhaust cam timing was retarded two teeth, resulting in late closing of the exhaust valve. The proper exhaust valve timing resulted in a slight amount of exhaust being retained in the cylinder. This extra exhaust was added to the amount supplied by the EGR valve and helped reduce NO_x emissions. After repositioning the timing belt, the vehicle passed the emissions test well within the limits.

REAL WORLD FIX

O2S Shows Rich, but Pulse Width Is Low

A service technician was attempting to solve a driveability problem. The computer did not indicate any diagnostic trouble codes (DTCs). A check of the oxygen sensor voltage indicated a higher-than-normal reading almost all the time. The pulse width to the port injectors was lower than normal. The lower-than-normal pulse width indicates that the computer is attempting to reduce fuel flow into the engine by decreasing the amount of on-time for all the injectors.

What could cause a rich mixture if the injectors were being commanded to deliver a lean mixture? Finally the technician shut off the engine and took a careful look at the entire fuel-injection system. Although the vacuum hose was removed from the fuel-pressure regulator, fuel was found dripping from the vacuum hose. The problem was a defective fuel-pressure regulator that allowed an uncontrolled amount of fuel to be drawn by the intake manifold vacuum into the cylinders. While the computer tried to reduce fuel by reducing the pulse width signal to the injectors, the extra fuel being drawn directly from the fuel rail caused the engine to operate with too rich an air–fuel mixture.

TESTING FOR OXIDES OF NITROGEN

Because the formation of NO_x occurs mostly under load, the most efficient method to test for NO_x is to use a portable exhaust analyzer that can be carried in the vehicle while the vehicle is being driven under a variety of conditions.

SPECIFICATIONS FOR NO_x From experience, a maximum reading of 1,000 parts per million (PPM) of NO_x under loaded driving conditions will generally mean that the vehicle will pass an enhanced I/M roller test. A reading of over 100 PPM at idle should be considered excessive.

? FREQUENTLY ASKED QUESTION

When Filling My Fuel Tank, Why Should I Stop When the Pump Clicks Off?

Every fuel tank has an upper volume chamber that allows for expansion of the fuel when hot. The volume of the chamber is between 10% and 20% of the volume of the tank. For example, if a fuel tank had a capacity of 20 gallons, the expansion chamber volume would be from 2 to 4 gallons. A hose is attached at the top of the chamber and vented to the charcoal canister. If extra fuel is forced into this expansion volume, liquid gasoline can be drawn into the charcoal canister. This liquid fuel can saturate the canister and create an overly rich air-fuel mixture when the canister purge valve is opened during normal vehicle operation. This extra-rich air-fuel mixture can cause the vehicle to fail an exhaust emissions test, reduce fuel economy, and possibly damage the catalytic converter. To avoid problems, simply add fuel to the next dime's worth after the nozzle clicks off. This will ensure that the tank is full yet not overfilled.

EVAPORATIVE EMISSION CONTROL SYSTEM

PURPOSE AND FUNCTION The purpose of the evaporative emission control system is to trap and hold gasoline vapors, also called **volatile organic compounds (VOCs).** The **evaporative control (EVAP) system** includes the charcoal canister, hoses, and valves. These vapors are routed into a charcoal canister, then into the intake airflow, where they are burned in the engine instead of being released into the atmosphere.

COMMON COMPONENTS The fuel tank filler caps used on vehicles with modern EVAP systems are a special design. Most EVAP fuel tank filler caps have a built-in pressure-vacuum relief valve. When pressure or vacuum exceeds a calibrated value, the valve opens. Once the pressure or vacuum has been relieved, the valve closes. If a sealed cap is used on an EVAP system that requires a pressure-vacuum relief design, a vacuum may develop in the fuel system, or the fuel tank may be damaged by fuel expansion or contraction. ● **SEE FIGURE 83–1.**

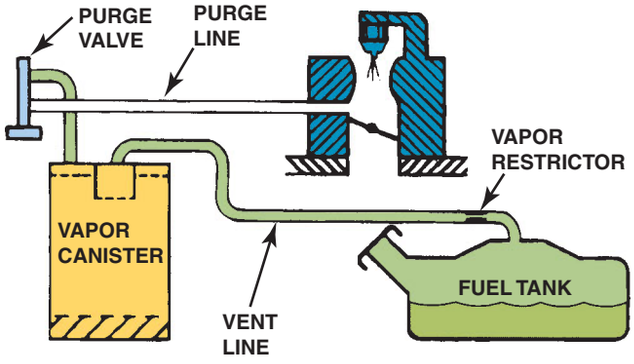

FIGURE 83–3 The EVAP system includes all of the lines, hoses, and valves, plus the charcoal canister.

EVAP SYSTEM OPERATION The canister is located under the hood or underneath the vehicle and is filled with activated charcoal granules that can hold up to one-third of their own weight in fuel vapors. ● **SEE FIGURE 83–2.**

NOTE: Some vehicles with large or dual fuel tanks may have dual canisters.

Activated charcoal is an effective vapor trap because of its great surface area. Each gram of activated charcoal has a surface area of 1,100 square meters, or more than 1/4 acre. Typical canisters hold either 300 or 625 grams of charcoal *with a surface area equivalent to 80 or 165 football fields.* By a process called **adsorption,** the fuel vapor molecules adhere to the carbon surface. This attaching force is not strong, so the system purges the vapor molecules quite simply by sending a fresh airflow through the charcoal:

- **Vapor purging.** During engine operation, stored vapors are drawn from the canister into the engine through a hose connected to the throttle body or the air cleaner. This "purging" process mixes unburned gasoline (hydrocarbons, abbreviated HCs) vapors from the canister with the existing air-fuel charge. ● **SEE FIGURES 83–3 AND 83–4.**

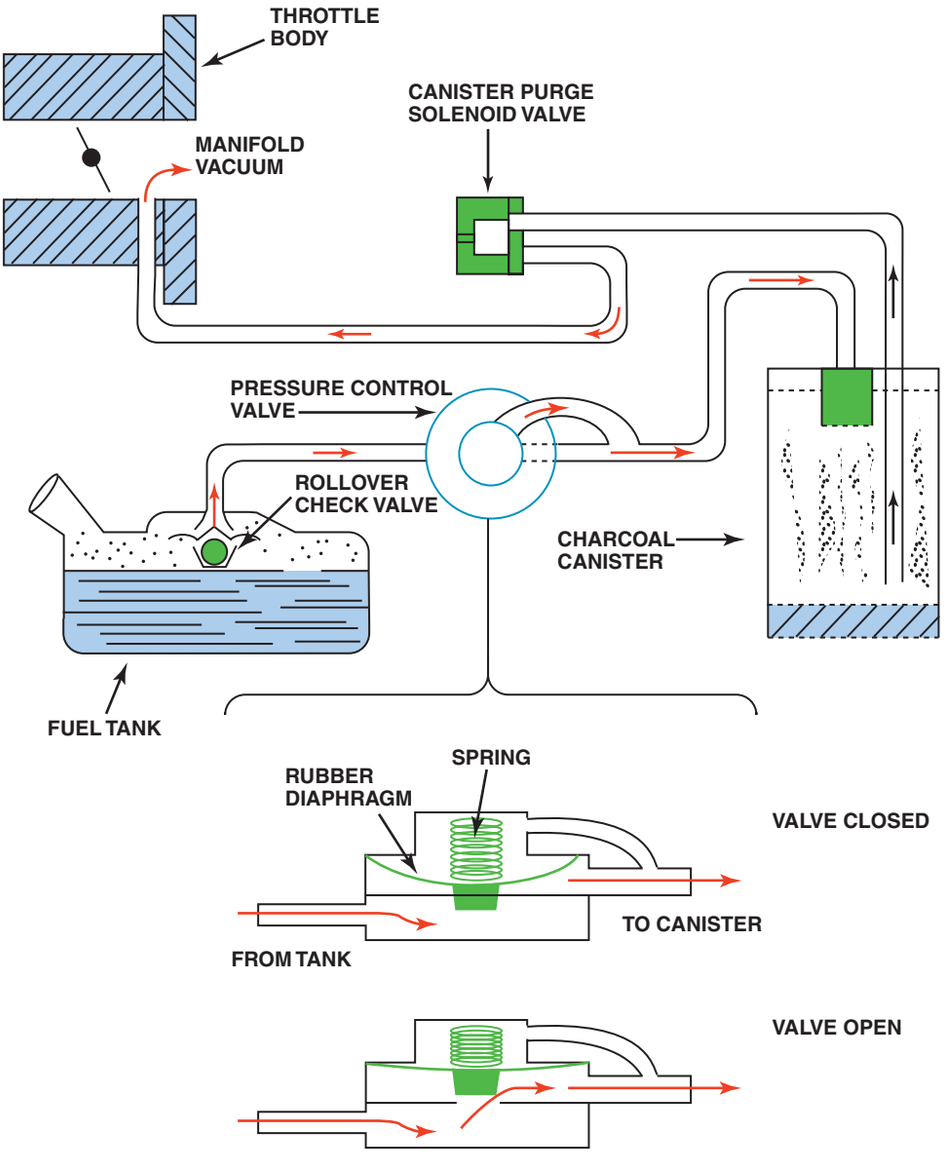

FIGURE 83–4 A typical EVAP system. Note that when the computer turns on the canister purge solenoid valve, manifold vacuum draws any stored vapors from the canister into the engine. Manifold vacuum also is applied to the pressure control valve. When this valve opens, fumes from the fuel tank are drawn into the charcoal canister and eventually into the engine. When the solenoid valve is turned off (or the engine stops and there is no manifold vacuum), the pressure control valve is spring-loaded shut to keep vapors inside the fuel tank from escaping to the atmosphere.

- **Computer-controlled purge.** The PCM controls when the canister purges on most engines. This is done by an electric vacuum solenoid and one or more purge valves. Under normal conditions, most engine control systems permit purging only during closed-loop operation at cruising speeds. During other engine operation conditions, such as open-loop mode, idle, deceleration, or wide-open throttle, the PCM prevents canister purging.

EVAPORATIVE PRESSURES

Pressures can build inside the fuel system and are usually measured in units of inches of water, abbreviated "in. H_2O" (28 in. H_2O equals 1 pound per square inch, or 1 PSI). Pressure buildup can be caused by the following:

- Fuel evaporation rates (volatility)
- Gas tank size (fuel surface area and volume)
- Fuel level (liquid versus vapor)
- Fuel slosh (driving conditions)
- Temperature (ambient, in-tank, close to the tank)
- Returned fuel from the rail

Some scan tools display other units of measure for the EVAP system that makes understanding the system difficult. ● **SEE CHART 83–1** for pressure conversions between pounds per square inch (PSI), inches of mercury (in. Hg), and inches of water (in. H_2O).

NONENHANCED EVAPORATIVE CONTROL SYSTEMS

Prior to 1996, evaporative systems were referred to as nonenhanced evaporative control (EVAP) systems. This term refers to evaporative systems that had limited diagnostic capabilities. While they are often PCM controlled, their diagnostic capability is usually limited to their ability to detect if purge has occurred. Many of these older systems

have a diagnostic switch that could sense if purge is occurring and set a code if no purge is detected. This system does not check for leaks. On some vehicles, the PCM also has the capability of monitoring the integrity of the purge solenoid and circuit. These systems' limitations are their ability to check the integrity of the evaporative system on the vehicle. They could not detect leaks or missing or loose gas caps that could lead to excessive evaporative emissions from the vehicle. Nonenhanced evaporative systems use either a canister purge solenoid or a vapor management valve to control purge vapor.

ENHANCED EVAPORATIVE CONTROL SYSTEM

BACKGROUND Beginning in 1996 with OBD-II vehicles, manufacturers were required to install systems that are able to detect both purge flow and evaporative system leakage:

- The systems on models produced between 1996 and 2000 must be able to detect a leak as small as 0.040 inches in diameter.
- Beginning in the model year 2000, the enhanced systems started a phase-in of 0.020-inch diameter leak detection.
- All vehicles built after 1995 have enhanced evaporative systems with the ability to detect purge flow and system leakage. If either of these two functions fails, the system is required to set a diagnostic trouble code (DTC) and turn on the malfunction indicator lamp (MIL) to warn the driver of the failure.
  ● **SEE FIGURE 83–5.**

VENT VALVE The canister **vent valve** is a *normally open* valve and is closed only when commanded by the PCM during testing of the system. The vent valve is closed only during testing by the PCM as part of the mandated OBD-II standards. The vent solenoid is located under the vehicle in most cases and is exposed to the environment, making this valve subject to rust and corrosion.

PURGE VALVE The canister **purge valve,** also called the *canister purge (CANP) solenoid,* is normally closed and is pulsed open by the PCM during purging. The purge valve is connected to intake manifold vacuum using a rubber hose to draw gasoline vapors from the charcoal canister into the engine when the purge valve is commanded open. Most purge valves are pulsed on and off to better control the amount of fumes being drawn into the intake manifold.

TECH TIP

Problems after Refueling? Check the Purge Valve

The purge valve is normally closed and open only when the PCM is commanding the system to purge. If the purge solenoid were to become stuck in the open position, gasoline fumes would be allowed to flow directly from the gas tank to the intake manifold. When refueling, this would result in a lot of fumes being forced into the intake manifold and as a result cause a hard-to-start condition after refueling. This would also result in a rich exhaust and likely black exhaust when first starting the engine after refueling. While the purge solenoid is usually located under the hood of most vehicles and is less subject to rust and corrosion as with the vent valve, it can still fail.

LEAK DETECTION PUMP SYSTEM

PURPOSE AND FUNCTION Many vehicles use a vacuum operated **leak detection pump (LDP)** as part of the evaporative control system diagnosis equipment. ● **SEE FIGURE 83–6.**

OPERATION The system works to test for leaks as follows:

- The purge solenoid is normally closed.
- The vent valve in the LDP is normally open. Filtered fresh air is drawn through the LDP to the canister.
- The LDP uses a spring attached to a diaphragm to apply pressure (7.5 in. H_2O) to the fuel tank.
- The PCM monitors the LDP switch that is triggered if the pressure drops in the fuel tank.
- The time between LDP solenoid off and LDP switch close is called the pump period. This time period is inversely proportional to the size of the leak. The shorter the pump period, the larger the leak. The longer the pump period, the smaller the leak.

  EVAP large leak (greater than 0.080 in.): less than 0.9 second

  EVAP medium leak (0.040 to 0.080 in.): 0.9 to 1.2 seconds

  EVAP small leak (0.020 to 0.040 in.): 1.2 to 6 seconds

ONBOARD REFUELING VAPOR RECOVERY

PURPOSE AND FUNCTION The **onboard refueling vapor recovery (ORVR)** system was first introduced on some 1998 vehicles. Previously designed EVAP systems allowed fuel vapor to escape to the atmosphere during refueling.

OPERATION The primary feature of most ORVR systems is the restricted tank filler tube, which is about 1 inch (25 mm) in diameter. This reduced size filler tube creates an aspiration effect, which tends to draw outside air into the filler tube. During refueling, the fuel tank is vented to the charcoal canister, which captures the gas fumes, and with air flowing into the filler tube, no vapors can escape to the atmosphere. ● **SEE FIGURE 83–7.**

DIAGNOSING THE EVAP SYSTEM

SYMPTOMS Before vehicle emissions testing began in many parts of the country, little service work was done on the evaporative emission system. Common engine performance

FIGURE 83–8 Some vehicles will display a message if an evaporative control system leak is detected that could be the result of a loose gas cap.

FIGURE 83–9 To test for a leak, this tester was set to the 0.020-inch hole and turned on. The ball rose in the scale on the left, and the red arrow was moved to that location. If when testing the system for leaks the ball rises higher than the arrow, then the leak is larger than 0.02 inch. If the ball does not rise to the level of the arrow, the leak is smaller than 0.020 inch.

problems that can be caused by a fault in this system include the following:

- **Poor fuel economy.** A leak in a vacuum-valve diaphragm can result in engine vacuum drawing in a constant flow of gasoline vapors from the fuel tank. This usually results in a drop in fuel economy of 2 to 4 miles per gallon (mpg). Use a hand-operated vacuum pump to check that the vacuum diaphragm can hold vacuum.
- **Poor performance.** A vacuum leak in the system can cause the engine to run rough. Age, heat, and time all contribute to the deterioration of rubber hoses.

STATE EVAP TESTS

Enhanced exhaust emissions (I/M-240) testing tests the evaporative emission system. A leak in the system is tested by pressurizing the entire fuel system to a level below 1 PSI (about 14 in. H_2O). The system is typically pressurized with nitrogen, a nonflammable gas that makes up 78% of our atmosphere. The pressure in the system is then shut off and the pressure monitored. If the pressure drops below a set standard, then the vehicle fails the test. This test determines if there is a leak in the system.

HINT: To help pass the evaporative section of an enhanced emissions test, arrive at the test site with less than a half tank of fuel. This means that the rest of the volume of the fuel tank is filled with air. It takes longer for the pressure to drop from a small leak when the volume of the air is greater compared to when the tank is full and the volume of air remaining in the tank is small.

FIGURE 83–10 This unit is applying smoke to the fuel tank through an adapter, and the leak was easily found to be the gas cap seal.

LOCATING LEAKS IN THE SYSTEM

Leaks in the evaporative emission control system will cause the malfunction check gas cap indication lamp to light on some vehicles. ● **SEE FIGURE 83–8.**

A leak will also cause a gas smell, which would be most noticeable if the vehicle were parked in an enclosed garage. The first step is to determine if there is a leak in the system by setting the EVAP tester to rate the system for either a 0.040-inch-or a 0.020-inch-hole-size leak. ● **SEE FIGURE 83–9.**

After it has been determined that a leak exists and it is larger than specified, one of two methods can be used to check for leaks in the evaporative system:

- **Smoke machine testing.** The most efficient method of leak detection is to introduce smoke under low pressure from a machine specifically designed for this purpose. ● **SEE FIGURE 83–10.**
- **Nitrogen gas pressurization.** This method uses nitrogen gas under a very low pressure (lower than 1 PSI) in the fuel system. The service technician then listens for the escaping air, using amplified headphones. ● **SEE FIGURE 83–11.**

EVAPORATIVE SYSTEM MONITOR

OBD-II REQUIREMENTS

OBD-II computer programs not only detect faults but also *periodically test various systems* and alert the driver before emissions-related components are harmed by system faults:

- Serious faults cause a blinking malfunction indicator lamp (MIL) or even an engine shutdown.
- Less serious faults may simply store a code but not illuminate the MIL.

The OBD-II requirements did not affect fuel system design. However, one new component, a fuel evaporative canister purge line pressure sensor, was added for monitoring purge line pressure during tests. The OBD-II requirements state that vehicle fuel systems are to be routinely tested *while under way* by the PCM.

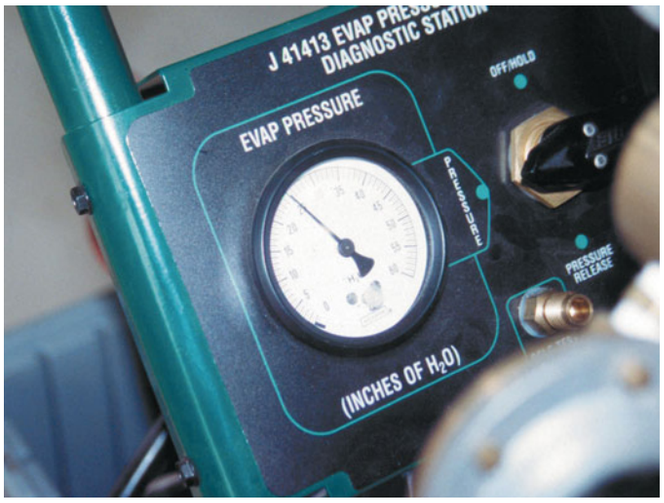

FIGURE 83–11 An emission tester that uses nitrogen to pressurize the fuel system.

FIGURE 83–12 The fuel tank pressure sensor (black unit with three wires) looks like a MAP sensor and is usually located on top of the fuel pump module (white unit).

All OBD-II vehicles perform a canister purge system pressure test, as commanded by the PCM. While the vehicle is being driven, the vapor line between the canister and the purge valve is monitored for pressure changes:

- When the canister purge solenoid is open, the line should be under a vacuum since vapors must be drawn from the canister into the intake system. However, when the purge solenoid is closed, there should be no vacuum in the line. The pressure sensor detects if a vacuum is present, and the information is compared to the command given to the solenoid.
- If, during the canister purge cycle, no vacuum exists in the canister purge line, a code is set indicating a possible fault, which could be caused by an inoperative or clogged solenoid or a blocked or leaking canister purge fuel line. Likewise, if vacuum exists when no command for purge is given, a stuck solenoid is evident, and a code is set. The EVAP system monitor tests for purge volume and leaks.

A typical EVAP monitor first closes off the system to atmospheric pressure and opens the purge valve during cruise operation. A **fuel tank pressure (FTP)** sensor then monitors the rate with which vacuum increases in the system. The monitor uses this information to determine the purge volume flow rate. To test for leaks, the EVAP monitor closes the purge valve, creating a completely closed system. The fuel tank pressure sensor then monitors the leak-down rate. If the rate exceeds PCM-stored values, a leak greater than or equal to the OBD-II standard of 0.04 inch (1 mm) or 0.02 inch (0.5 mm) exists. After two consecutive failed trips testing either purge volume or the presence of a leak, the PCM lights the MIL and sets a DTC.

The fuel tank pressure sensor is similar to a MAP sensor, and instead of monitoring intake manifold absolute pressure, it is used to monitor fuel tank pressure. ● **SEE FIGURE 83–12.**

ENGINE-OFF NATURAL VACUUM System integrity (leakage) can also be checked after the engine is shut off. The premise is that a warm evaporative system will cool down after the engine is shut off and the vehicle is stable. A slight vacuum will be created in the gas tank during this cool-down period. If a specific level of vacuum is reached and maintained, the system is said to have integrity (no leakage). Actually, the vacuum is created after a period of time because the vapor pressure tends to increase after the engine is shut off and gradually decreases over time. The PCM monitors the pressure rise and decrease over time and triggers a diagnostic trouble code (DTC) if the pressure indicates a leak in the system. ● **SEE FIGURE 83–13.**

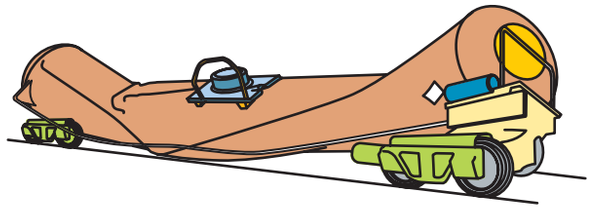

FIGURE 83–13 A tank car was cleaned using steam, and then both the bottom drain and the top vent were closed. The next day, the tank had collapsed because of the air pressure difference when the inside cooled. The higher outside air pressure caused the tank to collapse.

TECH TIP

Always Tighten the Cap Correctly

Many diagnostic trouble codes (DTCs) are set because the gas cap has not been properly installed. To be sure that a screw-type gas cap is properly sealed, tighten it until you hear three clicks. The clicking is a ratchet device, and the clicking does not harm the cap. Therefore, if a P0440 or similar DTC is set, check the cap. ● **SEE FIGURE 83–14.**

TYPICAL EVAP MONITOR

The PCM will run the EVAP monitor when the following enable criteria are met:

- Barometric pressure (BARO) greater than 70 kPa (20.7 in. Hg or 10.2 PSI)
- Intake air temperature (IAT) between 39°F and 86°F (4°C to 30°C) at engine start-up
- Engine coolant temperature (ECT) between 39°F and 86°F (4°C to 30°C) at engine start-up
- ECT and IAT within 3°F of each other at engine start-up
- Fuel level within 15% to 85%
- Throttle position (TP) sensor between 9% and 35%

A typical EVAP monitor first closes off the system to atmospheric pressure and opens the purge valve during cruise operation.

FIGURE 83–14 This Toyota cap warns that the check engine light will come on if not tightened until one click.

FIGURE 83–16 The fuel level must be above 15% and below 85% before the EVAP monitor will run on most vehicles.

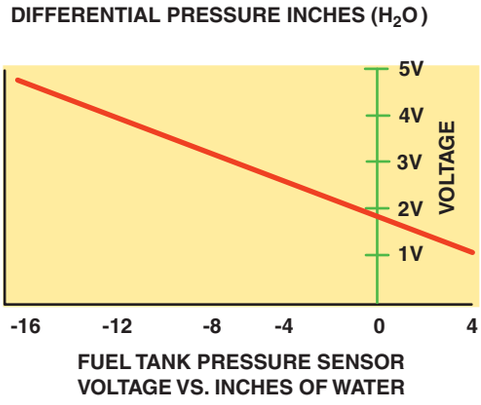

FIGURE 83–15 To easily check the fuel tank pressure sensor, remove the cap, and the sensor should read about 1.7 volts.

A fuel tank pressure (FTP) sensor then monitors the rate with which vacuum increases in the system. ● **SEE FIGURE 83–15.**

The monitor uses this information to determine the purge volume flow rate. To test for leaks, the EVAP monitor closes the purge valve, creating a completely closed system. The fuel tank pressure sensor then monitors the leak-down rate. If the rate exceeds PCM-stored values, a leak greater than or equal to the OBD-II standard of 0.04 inch (1 mm) or 0.02 inch (0.5 mm) exists.

RUNNING THE EVAP MONITOR Four tests are performed during a typical EVAP monitor. A DTC is assigned to each test:

1. **Weak vacuum test (P0440–large leak).** This test identifies gross leaks. During the monitor, the vent solenoid is closed, and the purge solenoid is duty cycled. The fuel tank pressure (FTP) should indicate a vacuum of approximately 6 to 10 in. H_2O.
2. **No flow during purging (P0441–no flow during purging).** This test uses the fuel tank pressure (FTP) sensor to determine that there was no change in fuel tank pressure during purging. This fault could be due to a defective purge valve or a gross leak caused by faults such as a defective or missing gas cap.
3. **Small leak test (P0442–small leak).** After the large leak test passes, the PCM checks for a small leak by keeping the vent solenoid closed and closing the purge solenoid. The system is now sealed. The PCM measures the change in FTP voltage over time.

TECH TIP

Keep the Fuel Tank Properly Filled

Most evaporative system monitors will not run unless the fuel level is between 15% and 85%. In other words, if a driver always runs with close to an empty tank or always tries to keep the tank full, the EVAP monitor may not run. ● **SEE FIGURE 83–16.**

4. **Excess vacuum test (P0446).** This test checks for vent path restrictions. With the vent solenoid open and purge commanded, the PCM should not see excessive vacuum in the EVAP system. Typical EVAP system vacuum with the vent solenoid open is about 5 to 6 in. H_2O.

EXHAUST GAS RECIRCULATION SYSTEMS

OBJECTIVES: **After studying Chapter 84, the reader should be able to:** • Prepare for the ASE Engine Performance (A8) certification test content area "D" (Emission Control Systems). • Describe the purpose and function of the exhaust gas recirculation system. • Discuss how the exhaust gas recirculation system is tested under OBD-II regulations. • Explain methods for diagnosing and testing for faults in the exhaust gas recirculation system.

KEY TERMS: Delta pressure feedback EGR (DPFE) sensor 939 • Detonation 936 • Digital EGR valve 938 • EGR valve position (EVP) sensor 938 • Electronic vacuum regulator valve (EVRV) 940 • Exhaust gas recirculation (EGR) 936 • Inert 936 • Linear EGR valve 938 • Nitrogen oxides (NO_x) 936 • Pressure feedback EGR (PFE) sensor 938

FIGURE 84–1 Nitrogen oxides (NO_x) create a red-brown haze that often hangs over major cities.

EXHAUST GAS RECIRCULATION SYSTEMS

INTRODUCTION **Exhaust gas recirculation (EGR)** is an emission control system that lowers the amount of **nitrogen oxides (NO_x)** formed during combustion. In the presence of sunlight, NO_x reacts with hydrocarbons in the atmosphere to form ozone (O_3) or photochemical smog, an air pollutant.

NO_x FORMATION Nitrogen (N_2) and oxygen (O_2) molecules are separated into individual atoms of nitrogen and oxygen during the combustion process. These molecules then bond to form NO_x (NO, NO_2). When combustion flame front temperatures exceed 2,500°F (1,370°C), NO_x is formed inside the cylinder, which is then discharged into the atmosphere from the tailpipe. ● **SEE FIGURE 84–1.**

CONTROLLING NO_x To handle the NO_x generated above 2,500°F (1,370°C), the most efficient method to meet NO_x emissions without significantly affecting engine performance, fuel economy, and other exhaust emissions is to use exhaust gas recirculation (EGR). The EGR system routes small quantities, usually between 6% and 10%, of exhaust gas into the intake manifold.

Here, the exhaust gas mixes with and takes the place of some intake charge. This leaves less room for the intake charge to enter the combustion chamber. The recirculated exhaust gas is **inert** (chemically inactive) and does not enter into the combustion process. The result is a lower peak combustion temperature. When the combustion temperature is lowered, the production of oxides of nitrogen is reduced.

The EGR system has some means of interconnecting the exhaust and intake manifolds. ● **SEE FIGURE 84–2.**

The EGR valve controls the flow of exhaust gases through the interconnecting passages:

- On V-type engines, the intake manifold crossover is used as a source of exhaust gas for the EGR system. A cast passage connects the exhaust crossover to the EGR valve. The exhaust gas is sent from the EGR valve to openings in the manifold.
- On inline-type engines, an external tube is generally used to carry exhaust gas to the EGR valve. This tube is often designed to be long so that the exhaust gas is cooled before it enters the EGR valve.

EGR SYSTEM OPERATION Since small amounts of exhaust are all that is needed to lower peak combustion temperatures, the orifice through which the exhaust passes is small.

EGR is usually not required during the following conditions because the combustion temperatures are low:

- During idle speed
- When the engine is cold
- At wide-open throttle (WOT) (Not allowing EGR allows the engine to provide extra power when demanded. While the NO_x formation is high during these times, the overall effect of not using EGR during WOT conditions is minor.)

The level of NO_x emission changes according to engine speed, temperature, and load. Many systems use a cooler to reduce the temperature of the exhaust gases before they enter the intake manifold. The cooler the exhaust gases, the more effective they are at reducing the formation of NOx.

EGR BENEFITS In addition to lowering NO_x levels, the EGR system also helps control detonation. **Detonation,** also called spark knock or ping, occurs when high pressure and heat cause the air-fuel mixture to ignite. This uncontrolled combustion can severely damage the engine.

Using the EGR system allows for greater ignition timing advance and for the advance to occur sooner without detonation problems, which increases power and efficiency.

POSITIVE AND NEGATIVE BACK PRESSURE EGR VALVES Some vacuum-operated EGR valves used on older engines are designed with a small valve inside that bleeds off any applied vacuum and prevents the valve from opening:

- **Positive back pressure EGR valves.** These EGR valves require a positive back pressure in the exhaust system. At low engine speeds and light engine loads, the EGR system is not needed, and the back pressure in it is also low. Without enough back pressure, the EGR valve does not open even though vacuum may be present at the EGR valve. ● **SEE FIGURE 84–3.**
- **Negative back pressure EGR valves.** On each exhaust stroke, the engine emits an exhaust "pulse." Each pulse represents a positive pressure. Behind each pulse is a small area of low pressure. Some EGR valves react to this low-pressure area by closing a small internal valve, which allows the EGR valve to be opened by vacuum.

The following conditions must occur before a back pressure-type vacuum-controlled EGR will operate:

1. Vacuum must be applied to the EGR valve itself. The vacuum source can be ported vacuum (above the throttle plate) or manifold vacuum (below the throttle plate) and by the computer through a solenoid valve.
2. Exhaust back pressure must be present to close an internal valve inside the EGR to allow the vacuum to move the diaphragm.

NOTE: Installing a high-performance exhaust system could prevent a back pressure vacuum-operated EGR valve from opening. If this occurs, excessive combustion chamber pressure may lead to severe spark knock, piston damage, or a blown head gasket.

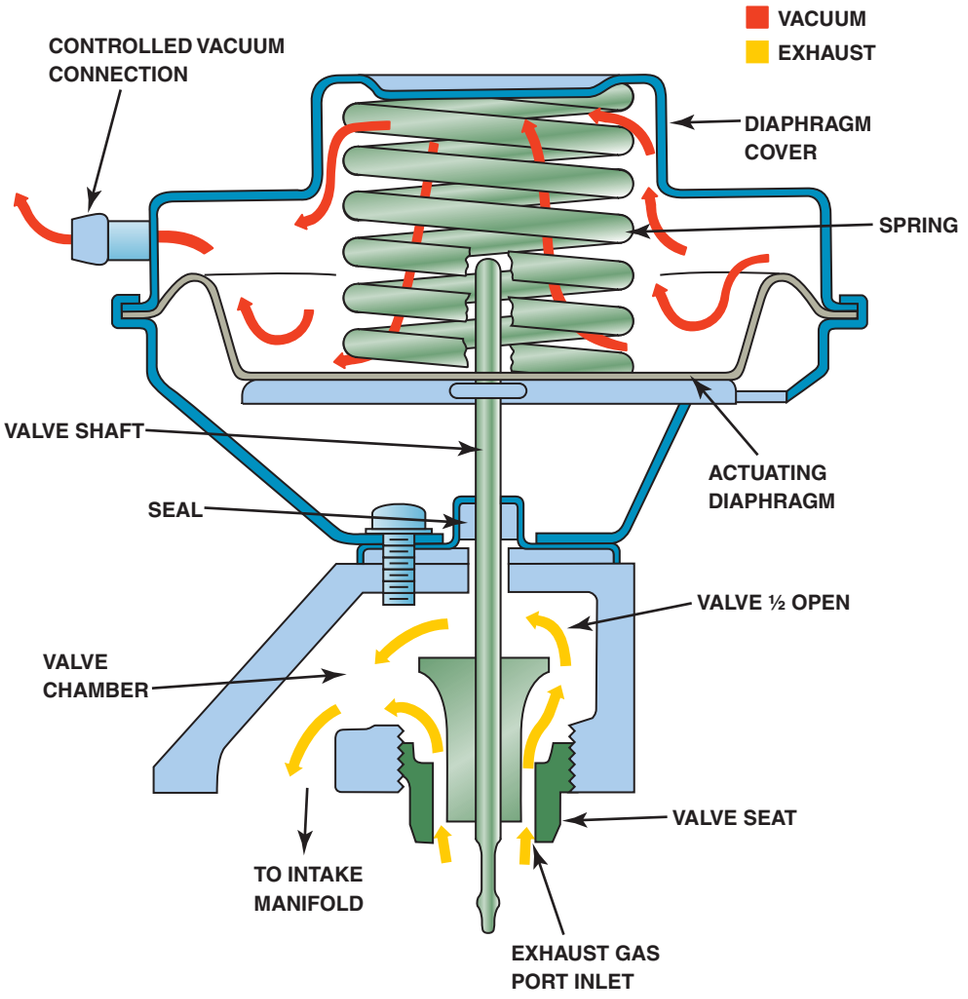

FIGURE 84–2 When the EGR valve opens, the exhaust gases flow through the valve and into passages in the intake manifold.

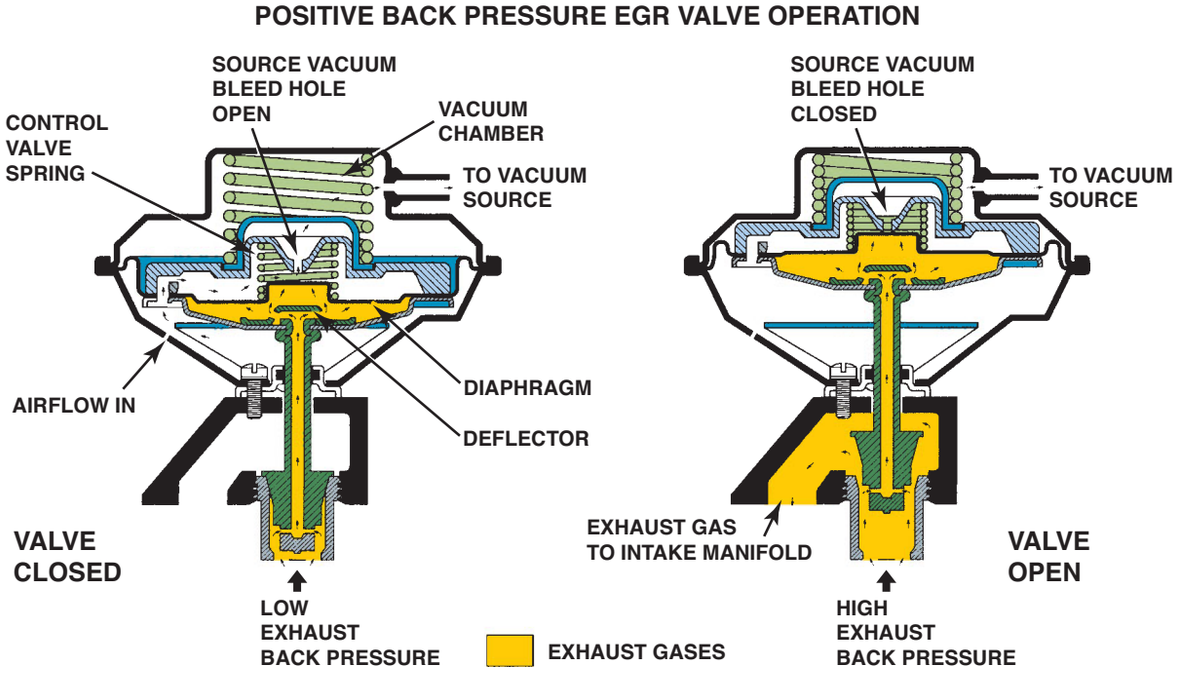

FIGURE 84–3 Back pressure in the exhaust system is used to close the control valve, allowing engine vacuum to open the EGR valve.

COMPUTER-CONTROLLED EGR SYSTEMS Most vehicles today use the powertrain control module (PCM) to operate the EGR system. Many PCM-controlled EGR systems have one or more solenoids controlling the EGR vacuum. The PCM controls a solenoid to shut off vacuum to the EGR valve at cold engine temperatures, idle speed, and WOT operation. If two solenoids are used, one acts as an off/on control of supply vacuum, while the second solenoid vents vacuum when EGR flow is not desired or needs to be reduced.

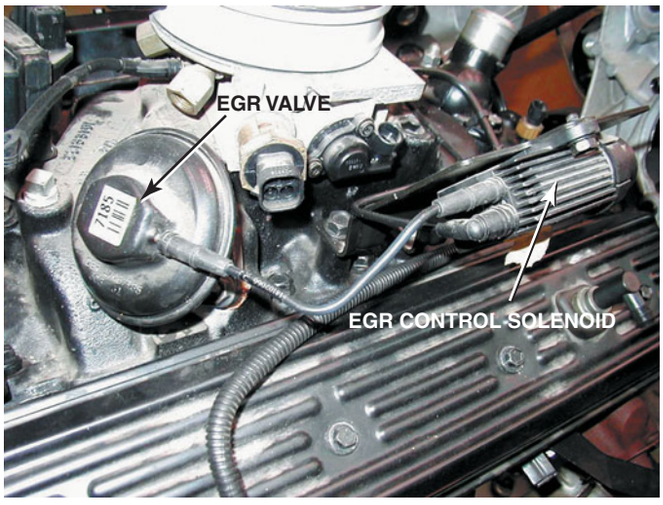

FIGURE 84–4 Typical vacuum-operated EGR valve. The operation of the valve is controlled by the PCM by pulsing the EGR control solenoid on and off.

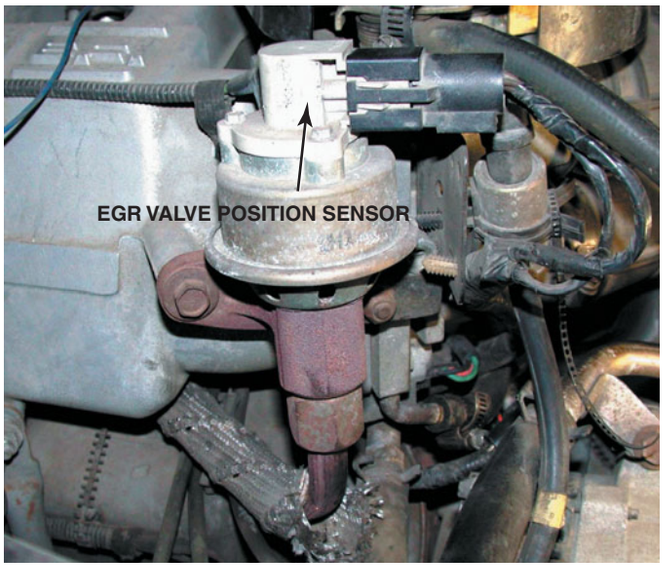

FIGURE 84–5 An EGR valve position sensor on top of an EGR valve.

The second solenoid is used to control a vacuum air bleed, allowing atmospheric pressure in to modulate EGR flow according to vehicle operating conditions. ● **SEE FIGURE 84–4.**

EGR VALVE POSITION SENSORS Most PCM vacuum-operated EGR systems use a sensor to indicate EGR operation. Onboard diagnostics generation II (OBD-II) EGR system monitors require an EGR sensor to verify that the valve opened. A linear potentiometer on the top of the EGR valve stem indicates valve position to the PCM. This is called an **EGR valve position (EVP) sensor.** Some later-model Ford EGR systems, however, use a feedback signal provided by an EGR exhaust back pressure sensor that converts the exhaust back pressure to a voltage signal. This sensor is called a **pressure feedback EGR (PFE) sensor.**

On some EGR systems, the top of the valve contains a vacuum regulator and EGR pintle-position sensor in one assembly sealed inside a nonremovable plastic cover. The pintle-position sensor provides a voltage output to the PCM, which increases as the duty cycle increases, allowing the PCM to monitor valve operation. ● **SEE FIGURE 84–5.**

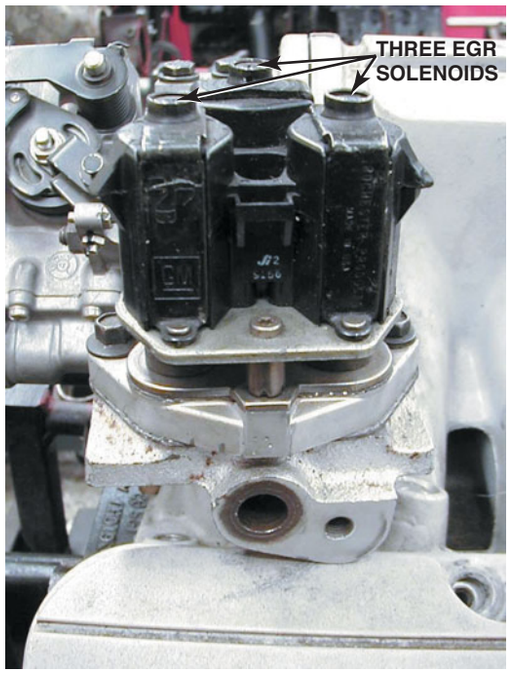

FIGURE 84–6 Digital EGR valve as used on some older General Motors engines.

TECH TIP

Find the Root Cause

Excessive back pressure, such as that caused by a partially clogged exhaust system, could cause the plastic sensors on the EGR valve to melt. Always check for a restricted exhaust whenever replacing a failed EGR valve sensor.

DIGITAL EGR VALVES General Motors used a **digital EGR valve** design on some engines. Unlike vacuum-operated EGR valves, the digital EGR valve consists of three solenoids controlled by the powertrain control module (PCM). Each solenoid controls a different size orifice in the base–small, medium, and large. The PCM controls the ground circuit of each of the solenoids individually. It can produce any of seven different flow rates, using the solenoids to open the three valves in different combinations. The digital EGR valve offers precise control and using a swivel pintle design helps prevent carbon deposit problems. ● **SEE FIGURE 84–6.**

LINEAR EGR Most General Motors and many other vehicles use a **linear EGR valve** that contains a pulse-width modulated solenoid to precisely regulate exhaust gas flow and a feedback potentiometer that signals the PCM regarding the actual position of the valve. ● **SEE FIGURES 84–7 AND 84–8.**

OBD-II EGR MONITORING STRATEGIES

PURPOSE AND FUNCTION In 1996, the U.S. EPA began requiring OBD-II systems in all passenger cars and most light-duty trucks. These systems include emission system monitors that alert

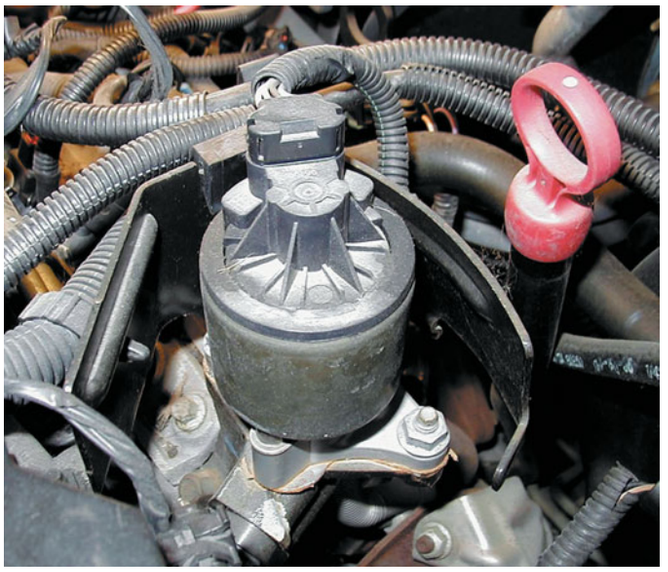

FIGURE 84–7 A General Motors linear EGR valve.

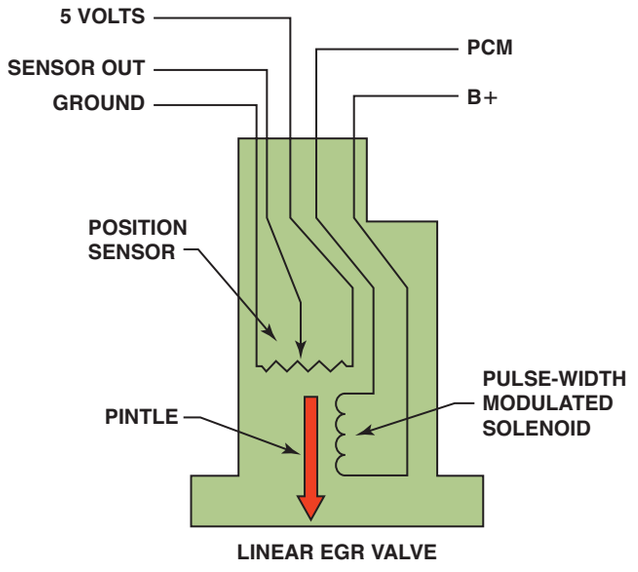

FIGURE 84–8 The EGR valve pintle is pulse-width modulated and a three-wire potentiometer provides pintle-position information back to the PCM.

the driver and the technician if an emission system is malfunctioning. The OBD-II system performs this test by opening and closing the EGR valve. The PCM monitors either the oxygen or MAP sensor for a change in signal voltage. If the EGR system fails, a diagnostic trouble code (DTC) is set. If the system fails two consecutive times, the malfunction indicator lamp (MIL) is lit.

MONITORING STRATEGIES EGR monitoring strategies include the following:

- Some vehicle manufacturers, such as Chrysler, monitor the difference in the exhaust oxygen sensor's voltage activity as the EGR valve opens and closes. Oxygen in the exhaust decreases when the EGR valve is open and increases when the EGR valve is closed because exhaust gas is inert (contains very little oxygen) and actually displaces oxygen. The PCM sets a DTC if the sensor signal does not change.
- Most Fords use an EGR monitor test sensor called a **delta pressure feedback EGR (DPFE) sensor.** This sensor measures the pressure differential between two sides of a metered orifice positioned just below the EGR valve's exhaust side. Pressure between the orifice and the EGR valve decreases when the EGR opens because it becomes exposed to the lower pressure in the intake. The DPFE sensor recognizes this pressure drop, compares it to the relatively higher pressure on the exhaust side of the orifice, and signals the value of the pressure difference to the PCM. ● **SEE FIGURE 84–9.**
- Many vehicle manufacturers use the manifold absolute pressure (MAP) sensor as the EGR monitor on some applications. After meeting the enable criteria (operating condition requirements), the EGR monitor is run. The PCM monitors the MAP sensor while it commands the EGR valve to open. The MAP sensor signal should change in response to the sudden change in manifold pressure or the fuel trim changes created by a change in the oxygen sensor voltage. If the signal value falls outside the acceptable value in the lookup table, a DTC sets. If the EGR fails on two consecutive trips, the PCM lights the MIL. ● **SEE FIGURE 84–10.**

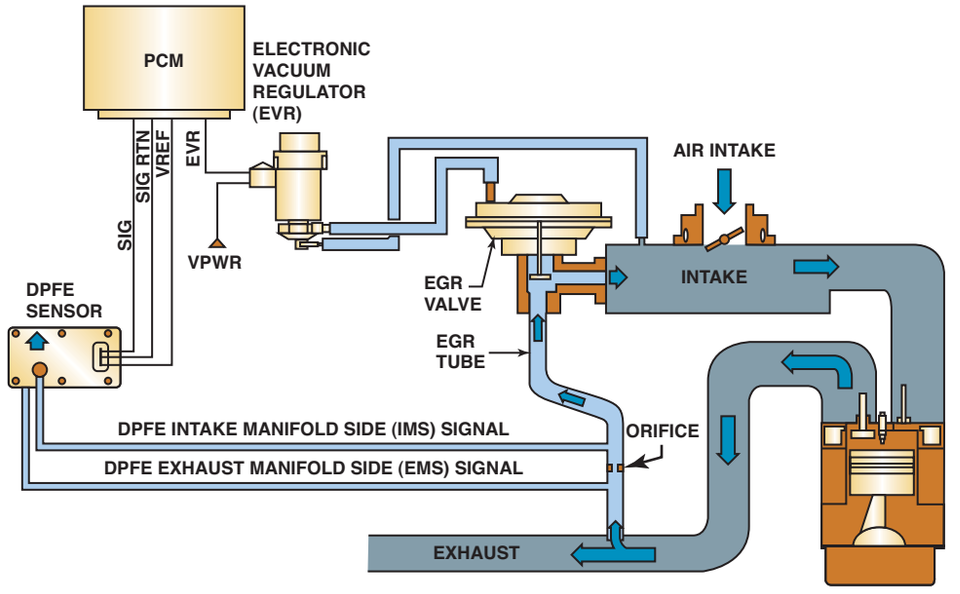

FIGURE 84–9 A typical Ford DPFE sensor and related components.

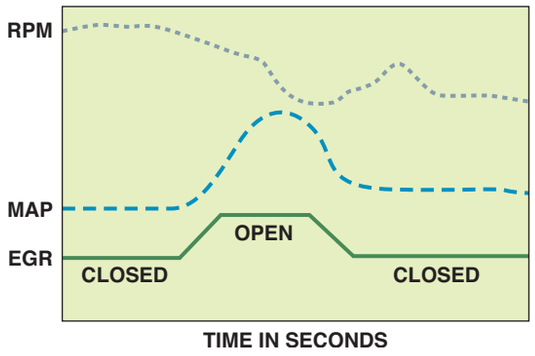

FIGURE 84–10 An OBD-II active test. The PCM opens the EGR valve and then monitors the MAP sensor and/or engine speed (RPM) to verify that it meets acceptable values.

TECH TIP

Watch Out for Carbon Balls!

EGR valves can get stuck partially open by a chunk of carbon, and the valve or solenoid will test as defective. When the valve (or solenoid) is removed, small chunks or balls of carbon often fall into the exhaust manifold passage. When the replacement valve is installed, the carbon balls can be drawn into the new valve again, causing the engine to idle roughly or stall.

To help prevent this problem, start the engine with the EGR valve or solenoid removed. Any balls or chunks of carbon will be blown out of the passage by the exhaust. Stop the engine and install the replacement EGR valve or solenoid.

DIAGNOSING A DEFECTIVE EGR SYSTEM

SYMPTOMS If the EGR valve is not opening or the flow of the exhaust gas is restricted, then the following symptoms are likely:

- Detonation (spark knock or ping) during acceleration or during cruise (steady-speed driving)
- Excessive oxides of nitrogen (NO_x) exhaust emissions

If the EGR valve is stuck open or partially open, then the following symptoms are likely:

- Rough idle or frequent stalling
- Poor performance/low power, especially at low engine speed

EGR TESTING PROCEDURES The first step in almost any diagnosis is to perform a thorough visual inspection. To check for proper operation of a vacuum-operated EGR valve, follow these steps:

STEP 1 **Check the vacuum diaphragm of the EGR valve to see if it can hold vacuum.** Because many EGR valves require exhaust back pressure to function correctly, the engine should be running at a fast idle during this test.

STEP 2 **Apply vacuum from a hand-operated vacuum pump and check for proper operation.** The valve itself should move when vacuum is applied, and the engine operation should be affected. The EGR valve should be able to hold the vacuum that was applied. If the vacuum drops off, then the valve is likely to be defective.

STEP 3 **Monitor engine vacuum drop.** Connect a vacuum gauge to an intake manifold vacuum source and monitor the engine vacuum at idle (should be 17 to 21 in. Hg at sea level). Raise the speed of the engine to 2,500 RPM and note the vacuum reading (should be 17 to 21 in. Hg or higher).

REAL WORLD FIX

The Blazer Story

The owner of a Chevrolet Blazer equipped with a 4.3-L, V-6 engine complained that the engine would stumble and hesitate at times. Everything seemed to be functioning correctly, except that the service technician discovered a weak vacuum going to the EGR valve at idle. This vehicle was equipped with an EGR valve-control solenoid, called an **electronic vacuum regulator valve (EVRV)** by General Motors Corporation. The PCM pulses the solenoid to control the vacuum that regulates the operation of the EGR valve. The technician checked the service manual for details on the workings of the system. The technician discovered that vacuum should be present at the EGR valve only when the gear selector indicates a drive gear (drive, low, reverse). Because the technician discovered the vacuum at the solenoid to be leaking, the solenoid was obviously defective and required replacement. After replacement of the solenoid (EVRV), the hesitation problem was solved.

NOTE: The technician also discovered in the service manual that blower-type exhaust hoses should not be connected to the tailpipe on any vehicle while performing an inspection of the EGR system. The vacuum created by the system could cause false EGR valve operation to occur.

TECH TIP

The Snake Trick

The EGR passages on many intake manifolds become clogged with carbon, which reduces the flow of exhaust and the amount of exhaust gases in the cylinders. This reduction can cause spark knock (detonation) and increased emissions of oxides of nitrogen (NO_x) (especially important in areas with enhanced exhaust emissions testing).

To quickly and easily remove carbon from exhaust passages, cut an approximately 1-foot (30-cm) length from stranded wire, such as garage door guide wire or an old speedometer cable. Flare the end and place the end of the wire into the passage. Set your drill on reverse and turn it on, and the wire will pull its way through the passage, cleaning the carbon as it goes, just like a snake in a drainpipe. Some vehicles, such as Hondas, require that plugs be drilled out to gain access to the EGR passages.
SEE FIGURE 84–11.

FIGURE 84–11 Removing the EGR passage plugs from the intake manifold on a Honda.

Activate the EGR valve using a scan tool or vacuum pump, if vacuum controlled, and observe the vacuum gauge. The results are as follows:

- The vacuum should drop 6 to 8 in. Hg.
- If the vacuum drops less than 6 to 8 in. Hg, the valve or the EGR passages are clogged.
- If the EGR valve is able to hold vacuum but the engine is not affected when the valve is opened, then the exhaust passage(s) must be checked for restriction.

See the Tech Tip "The Snake Trick." If the EGR valve will not hold vacuum, the valve itself is likely to be defective and require replacement.

POSITIVE CRANKCASE VENTILATION AND SECONDARY AIR-INJECTION SYSTEMS

OBJECTIVES: **After studying Chapter 85, the reader should be able to:** • Prepare for the ASE Engine Performance (A8) certification test content area "D" (Emission Control Systems). • Describe the purpose and function of the positive crankcase ventilation (PCV) and secondary air-injection (SAI) systems. • Discuss how the PCV and SAI systems are tested under OBD-II regulations. • Explain methods for diagnosing and testing faults in the PCV and secondary air injection (SAI) systems.

KEY TERMS: Air-injection reaction (AIR) 945 • Blowby 942 • Check valve 946 • Positive crankcase ventilation (PCV) 942 • Secondary air injection (SAI) 945 • Smog pump 945 • Thermactor pump 945

CRANKCASE VENTILATION

PURPOSE AND FUNCTION

The problem of crankcase ventilation has existed since the beginning of the automobile because no piston ring, new or old, can provide a perfect seal between the piston and the cylinder wall. When an engine is running, the pressure of combustion forces the piston downward. This same pressure also forces gases and unburned fuel from the combustion chamber, past the piston rings, and into the crankcase. This process of gases leaking past the rings is called **blowby,** and the gases form crankcase vapors.

These combustion by-products, particularly unburned hydrocarbons (HC) caused by blowby, must be ventilated from the crankcase. However, the crankcase cannot be vented directly to the atmosphere because the hydrocarbon vapors add to air pollution. **Positive crankcase ventilation (PCV)** systems were developed to ventilate the crankcase and recirculate the vapors to the engine's induction system so they can be burned in the cylinders. PCV systems help reduce HC and CO emissions.

All systems use the following:

1. PCV valve or calibrated orifice, or orifice and separator
2. PCV inlet air filter plus all connecting hoses
   ● **SEE FIGURE 85–1.**

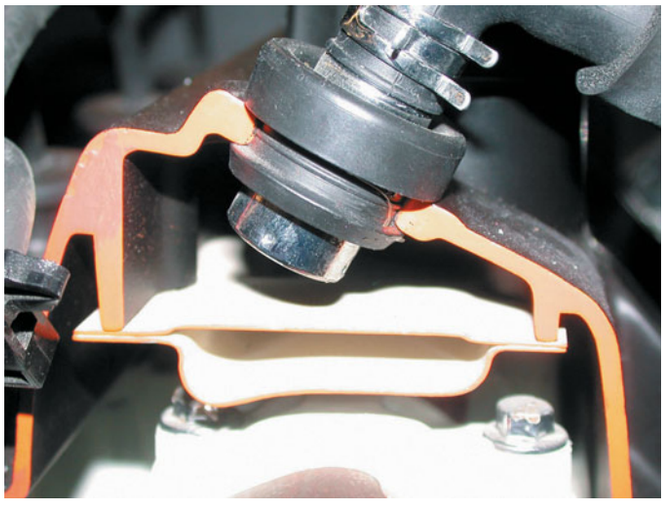

FIGURE 85–1 A PCV valve in a cutaway valve cover, showing the baffles that prevent liquid oil from being drawn into the intake manifold.

An oil/vapor or oil/water separator is used in some systems instead of a valve or orifice, particularly with turbocharged and fuel-injected engines. The oil/vapor separator lets oil condense and drain

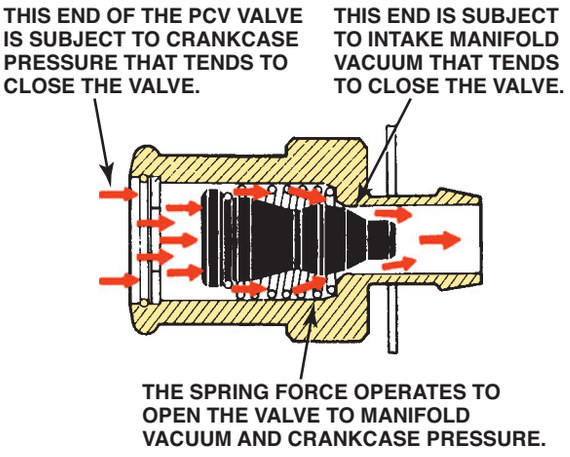

FIGURE 85–2 Spring force, crankcase pressure, and intake manifold vacuum work together to regulate the flow rate through the PCV valve.

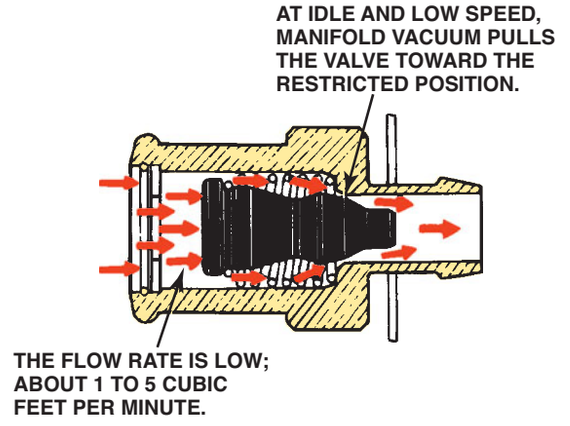

FIGURE 85–3 Air flows through the PCV valve during idle, cruising, and light-load conditions.

back into the crankcase. The oil/water separator accumulates moisture and prevents it from freezing during cold engine starts.

The air for the PCV system is drawn after the air cleaner filter, which acts as a PCV filter.

NOTE: Some older designs drew from the dirty side of the air cleaner, where a separate crankcase ventilation filter was used.

PCV VALVES

The PCV valve in most systems is a one-way valve containing a spring-operated plunger that controls valve flow rate. ● **SEE FIGURE 85–2.**

Flow rate is established for each engine, and a valve for a different engine should not be substituted. The flow rate is determined by the size of the plunger and the holes inside the valve. PCV valves usually are located in the valve cover or intake manifold.

The PCV valve regulates airflow through the crankcase under all driving conditions and speeds. When manifold vacuum is high (at idle, cruising, and light-load operation), the PCV valve restricts the airflow to maintain a balanced air-fuel ratio. ● **SEE FIGURE 85–3.**

It also prevents high intake manifold vacuum from pulling oil out of the crankcase and into the intake manifold. Under high speed or heavy loads, the valve opens and allows maximum airflow. ● **SEE FIGURE 85–4.**

If the engine backfires, the valve will close instantly to prevent a crankcase explosion. ● **SEE FIGURE 85–5.**

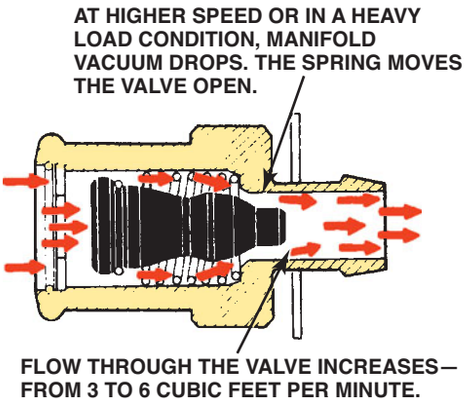

FIGURE 85–4 Air flows through the PCV valve during acceleration and when the engine is under a heavy load.

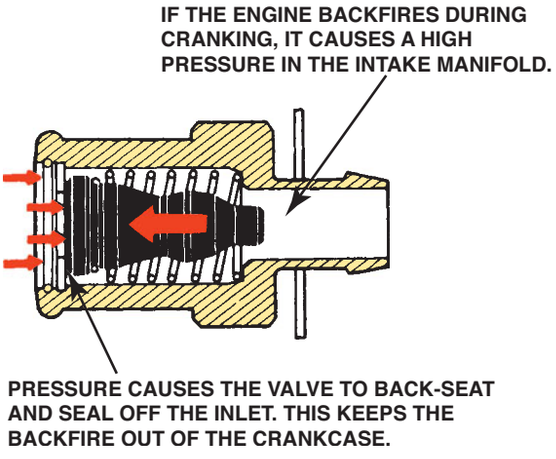

FIGURE 85–5 PCV valve operation in the event of a backfire.

ORIFICE-CONTROLLED SYSTEMS.

The closed PCV system used on some 4-cylinder engines contains a calibrated orifice instead of a PCV valve. The orifice may be located in the valve cover or intake manifold or in a hose connected between the valve cover, air cleaner, and intake manifold.

While most orifice flow control systems work the same as a PCV valve system, they may not use fresh air scavenging of the crankcase. Crankcase vapors are drawn into the intake manifold in calibrated amounts depending on manifold pressure and the orifice size. If vapor availability is low, as during idle, air is drawn in with the vapors. During off-idle operation, excess vapors are sent to the air cleaner.

At idle, PCV flow is controlled by a 0.05-inch (1.3-mm) orifice. As the engine moves off idle, ported vacuum pulls a spring-loaded valve off of its seat, allowing PCV flow to pass through a 0.09-inch (2.3-mm) orifice.

SEPARATOR SYSTEMS.

Turbocharged and many fuel-injected engines use an oil/vapor or oil/water separator and a calibrated orifice instead of a PCV valve. In the most common applications, the air intake throttle body acts as the source for crankcase ventilation vacuum, and a calibrated orifice acts as the metering device.

PCV SYSTEM DIAGNOSIS

SYMPTOMS. If the PCV valve or orifice is not clogged, intake air flows freely and the PCV system functions properly. Engine design includes the air and vapor flow as a calibrated part of the air-fuel mixture. In fact, some engines receive as much as 30% of the idle air through the PCV system. For this reason, a flow problem in the PCV system results in driveability problems.

REAL WORLD FIX

The Whistling Engine

An older vehicle was being diagnosed for a whistling sound whenever the engine was running, especially at idle. It was finally discovered that the breather in the valve cover was plugged and caused high vacuum in the crankcase. The engine was sucking air from what was likely the rear main seal lip, making the "whistle" noise. After replacing the breather and PCV, the noise stopped.

TECH TIP

Check for Oil Leaks with the Engine Off

The owner of an older vehicle equipped with a V-6 engine complained to his technician that he smelled burning oil, but only *after* shutting off the engine. The technician found that the rocker cover gaskets were leaking. But why did the owner only notice the smell of hot oil when the engine was shut off? Because of the positive crankcase ventilation (PCV) system, engine vacuum tends to draw oil away from gasket surfaces. When the engine stops, however, engine vacuum disappears, and the oil remaining in the upper regions of the engine will tend to flow down and out through any opening. Therefore, a good technician should check an engine for oil leaks not only with the engine running but also shortly after shutdown.

A blocked or plugged PCV system may cause the following to occur:

- Rough or unstable idle
- Excessive oil consumption
- Oil in the air filter housing
- Oil leaks due to excessive crankcase pressure

Before attempting expensive engine repairs, check the condition of the PCV system.

PCV SYSTEM PERFORMANCE CHECK. A properly operating positive crankcase ventilation system should be able to draw vapors from the crankcase and into the intake manifold. If the pipes, hoses, and PCV valve itself are not restricted, vacuum is applied to the crankcase. A slight vacuum is created in the crankcase (usually less than 1 in. Hg if measured at the dipstick) and is also applied to other areas of the engine. Oil drainback holes provide a path for oil to drain back into the oil pan. These holes also allow crankcase vacuum to be applied under the rocker covers and in the valley area of most V-type engines. Several methods can be used to test a PCV system.

RATTLE TEST. The rattle test is performed by simply removing the PCV valve and giving it a shake:

- If the PCV valve does *not* rattle, it is definitely defective and must be replaced.
- If the PCV valve *does* rattle, it does not necessarily mean that the PCV valve is good. All PCV valves contain springs that can become weaker with age and with heating and cooling cycles. Replace any PCV valve with the *exact* replacement according to the vehicle manufacturer's recommended intervals.

REAL WORLD FIX

The Oil-Burning Chevrolet Astro Van

An automotive instructor was driving a Chevrolet Astro van to Fairbanks, Alaska, in January. It was cold, around −32°F (−36°C). As he pulled into Fairbanks and stopped at a traffic light, he smelled burning oil. He thought it was the vehicle ahead of him because it was an older model and in poor condition. However, when he stopped at the hotel he still smelled burning oil. He looked under the van and discovered a large pool of oil. After checking the oil and finding very little left, he called a local shop and was told to bring it in. The technician looked over the situation and said, "You need to put some cardboard across the grill to stop the PCV valve from freezing up." Apparently the PCV valve froze, which then caused the normal blowby gases to force several quarts out the dipstick tube. After installing the cardboard, the instructor had no further problems.

CAUTION: Do not cover the radiator when driving unless under severe cold conditions and carefully watch the coolant temperature to avoid overheating the engine.

THE 3 × 5 CARD TEST. Remove the oil-fill cap (where oil is added to the engine) and start the engine.

NOTE: Use care on some overhead camshaft engines. With the engine running, oil may be sprayed from the open oil-fill opening.

Hold a 3 × 5 card over the opening (a dollar bill or any other piece of paper can be used for this test):

- If the PCV system, including the valve and hoses, is functioning correctly, the card should be held down on the oil-fill opening by the slight vacuum inside the crankcase.
- If the card will not stay, carefully inspect the PCV valve, hose(s), and manifold vacuum port for carbon buildup (restriction). Clean or replace as necessary.

NOTE: On some 4-cylinder engines, the 3 × 5 card may vibrate on the oil-fill opening when the engine is running at idle speed. This is normal because of the time intervals between intake strokes on a 4-cylinder engine.

SNAP-BACK TEST. The proper operation of the PCV valve can be checked by placing a finger over the inlet hole in the valve when the engine is running and removing the finger rapidly. Repeat several times. The valve should "snap back." If the valve does not snap back, replace the valve.

CRANKCASE VACUUM TEST. Sometimes the PCV system can be checked by testing for a weak vacuum at the oil dipstick tube using an inches-of-water manometer or gauge as follows:

STEP 1 Remove the oil-fill cap or vent PCV opening and cover the opening.

STEP 2 Remove the oil dipstick (oil level indicator).

STEP 3 Connect a water manometer or gauge to the dipstick tube.

STEP 4 Start the engine and observe the gauge at idle and at 2,500 RPM. ● **SEE FIGURE 85–6.**

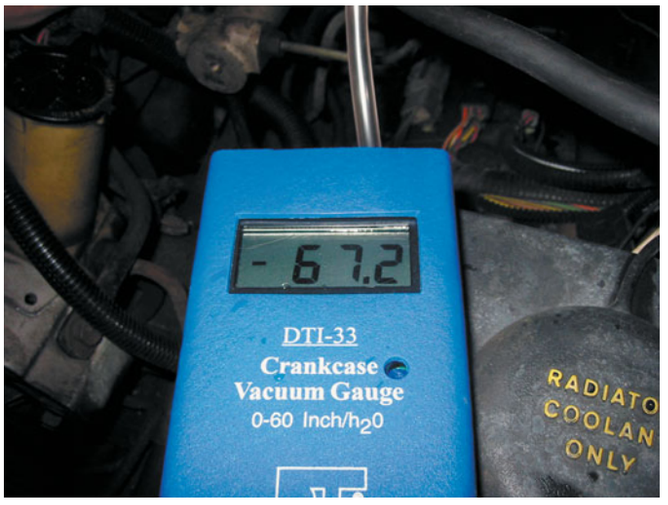

FIGURE 85–6 Using a gauge that measures vacuum in units of inches of water to test the vacuum at the dipstick tube, being sure that the PCV system is capable of drawing a vacuum on the crankcase (28 in. H_2O = 1 PSI, or about 2 in. Hg of vacuum).

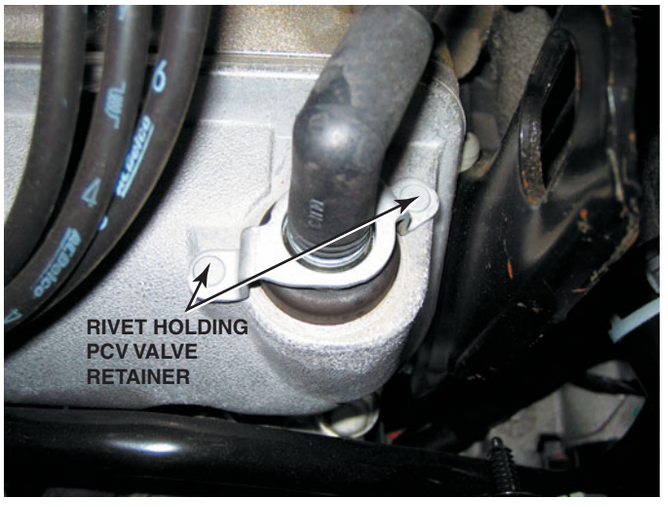

FIGURE 85–7 Most PCV valves used on newer vehicles are secured with fasteners, making it more difficult to disconnect and thereby less likely to increase emissions.

FREQUENTLY ASKED QUESTION

What Are the Wires for at the PCV Valve?

Ford uses an electric heater to prevent ice from forming inside the PCV valve and causing blockage.

Water is a by-product of combustion, and resulting moisture can freeze when the outside air temperature is low. General Motors and others clip a heater hose to the PCV hose to provide the heat needed to prevent an ice blockage.

The gauge should show some vacuum, especially at 2,500 RPM. If not, carefully inspect the PCV system for blockages or other faults.

PCV MONITOR. Starting with 2004 and newer vehicles, all vehicle PCMs monitor the PCV system for proper operation as part of the OBD-II system. The PCV monitor will fail if the PCM detects an opening between the crankcase and the PCV valve or between the PCV valve and the intake manifold. ● **SEE FIGURE 85–7.**

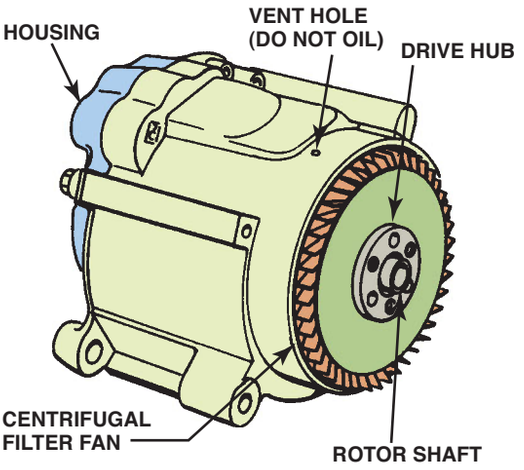

FIGURE 85–8 A typical belt-driven AIR pump. Air enters through the revolving fins behind the drive pulley. The fins act as an air filter because dirt is heavier than air, and therefore the dirt is deflected off of the fins at the same time air is being drawn into the pump.

SECONDARY AIR-INJECTION SYSTEM

PURPOSE AND FUNCTION The **secondary air-injection (SAI)** system provides the air necessary for the oxidizing process either at the exhaust manifold or inside the catalytic converter.

NOTE: This system is commonly called AIR, meaning air-injection reaction. Therefore, an AIR pump does pump air.

PARTS AND OPERATION The SAI pump, also called an AIR pump, a **smog pump,** or **thermactor pump,** is mounted at the front of the engine and can be driven by a belt from the crankshaft pulley. It pulls fresh air in through an external filter and pumps the air under slight pressure to each exhaust port through connecting hoses or a manifold. The typical SAI system includes the following components:

- A belt-driven pump with inlet air filter (older models) (● **SEE FIGURE 85–8.**)
- An electrically driven air pump (newer models)
- One or more air distribution manifolds and nozzles

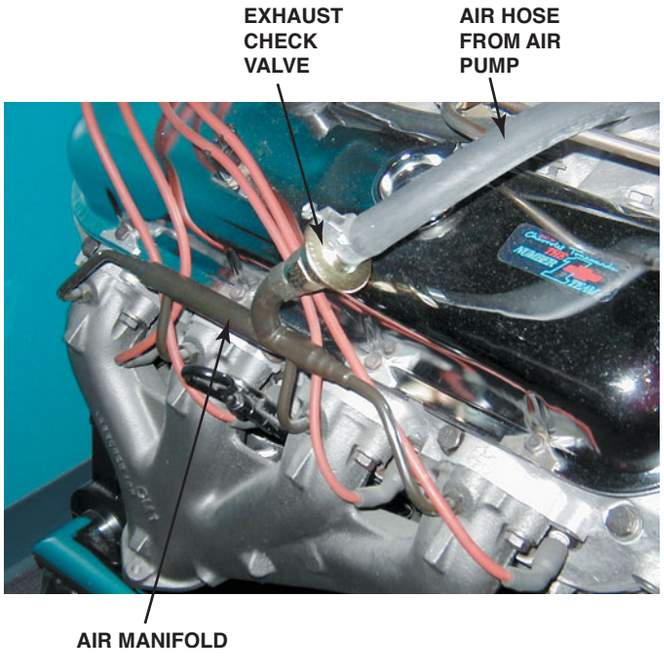

FIGURE 85–9 The external air manifold and exhaust check valve on a restored muscle car engine.

- One or more exhaust check valves
- Connecting hoses for air distribution
- Air management valves and solenoids on all newer applications

With the introduction of NOx reduction converters (also called dual-bed, three-way converters, or TWC), the output of the SAI pump is sent to the center of the converter, where the extra air can help oxidize unburned hydrocarbons (HC) and carbon monoxide (CO) into water vapor (H_2O) and carbon dioxide (CO_2).

The computer controls the airflow from the pump by switching on and off various solenoid valves.

AIR DISTRIBUTION MANIFOLDS AND NOZZLES

The secondary air-injection system sends air from the pump to a nozzle installed near each exhaust port in the cylinder head. This provides equal air injection for the exhaust from each cylinder and makes it available at a point in the system where exhaust gases are the hottest.

Air is delivered to the exhaust system in one of two ways:

1. An external air manifold, or manifolds, distributes the air through injection tubes with stainless-steel nozzles. The nozzles are threaded into the cylinder heads or exhaust manifolds close to each exhaust valve. This method is used primarily with smaller engines.
2. An internal air manifold distributes the air to the exhaust ports near each exhaust valve through passages cast in the cylinder head or the exhaust manifold. This method is used mainly with larger engines.

EXHAUST CHECK VALVES

All air-injection systems use one or more one-way check valves to protect the air pump and other components from reverse exhaust flow. A **check valve** contains a spring-type metallic disc or reed that closes under exhaust back pressure. Check valves are located between the air manifold and the switching valve(s). If exhaust pressure exceeds injection pressure or if the air pump fails, the check valve spring closes the valve to prevent reverse exhaust flow. ● **SEE FIGURE 85–9.**

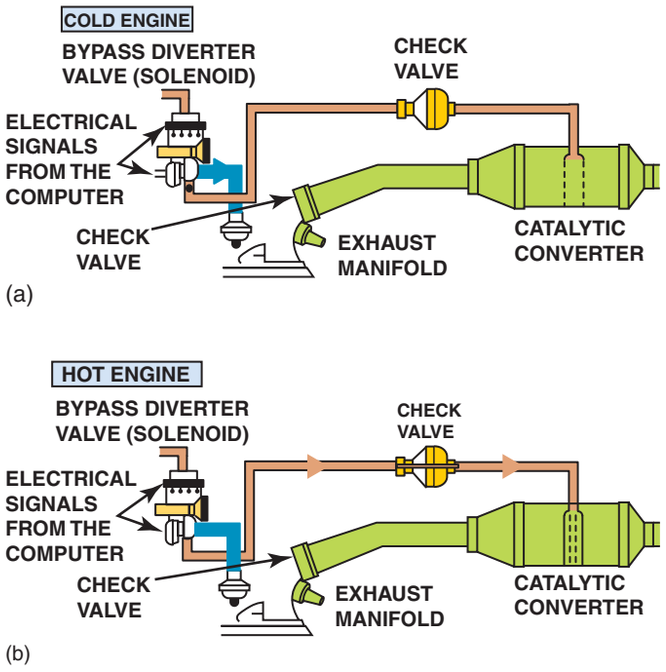

FIGURE 85–10 (a) When the engine is cold and before the oxygen sensor is hot enough to achieve closed loop, the airflow from the air pump is directed to the exhaust manifold(s) through the one-way check valves, which keep the exhaust gases from entering the switching solenoids and the pump itself. (b) When the engine achieves closed loop, the air is directed to the catalytic converter.

NOTE: These check valves commonly fail, resulting in excessive exhaust emissions (CO, especially). When the check valve fails, hot exhaust can travel up to and destroy the switching valve(s) and air pump itself.

BELT-DRIVEN AIR PUMPS

The belt-driven air pump uses a centrifugal filter just behind the drive pulley. As the pump rotates, underhood air is drawn into the pump and slightly compressed. The system uses either vacuum- or solenoid-controlled diverter valves to air directed to the following:

- The exhaust manifold, when the engine is cold to help oxidize carbon monoxide (CO) and unburned hydrocarbons (HC) into carbon dioxide (CO_2) and water vapor (H_2O)
- The catalytic converter when the engine is warm on some models to help provide the extra oxygen needed for the efficient conversion of CO and HC into CO_2 and H_2O
- The air cleaner, during deceleration or wide-open throttle (WOT) engine operation ● **SEE FIGURE 85–10.**

ELECTRIC MOTOR–DRIVEN AIR PUMPS

This style of pump is generally used only during cold engine operation and is computer controlled. The secondary air-injection (SAI) system helps reduce hydrocarbons (HC) and carbon monoxide (CO). The air flowing to the exhaust manifold also helps to warm the three-way catalytic converters quickly on engine start-up so conversion of exhaust gases may occur sooner:

- The SAI pump solenoids are controlled by the PCM. The PCM turns on the SAI pump by providing the ground to complete the circuit, which energizes the SAI pump solenoid relay. When air to the exhaust ports is desired, the PCM energizes the relay in order to turn on the solenoid and the SAI pump. ● **SEE FIGURE 85–11.**

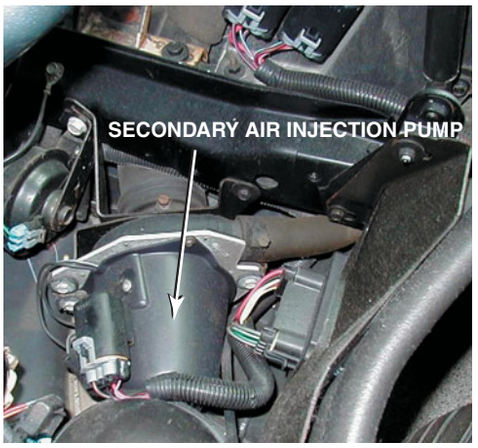

FIGURE 85–11 A typical electric motor–driven SAI pump. This unit is on a Chevrolet Corvette and only works when the engine is cold.

- The PCM turns on the SAI pump during start-up any time the engine coolant temperature is above 32°F (0°C). A typical electric SAI pump operates for a maximum of four minutes or until the system enters closed-loop operation.

SECONDARY AIR-INJECTION SYSTEM DIAGNOSIS

SYMPTOMS The air pump system should be inspected if an exhaust emissions test failure occurs. In severe cases, the exhaust will enter the air cleaner assembly, resulting in a horribly running engine because the extra exhaust displaces the oxygen needed for proper combustion. With the engine running, check for normal operation. ● **SEE CHART 85–1.**

VISUAL INSPECTION Carefully inspect all parts of the SAI system, including the following:

- Hoses and pipes (Any that have holes and leak air or exhaust require replacement.)
- Check valve(s), when a pump has become inoperative
- Exhaust gases, which could have gotten past the check valve and damaged the pump (Look for signs of overheated areas upstream from the check valves. In severe cases, the exhaust can enter the air cleaner assembly, destroying the air filter and greatly reducing engine power.)
- Drive belt on an engine-driven pump, for wear and proper tension (If the belt is worn or damaged, check that the AIR pump rotates.)

Engine Operation	Normal Operation of a Typical SAI System
Cold engine (open-loop operation)	Air is diverted to the exhaust manifold(s) or cylinder head
Warm engine (closed-loop operation)	Air is diverted to the catalytic converter
Deceleration	Air is diverted to the air cleaner assembly
Wide-open throttle	Air is diverted to the air cleaner assembly

CHART 85–1

FOUR-GAS EXHAUST ANALYSIS An SAI system can be easily tested using an exhaust gas analyzer and the following steps:

1. Start the engine and allow it to run until normal operating temperature is achieved.
2. Connect the analyzer probe to the tailpipe and observe the exhaust readings for hydrocarbons (HC) and carbon monoxide (CO).
3. Using the appropriate pinch-off pliers, shut off the airflow from the SAI system. Observe the HC and CO readings. If the SAI system is working correctly, the HC and CO levels should increase when the SAI system is shut off.
4. Record the O_2 reading with the SAI system still inoperative. Unclamp the pliers and watch the O_2 readings. If the system is functioning correctly, the O_2 level should increase by 1% to 4%.

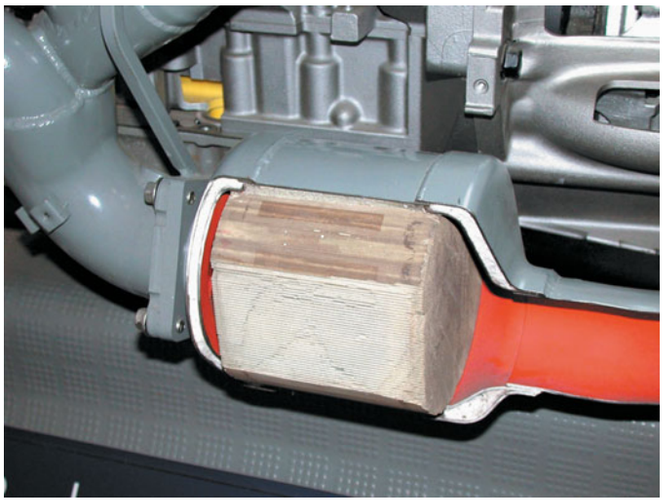

FIGURE 86–1 Most catalytic converters are located as close to the exhaust manifold as possible, as seen in this display of a Chevrolet Corvette.

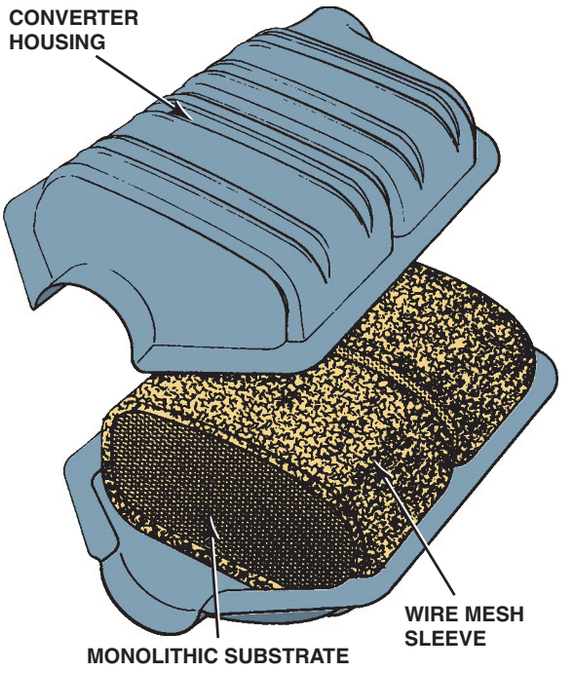

FIGURE 86–2 A typical catalytic converter with a monolithic substrate.

CATALYTIC CONVERTERS

PURPOSE AND FUNCTION

A **catalytic converter** is an after-treatment device used to reduce exhaust emissions outside of the engine. The catalytic converter uses a *catalyst:*

- A **catalyst** is a chemical that helps start a chemical reaction but does not enter into the chemical reaction.
- The catalyst materials on the surface of the material inside the converter help create a chemical reaction.
- The chemical reaction changes harmful exhaust emissions into nonharmful exhaust emissions.
- The *converter* therefore converts harmful exhaust gases into water vapor (H_2O) and carbon dioxide (CO_2).

This device is installed in the exhaust system between the exhaust manifold and the muffler and usually is positioned beneath the passenger compartment. The location of the converter is important since as much of the exhaust heat as possible must be retained for effective operation. The nearer it is to the engine, the better. ● **SEE FIGURE 86–1.**

CATALYTIC CONVERTER CONSTRUCTION

Most catalytic converters are constructed of a ceramic material in a honeycomb shape with square openings for the exhaust gases:

- There are approximately 400 openings per square inch (62 per sq. cm), and the wall thickness is about 0.006 inch (1.5 mm).
- The substrate is then coated with a porous aluminum material called the **washcoat,** which makes the surface rough.
- The catalytic materials are then applied on top of the washcoat. The substrate is contained within a round or oval shell made by welding together two stamped pieces of aluminum or stainless steel. ● **SEE FIGURE 86–2.**

The ceramic substrate in monolithic converters is not restrictive; however, the converter can be physically broken if exposed to shock or severe jolts. Monolithic converters can be serviced only as a unit.

An exhaust pipe is connected to the manifold or header to carry gases through a catalytic converter and then to the muffler or silencer. V-type engines can use dual converters or route the exhaust into one catalytic converter by using a Y-exhaust pipe.

CATALYTIC CONVERTER OPERATION

The converter substrate contains small amounts of **rhodium, palladium,** and **platinum.** These elements act as catalysts. As mentioned, a catalyst is an element that starts a chemical reaction without becoming a part of, or being consumed in, the process. In a **three-way** (catalytic) **converter (TWC)** all three exhaust emissions (NO_x, HC, and CO) are converted to carbon dioxide (CO_2) and water (H_2O). As the exhaust gas passes through the catalyst, oxides of nitrogen (NO_x) are chemically reduced (that is, nitrogen and oxygen are separated) in the first section of the catalytic converter. In the second section of the catalytic converter, most of the hydrocarbons and carbon monoxide remaining in the exhaust gas are oxidized to form harmless carbon dioxide (CO_2) and water vapor (H_2O). ● **SEE FIGURE 86–3.**

Since the early 1990s, many converters also contain **cerium,** an element that can store oxygen. The purpose of the cerium is to provide oxygen to the oxidation bed of the converter when the exhaust is rich and lacks enough oxygen for proper oxidation. When the exhaust is lean, the cerium absorbs the extra oxygen. For the most efficient operation, the converter should have a 14.7:1 air-fuel ratio but can use a mixture that varies slightly:

- A rich exhaust is required for reduction–stripping the oxygen (O_2) from the nitrogen in NO_x.
- A lean exhaust is required to provide the oxygen necessary to oxidize HC and CO (combining oxygen with HC and CO to form H_2O and CO_2).

If the catalytic converter is not functioning correctly, ensure that the air-fuel mixture being supplied to the engine is correct and that the ignition system is free of defects.

CONVERTER LIGHT-OFF TEMPERATURE

The catalytic converter does not work when cold, so it must be heated to its **light-off temperature** of close to 500°F (260°C) before it starts working at 50% effectiveness. When fully effective, the converter reaches a

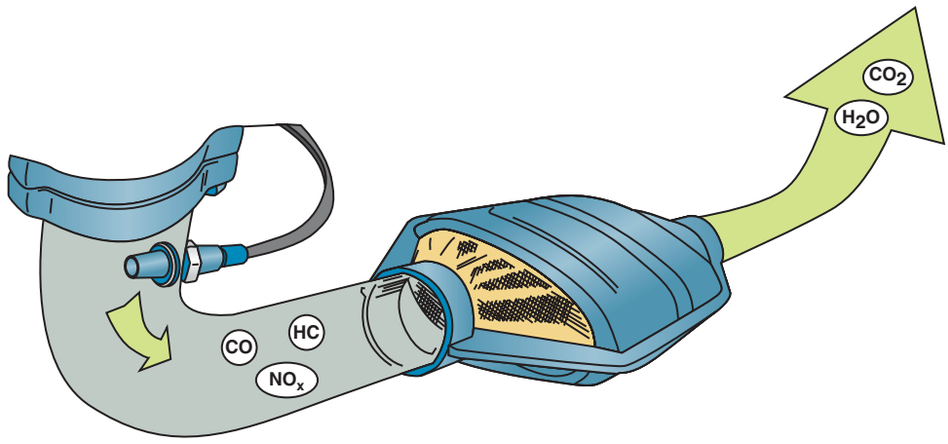

FIGURE 86–3 The three-way catalytic converter first separates the NO_x into nitrogen and oxygen and then converts the HC and CO into harmless water (H_2O) and carbon dioxide (CO_2). The nitrogen (N) passes through the converter and exits the tailpipe and enters the atmosphere which is about 78% nitrogen.

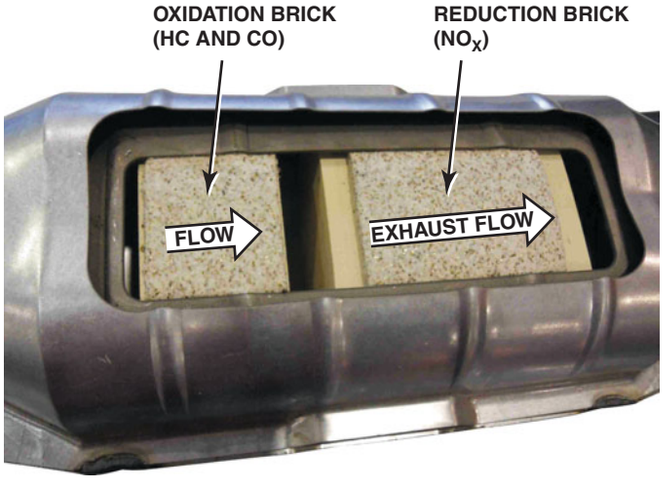

FIGURE 86–4 The small oxidation section of the converter helps build heat for the reduction section to reduce NO_x emissions in the rear brick on most newer vehicles.

temperature range of 900°F to 1,600°F (482°C to 871°C). In spite of the intense heat, however, catalytic reactions do not generate a flame associated with a simple burning reaction. Because of the extreme heat (almost as hot as combustion chamber temperatures), a converter remains hot long after the engine is shut off. Most vehicles use a series of heat shields to protect the passenger compartment and other parts of the chassis from excessive heat. Vehicles have been known to start fires because of the hot converter causing tall grass or dry leaves beneath the just-parked vehicle to ignite, especially if the engine is idling. This is most likely to occur if the heat shields have been removed from the converter.

CONVERTER USAGE A catalytic converter must be located as close as possible to the exhaust manifold to work effectively. The farther back the converter is positioned in the exhaust system, the more the exhaust gases cool before they reach the converter. Since positioning in the exhaust system affects the oxidation process, vehicle manufacturers that use only an oxidation converter generally locate it underneath the front of the passenger compartment.

Some vehicles have used a small, quick heating oxidation converter called a **preconverter** or a **pup (mini) converter** that connects directly to the exhaust manifold outlet. These have a small catalyst surface area close to the engine that heats up rapidly to start the oxidation process more quickly during cold engine warm-up. For this reason, they were often called **light-off converters (LOCs).** The larger main converter, under the passenger compartment, completes the oxidation reaction started in the LOC.

Most older vehicles used a catalytic converter that had the reduction section first to separate the oxygen from the nitrogen in NOx. The oxygen released during this action help provide extra oxygen to help oxidize the HC and CO into harmless water (H_2O) and carbon dioxide (CO_2). However, since 2004, emission standards for oxides of nitrogen are stricter, and therefore a larger reduction section is often needed. Therefore, the reduction section is now often after the oxidation section, which is the opposite of the way it was in converters for older models. ● **SEE FIGURE 86–4.**

OBD-II CATALYTIC CONVERTER PERFORMANCE The PCM determines if the catalytic converter is ready for testing based on the following conditions, which may vary by vehicle make, model, and year:

- Closed-loop status achieved
- IAT sensor temperature higher than 32°F (0°C)
- ECT sensor temperature higher than 165°F (18°C)
- MAF sensor input from 15 to 32 g/sec
- Engine load less than 65% and steady
- Engine speed less than 4,000 RPM
- All of the above conditions met for at least four minutes

These factors are the enable criteria that must be achieved before the OBD-II catalyst monitor will run.

OBD-II CATALYTIC CONVERTER PERFORMANCE

With OBD-II-equipped vehicles, catalytic converter performance is monitored by a heated oxygen sensor (HO_2S) both before and after the converter. ● **SEE FIGURE 86–5.**

The converters used on these vehicles have **oxygen storage capacity (OSC),** due mostly to the cerium coating in the catalyst rather than the precious metals used. When the three-way converter

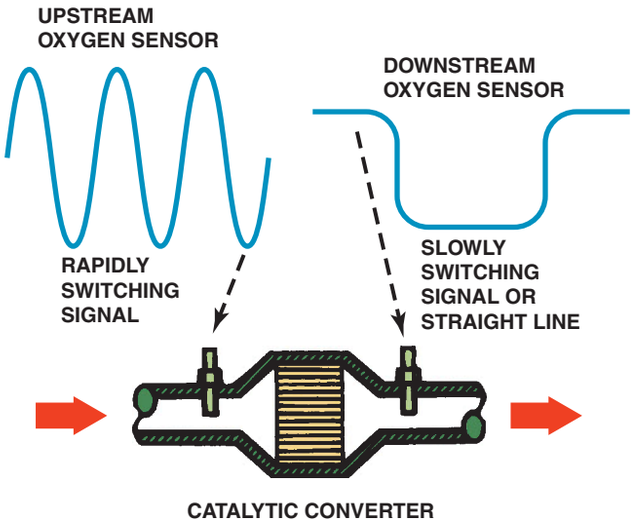

FIGURE 86–5 The OBD-II catalytic converter monitor compares the signals of upstream and downstream oxygen sensors to determine converter efficiency.

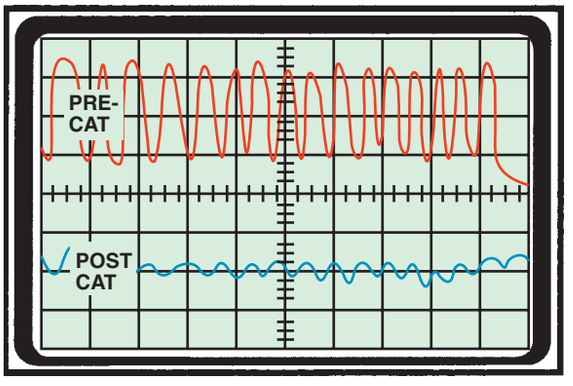

FIGURE 86–6 The waveform of a downstream O2S sensor from a properly functioning converter shows little, if any, activity.

(TWC) is operating as it should, the postconverter HO_2S is far less active than the preconverter sensor. The converter stores, then releases, the oxygen during normal reduction and oxidation of the exhaust gases, smoothing out the variations in oxygen being released.

Where a cycling sensor voltage output is expected before the converter, because of the converter action, the postconverter HO_2S should read a steady signal with little fluctuation. ● **SEE FIGURE 86–6.**

NOTE: Because of more demanding exhaust emission standards for oxides of nitrogen (NO_x) starting in 2004, the reduction part of the converter is now usually located downstream from the oxidation section. This is opposite of the way an older style converter was constructed. With better fuel injection systems and ignition systems, the amount of CO and HC exhaust emissions is lower than in the past. By using the oxidation section first creates heat to help the reduction section better control oxides of nitrogen emissions. The rear "brick" or reduction section is also larger than the oxidation section.

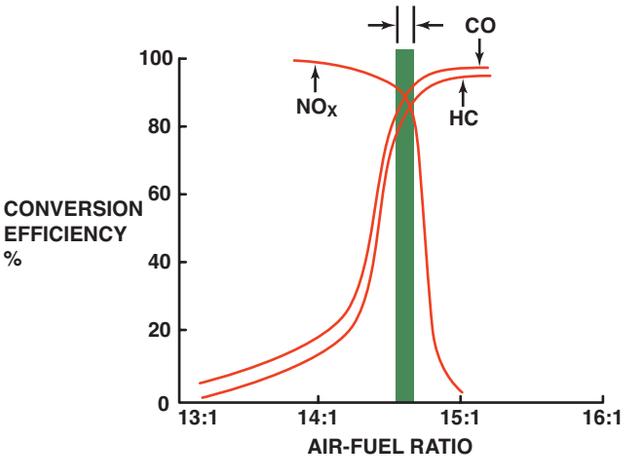

FIGURE 86–7 The highest catalytic converter efficiency occurs when the air-fuel mixture is about 14.7:1.

CONVERTER-DAMAGING CONDITIONS

Since converters have no moving parts, they require no periodic service. Under federal law, catalyst effectiveness is warranted for 80,000 miles or eight years.

The three main causes of premature converter failure are the following:

- **Contamination.** Substances that can destroy the converter include exhaust that contains excess engine oil, antifreeze, sulfur (from poor fuel), and various other chemical substances.
- **Excessive temperatures.** Although a converter operates at high temperatures, it can be destroyed by excessive temperatures. This most often occurs either when too much unburned fuel enters the converter, or with excessively lean mixtures. Excessive temperatures may be caused by long idling periods on some vehicles since more heat develops at those times than when driving at normal highway speeds. Severe high temperatures can cause the converter to melt down, leading to the internal parts breaking apart and either clogging the converter or moving downstream to plug the muffler. In either case, the restricted exhaust flow severely reduces engine power.
- **Improper air-fuel mixtures.** Rich mixtures or raw fuel in the exhaust can be caused by engine misfiring or an excessively rich air-fuel mixture resulting from a defective coolant temp sensor or defective fuel injectors. Lean mixtures are commonly caused by intake manifold leaks. When either of these circumstances occurs, the converter can become a catalytic furnace, causing the previously described damage. For most efficient catalytic converter operation, the air-fuel mixture should be near 14.7:1. ● **SEE FIGURE 86–7.**

To avoid excessive catalyst temperatures and the possibility of fuel vapors reaching the converter, observe the following rules:

1. Do not use fuel additives or cleaners that are not converter safe.
2. Do not crank an engine for more than 40 seconds when it is flooded or misfiring.
3. Do not turn off the ignition switch when the vehicle is in motion.
4. Do not disconnect a spark plug wire for more than 30 seconds.
5. Repair engine problems such as dieseling, misfiring, or stumbling as soon as possible.

DIAGNOSING CATALYTIC CONVERTERS

TAP TEST The simple **tap test** involves tapping (not pounding) on the catalytic converter using a rubber mallet. If the substrate inside the converter is broken, the converter will rattle when hit. If the converter rattles, a replacement converter is required. ● **SEE FIGURE 86–8.**

TESTING BACK PRESSURE WITH A PRESSURE GAUGE Exhaust system back pressure can be measured directly by installing a pressure gauge in an exhaust opening. This can be accomplished in one of the following ways:

1. To test backpressure, remove the inside of an old, discarded oxygen sensor and thread in an adapter to convert it to a vacuum or pressure gauge.

   NOTE: An adapter can be easily made by inserting a metal tube or pipe into an old oxygen sensor housing. A short section of brake line works great. The pipe can be brazed to the oxygen sensor housing, or it can be glued with epoxy. An 18-mm compression gauge adapter can also be adapted to fit into the oxygen sensor opening. ● **SEE FIGURE 86–9.**

FIGURE 86–8 A catalytic converter that rattles when tapped was removed, and the substrate, or what was left of it, fell out. This converter has to be replaced and the root cause of why it failed found and corrected.

FREQUENTLY ASKED QUESTION

Can a Catalytic Converter Be Defective without Being Clogged?

Yes. Catalytic converters can fail by being chemically damaged or poisoned without being mechanically clogged. Therefore, the catalytic converter should be tested not only for physical damage (clogging) by performing a back pressure or vacuum test and a rattle test but also for temperature rise, usually with a pyrometer or propane test, to check the efficiency of the converter.

2. To test the exhaust back pressure at the exhaust gas recirculation (EGR) valve, remove the EGR valve and fabricate a plate equipped with a fitting for a pressure gauge.
3. To test at the secondary air-injection (SAI) check valve, remove the check valve from the exhaust tubes leading to the exhaust manifold. Use a rubber cone with a tube inside to seal against the exhaust tube. Connect the tube to a pressure gauge.

At idle, the maximum back pressure should be less than 1.5 PSI (10 kPa), and it should be less than 2.5 PSI (15 kPa) at 2,500 RPM. Pressure readings higher than these indicate that the exhaust system is restricted, and further testing will be needed to determine the location of the restriction. ● **SEE FIGURE 86–10.**

TESTING FOR BACK PRESSURE USING A VACUUM GAUGE An exhaust restriction can be tested indirectly by checking the intake manifold vacuum with the engine operating at a fast idle speed (about 2,500 RPM). If the exhaust is restricted, some exhaust can pass, and the effect may not be noticeable when the engine is at idle speed. However, when the engine is operating at a higher speed,

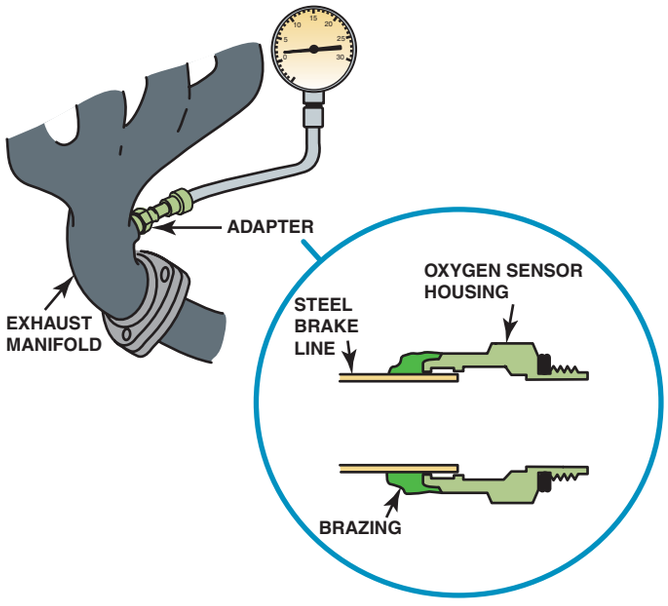

FIGURE 86–9 A back pressure tool can be made by using an oxygen sensor housing and epoxy or braze to hold the tube to the housing.

FIGURE 86–10 This partially melted catalytic converter tested okay at idle but had excessive back pressure at higher engine speeds.

the exhaust gases can build up behind the restriction and eventually will not be able to leave the combustion chamber. When some of the exhaust is left behind at the end of the exhaust stroke, the resulting pressure in the combustion chamber reduces engine vacuum. To test for an exhaust restriction using a vacuum gauge, perform the following steps:

STEP 1 Attach a vacuum gauge to an intake manifold vacuum source.

STEP 2 Start the engine. Record the engine manifold vacuum reading. The engine vacuum should read 17 to 21 in. Hg when the engine is at idle speed.

STEP 3 Increase the engine speed to 2,500 RPM and hold that speed for 60 seconds while looking at the vacuum gauge.

Results

- If the vacuum reading is equal to or higher than the vacuum reading when the engine was at idle speed, the exhaust system is *not* restricted.
- If the vacuum reading is lower than the vacuum reading when the engine was at idle speed, then the exhaust *is* restricted. Further testing will be needed to determine the location of the restriction.

TESTING A CATALYTIC CONVERTER FOR TEMPERATURE RISE

A properly working catalytic converter should be able to reduce NO_x exhaust emissions into nitrogen (N) and oxygen (O_2) and oxidize unburned hydrocarbon (HC) and carbon monoxide (CO) into harmless carbon dioxide (CO_2) and water vapor (H_2O). During these chemical processes, the catalytic converter should increase in temperature at least 10% if the converter is working properly. To test the converter, operate the engine at 2,500 RPM for at least two minutes to fully warm the converter. Measure the inlet and the outlet temperatures using an infrared pyrometer as show in ● **FIGURE 86–11.**

NOTE: If the engine is extremely efficient, the converter may not have any excessive unburned hydrocarbons or carbon monoxide to convert! In this case, a spark plug wire could be grounded out using a vacuum hose and a test light to create some unburned hydrocarbon in the exhaust. Do not ground out a cylinder for longer than 10 seconds, or the excessive amount of unburned hydrocarbon could overheat and damage the converter.

CATALYTIC CONVERTER EFFICIENCY TESTS

The efficiency of a catalytic converter can be determined using an exhaust gas analyzer:

- **Oxygen level test.** With the engine warm and in closed loop, check the oxygen (O_2) and carbon monoxide (CO) levels. A good converter should be able to oxide the extra hydrocarbons caused by the rapid acceleration:
  - If O_2 is zero, go to the snap-throttle test.
  - If O_2 is greater than zero, check the CO level.
  - If CO is greater than zero, the converter is *not* functioning correctly.

FIGURE 86–11 The temperature of the outlet should be at least 10% hotter than the temperature of the inlet. If a converter is not working, the inlet temperature will be hotter than the outlet temperature.

TECH TIP

Aftermarket Catalytic Converters

Some replacement aftermarket (nonfactory) catalytic converters do not contain the same amount of cerium as the original part. Cerium is the element that is used in catalytic converters to store oxygen. As a result of the lack of cerium, the correlation between the oxygen storage and the conversion efficiency may be affected enough to set a false diagnostic trouble code (P0422).

NOTE: If an aftermarket converter is being installed, be sure that the distance between the rear of the catalyst block is the same distance from the rear oxygen sensor as the factory converter to be ensured of proper operation. Always follow the instructions that come with the replacement converter. ● **SEE FIGURE 86–12.**

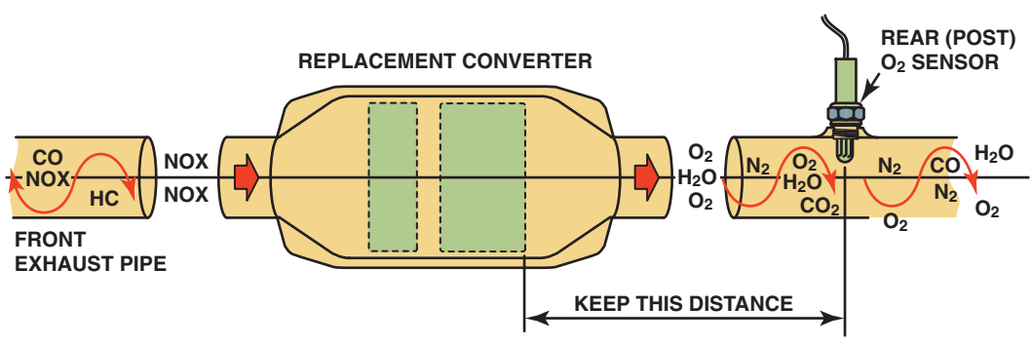

FIGURE 86–12 Whenever replacing a catalytic converter with a universal unit, first measure the distance between the rear brick and the center of the rear oxygen sensor. Be sure that the replacement unit is installed to the same dimension.

- **Snap-throttle test.** With the engine warm and in closed loop, snap the throttle to wide-open throttle (WOT) in park or neutral and observe the oxygen reading:
  - The O_2 reading should not exceed 1.2%; if it does, the converter is *not* working.
  - If the O_2 rises to 1.2%, the converter may have low efficiency.
  - If the O_2 remains below 1.2%, then the converter is okay.

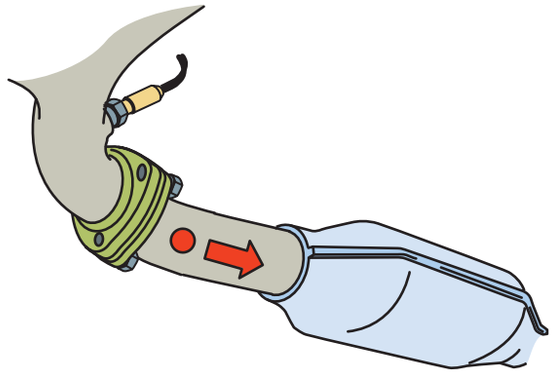
CATALYTIC CONVERTER REPLACEMENT GUIDELINES

Because a catalytic converter is a major exhaust gas emission control device, the U.S. Environmental Protection Agency (EPA) has strict guidelines for its replacement, including the following:

- If a converter is replaced on a vehicle with less than 80,000 miles or eight years, depending on the year of the vehicle, an original equipment catalytic converter *must* be used as a replacement.
- The replacement converter must be of the same design as the original. If the original had an AIR pump fitting, so must the replacement.
- The old converter must be kept for possible inspection by the authorities for 60 days.
- A form must be completed and signed by both the vehicle owner and a representative from the service facility. This form must state the cause of the converter failure and must remain on file for two years.

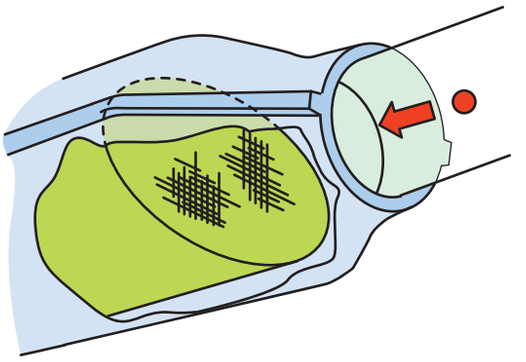
TECH TIP

Catalytic Converters Are Murdered



Catalytic converters start a chemical reaction but do not enter into the chemical reaction. Therefore, catalytic converters neither wear out nor die of old age. If a catalytic converter is found to be defective (nonfunctioning or clogged), look for the *root* cause. Remember this:

"Catalytic converters do not commit suicide–they're murdered."



Items that should be checked when a defective catalytic converter is discovered include all components of the ignition and fuel systems. Excessive unburned fuel can cause the catalytic converter to overheat and fail. The oxygen sensor must be working and fluctuating from 0.5 to 5 Hz (times per second) to provide the necessary air-fuel mixture variations for maximum catalytic converter efficiency.

ON-BOARD DIAGNOSTICS GENERATION-II (OBD-II) SYSTEMS

PURPOSE AND FUNCTION OF OBD II

During the 1980s, most manufacturers began equipping their vehicles with full-function control systems capable of alerting the driver of a malfunction and of allowing the technician to retrieve codes that identify circuit faults. These early diagnostic systems were meant to reduce emissions and speed up vehicle repair.

The automotive industry calls these systems **On-Board Diagnostics (OBDs).** The **California Air Resources Board (CARB)** developed the first regulation requiring manufacturers selling vehicles in that state to install OBD. OBD Generation I (OBD I) applies to all vehicles sold in California beginning with the 1988 model year. It specifies the following requirements:

1. An instrument panel warning lamp able to alert the driver of certain control system failures, now called a **malfunction indicator lamp (MIL).** ● **SEE FIGURE 87–1.**
2. The system's ability to record and transmit diagnostic trouble codes (DTCs) for emission-related failures.
3. Electronic system monitoring of the HO2S, EGR valve, and evaporative purge solenoid. Although not U.S. EPA-required, during this time most manufacturers also equipped vehicles sold outside of California with OBD I.

By failing to monitor the catalytic converter, the evaporative system for leaks, and the presence of engine misfire, OBD I did not do enough to lower automotive emissions. This led the CARB and the EPA to develop OBD Generation II (OBD II).

FIGURE 87–1 A typical malfunction indicator lamp (MIL) often labeled "check engine" or "service engine soon" (SES).

OBD-II OBJECTIVES

Generally, the CARB defines an OBD-II-equipped vehicle by its ability to do the following:

1. Detect component degradation or a faulty emission-related system that prevents compliance with federal emission standards.
2. Alert the driver of needed emission-related repair or maintenance.
3. Use standardized DTCs and accept a generic scan tool.

These requirements apply to all 1996 and later model light-duty vehicles. The Clean Air Act of 1990 directed the EPA to develop new regulations for OBD. The primary purpose of OBD II is emission-related, whereas the primary purpose of OBD I (1988) was to detect faults in sensors or sensor circuits. OBD-II regulations require that not only sensors be tested but also all exhaust emission control devices, and that they be verified for proper operation.

All new vehicles must pass the **Federal Test Procedure (FTP)** for exhaust emissions while being tested for 1874 seconds on dynamometer rollers that simulate the urban drive cycle around downtown Los Angeles.

NOTE: IM 240 is simply a shorter 240-second version of the 505-second federal test procedure.

The regulations for OBD-II vehicles state that the vehicle computer must be capable of testing for, and determining, if the exhaust emissions are within 1.5 times the FTP limits. To achieve this goal, the computer must do the following:

1. Test all exhaust emission system components for correct operation.
2. Actively operate the system and measure the results.
3. Continuously monitor all aspects of the engine operation to be certain that the exhaust emissions do not exceed 1.5 times the FTP.
4. Check engine operation for misfire.
5. Turn on the MIL (check engine) if the computer senses a fault in a circuit or system.
6. Record a **freeze-frame,** which is a snapshot of important engine data at the time the DTC was set.
7. Flash the MIL if an engine misfire occurs that could damage the catalytic converter.

DIAGNOSTIC EXECUTIVE AND TASK MANAGER

On OBD-II systems, the powertrain control module (PCM) incorporates a special segment of software. On Ford and GM systems, this software is called the **diagnostic executive.** On Chrysler systems, it is called the **task manager.** This software program is designed to manage the operation of all OBD-II monitors by controlling the sequence of steps necessary to execute the diagnostic tests and monitors.

MONITORS

A monitor is an organized method of testing a specific part of the system. Monitors are simply tests that the computer performs to evaluate components and systems. If a component or system failure is detected while a monitor is running, a DTC will be stored and the MIL illuminated during the second trip. The two types of monitors are continuous and noncontinuous.

CONTINUOUS MONITORS

As required conditions are met, continuous monitors begin to run. These continuous monitors will run for the remainder of the vehicle drive cycle. The three continuous monitors are as follows:

- **Comprehensive component monitor (CCM).** This monitor watches the sensors and actuators in the OBD-II system. Sensor values are constantly compared with known-good values stored in the PCM's memory.

  The CCM is an internal program in the PCM designed to monitor a failure in any electronic component or circuit (including emission-related and non-emission-related circuits) that provide input or output signals to the PCM. The PCM considers that an input or output signal is inoperative when a failure exists due to an open circuit, out-of-range value, or if an onboard rationality check fails. If an emission-related fault is detected, the PCM will set a code and activate the MIL (requires two consecutive trips).

  Many PCM sensors and output devices are tested at key-on or immediately after engine start-up. However, some devices are only tested by the CCM after the engine meets certain engine conditions. The number of times the CCM must detect a fault before it will activate the MIL depends upon the manufacturer, but most require two consecutive trips to activate the MIL. The components tested by the CCM include:

  Four-wheel-drive low switch
  Brake switch
  Camshaft (CMP) and crankshaft (CKP) sensors
  Clutch switch (manual transmissions/transaxles only)
  Cruise servo switch
  Engine coolant temperature (ECT) sensor
  EVAP purge sensor or switch
  Fuel composition sensor
  Intake air temperature (IAT) sensor
  Knock sensor (KS)
  Manifold absolute pressure (MAP) sensor
  Mass airflow (MAF) sensor
  Throttle-position (TP) sensor
  Transmission temperature sensor
  Transmission turbine speed sensor
  Vacuum sensor
  Vehicle speed (VS) sensor
  EVAP canister purge and EVAP purge vent solenoid
  Idle air control (IAC)
  Ignition control system
  Transmission torque converter clutch solenoid
  Transmission shift solenoids

- **Misfire monitor.** This monitor watches for engine misfire. The PCM uses the information received from the crankshaft position sensor (CKP) to calculate the time between the edges of the reluctor, as well as the rotational speed and acceleration. By comparing the acceleration of each firing event, the PCM can determine if a cylinder is not firing correctly.

  Misfire type A. Upon detection of a misfire type A (200 revolutions), which would cause catalyst damage, the MIL will blink once per second during the actual misfire, and a DTC will be stored.

  Misfire type B. Upon detection of a misfire type B (1,000 revolutions), which will exceed 1.5 times the EPA federal test procedure (FTP) standard or cause a vehicle to fail an inspection and maintenance tailpipe emissions test, the MIL will illuminate and a DTC will be stored.

  The DTC associated with multiple cylinder misfire for a type A or type B misfire is DTC P0300. The DTCs associated with an individual cylinder misfire for a type A or type B misfire are DTCs P0301, P0302, P0303, P0304, P0305, P0306, P0307, P0308, P0309, and P0310.

- **Fuel trim monitor.** The PCM continuously monitors short- and long-term fuel trim. Constantly updated adaptive fuel tables are stored in long-term memory (KAM), and used by the PCM for compensation due to wear and aging of the fuel system components. The MIL will illuminate when the PCM determines the fuel trim values have reached and stayed at their limits for too long a period of time.

NONCONTINUOUS MONITORS

Noncontinuous monitors run (at most) once per vehicle drive cycle. The noncontinuous monitors are as follows:

O2S monitor
O2S heater monitor
Catalyst monitor
EGR monitor
EVAP monitor
Secondary AIR monitor
Transmission monitor
PCV system monitor
Thermostat monitor

Once a noncontinuous monitor has run to completion, it will not be run again until the conditions are met during the next vehicle drive cycle. Also after a noncontinuous monitor has run to completion, the readiness status on your scan tool will show "complete" or "done" for that monitor. Monitors that have not run to completion will show up on your scanner as "incomplete."

OBD-II MONITOR INFORMATION

COMPREHENSIVE COMPONENT MONITOR

The circuits and components covered by the comprehensive component monitor (CCM) do not include those directly monitored by another monitor.

However, OBD II also requires that inputs from powertrain components to the PCM be tested for **rationality,** and that outputs to powertrain components from the PCM be tested for **functionality.** Both inputs and outputs are to be checked *electrically.* Rationality checks refer to a PCM comparison of input values to values from other sensors to determine if they make sense and are normal (rational).

Example:

TPS	3 V
MAP	18 in./Hg
RPM	700 RPM
PRNDL	Park

NOTE: Comprehensive component monitors are continuous. Therefore enabling conditions do not apply.

- Monitor runs continuously
- Monitor includes sensors, switches, relays, solenoids, and PCM hardware
- All are checked for opens, shorts-to-ground, and shorts-to-voltage
- Inputs are checked for rationality
- Outputs are checked for functionality
- Most are one-trip DTCs
- Freeze-frame is priority 3
- Three consecutive good trips are used to extinguish the MIL
- Forty warm-up cycles are necessary to self erase the DTC and freeze frame
- Two minutes run time without reoccurrence of the fault constitutes a "good trip"

CONTINUOUS RUNNING MONITORS

Continuous monitors run continuously and only stop if they fail and include:

- Fuel system: rich/lean
- Misfire: catalyst damaging/FTP (emissions)
- Two-trip faults (except early generation catalyst damaging misfire)
- MIL, DTC, freeze-frame after two consecutive faults
- Freeze-frame is priority 2 on first trip
- Freeze-frame is priority 4 on maturing trip
- Three consecutive good trips in a similar condition window are used to extinguish the MIL
- Forty warm-up cycles are used to erase DTC and freeze-frame (80 to erase one-trip failure if similar conditions cannot be met)

ONCE PER TRIP MONITORS

- Monitor runs once per trip, pass or fail
- O_2 response, O_2 heaters, EGR, purge flow EVAP leak, secondary air, catalyst
- Two-trip DTCs
- MIL, DTC, freeze-frame after two consecutive faults
- Freeze-frame is priority 1 on first trip
- Freeze-frame is priority 3 on maturing trip
- Three consecutive good trips are used to extinguish the MIL
- Forty warm-up cycles are used to erase DTC and freeze-frame

EXPONENTIALLY WEIGHTED MOVING AVERAGE (EWMA) MONITORS

The **exponentially weighted moving average (EWMA) monitor** is a mathematical method used to determine performance.

This method smooths out any variables in the readings over time and results in a running average. This method is used by some vehicle manufacturers for two monitors.

1. Catalyst monitor
2. EGR monitor

ENABLING CRITERIA

With so many different tests (monitors) to run, the PCM needs an internal director to keep track of when each monitor should run. As mentioned, different manufacturers have different names for this director, such as the diagnostic executive or the task manager. Each monitor has enabling criteria. These criteria are a set of conditions that must be met before the task manager will give the go-ahead for each monitor to run. Most enabling criteria follow simple logic, for example:

- The task manager will not authorize the start of the O2S monitor until the engine has reached operating temperature and the system has entered closed loop.
- The task manager will not authorize the start of the EGR monitor when the engine is at idle, because the EGR is always closed at this time.

Because each monitor is responsible for testing a different part of the system, the enabling criteria can differ greatly from one monitor to the next. The task manager must decide when each monitor should run, and in what order, to avoid confusion.

There may be a conflict if two monitors were to run at the same time. The results of one monitor might also be tainted if a second monitor were to run simultaneously. In such cases, the task manager decides which monitor has a higher priority. Some monitors also depend on the results of other monitors before they can run.

A monitor may be classified as pending if a failed sensor or other system fault is keeping it from running on schedule.

The task manager may suspend a monitor if the conditions are not correct to continue. For example, if the catalyst monitor is running during a road test and the PCM detects a misfire, the catalyst monitor will be suspended for the duration of the misfire.

TRIP

A trip is defined as a key-on condition that contains the necessary conditions for a particular test to be performed followed by a key-off. These conditions are called the **enable criteria.** For example, for the EGR test to be performed, the engine must be at normal operating temperature and decelerating for a minimum amount of time. Some tests are performed when the engine is cold, whereas others require that the vehicle be cruising at a steady highway speed.

WARM-UP CYCLE

Once a MIL is deactivated, the original code will remain in memory until 40 warm-up cycles are completed without the fault reappearing. A warm-up cycle is defined as a trip with an engine temperature increase of at least 40°F and where engine temperature reaches at least 160°F (71°C).

MIL CONDITION: OFF

This condition indicates that the PCM has not detected any faults in an emissions-related component or system, or that the MIL circuit is not working.

FREQUENTLY ASKED QUESTION

What is a Drive Cycle?

A drive cycle is a vehicle being driven under specified speed and times that will allow all monitors to run. In other words, the powertrain control module (PCM) is looking at a series of data points representing speed and time and determines from these data points when the conditions are right to perform a monitor or a test of a component. These data points and therefore the drive cycle are vehicle specific and are not the same for each vehicle. Some common conditions for a drive cycle to successfully run all of the monitors include:

1. Cold start with intake air temperature (IAT) and engine coolant temperature (ECT) close to each other indicating that the engine has cooled to the temperature of the surrounding air temperature.
2. Fuel level within a certain range usually between 15% and 85%.
3. Vehicle speed within a certain speed range for an certain amount of time usually 4 to 12 minutes.
4. Stop and idle for a certain time.

Each monitor requires its own set of parameters needed to run the test and sometimes these conditions cannot be met. For example, some evaporate emissions control (EVAP) systems require a temperature that may not be possible in winter months in a cold climatic area.

A typical universal drive cycle that works for many vehicles includes the following steps.

MIL must be off.
No DTCs present.
Fuel fill between 15% and 85%.
Cold start—Preferred = 8-hour soak at 68°F to 86°F.
Alternative = ECT below 86°F.

STEP 1 With the ignition off, connect scan tool.
STEP 2 Start engine and drive between 20 and 30 mph for 22 minutes, allowing speed to vary.
STEP 3 Stop and idle for 40 seconds, gradually accelerate to 55 mph.
STEP 4 Maintain 55 mph for 4 minutes using a steady throttle input.
STEP 5 Stop and idle for 30 seconds, then accelerate to 30 mph.
STEP 6 Maintain 30 mph for 12 minutes.
STEP 7 Repeat steps 4 and 5 four times.

Using scan tool, check readiness. Always check service information for the exact drive cycle conditions for the vehicle being serviced for best results.

MIL CONDITION: ON STEADY This condition indicates a fault in an emissions-related component or system that could affect the vehicle emission levels.

MIL CONDITION: FLASHING This condition indicates a misfire or fuel control system fault that could damage the catalytic converter.

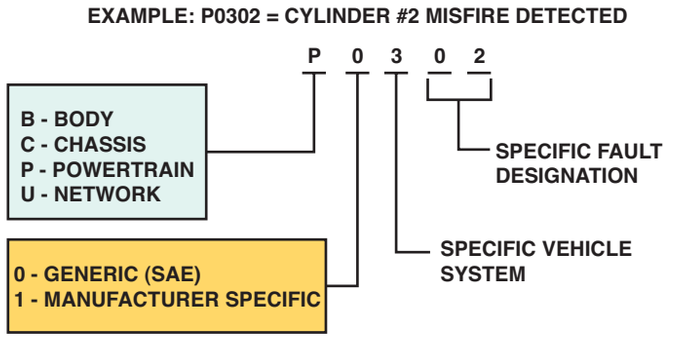

FIGURE 87–2 OBD-II DTC identification format.

NOTE: In a misfire condition with the MIL on steady, if the driver reaches a vehicle speed and load condition with the engine misfiring at a level that could cause catalyst damage, the MIL would start flashing. It would continue to flash until engine speed and load conditions caused the level of misfire to subside. Then the MIL would go back to the on-steady condition. This situation might result in a customer complaint of a MIL with an intermittent flashing condition.

MIL: OFF The PCM will turn off the MIL if any of the following actions or conditions occur:

- The codes are cleared with a scan tool.
- Power to the PCM is removed at the battery or with the PCM power fuse for an extended period of time (may be up to several hours or longer).
- A vehicle is driven on three consecutive trips with a warm-up cycle and meets all code set conditions without the PCM detecting any faults.

The PCM will set a code if a fault is detected that could cause tailpipe emissions to exceed 1.5 times the FTP standard; however, the PCM will not deactivate the MIL until the vehicle has been driven on three consecutive trips with vehicle conditions similar to actual conditions present when the fault was detected. This is not merely three vehicle start-ups and trips. It means three trips during which certain engine operating conditions are met so that the OBD-II monitor that found the fault can run again and pass the diagnostic test.

OBD-II DTC NUMBERING DESIGNATION

A scan tool is required to retrieve DTCs from an OBD-II vehicle. Every OBD-II scan tool will be able to read all generic **Society of Automotive Engineers (SAE)** DTCs from any vehicle. ● **SEE FIGURE 87–2** for definitions and explanations of OBD alphanumeric DTCs. The diagnostic trouble codes (DTCs) are grouped into major categories, depending on the location of the fault on the system involved.

Pxxx codes—powertrain DTCs (engine, transmission-related faults)

Bxxx codes—body DTCs (accessories, interior-related faults)

Cxxx codes—chassis DTCs (suspension and steering-related faults)

Uxxx codes—network DTCs (module communication-related faults)

DTC NUMBERING EXPLANATION The number in the hundredth position indicates the specific vehicle system or subgroup that failed. This position should be consistent for P0xxx and P1xxx type codes. The following numbers and systems were established by SAE:

- P0100—Air metering and fuel system fault
- P0200—Fuel system (fuel injector only) fault
- P0300—Ignition system or misfire fault
- P0400—Emission control system fault
- P0500—Idle speed control, vehicle speed (VS) sensor fault
- P0600—Computer output circuit (relay, solenoid, etc.) fault
- P0700—Transaxle, transmission faults

NOTE: The tens and ones numbers indicate the part of the system at fault.

TYPES OF DTCS Not all OBD-II DTCs are of the same importance for exhaust emissions. Each type of DTC has different requirements for it to set, and the computer will only turn on the MIL for emissions-related DTCs.

TYPE A CODES. A type A DTC is emission-related and will cause the MIL to be turned on the first trip if the computer has detected a problem. Engine misfire or a very rich or lean air–fuel ratio, for example, would cause a type A DTC. These codes alert the driver to an emission problem that may cause damage to the catalytic converter.

TYPE B CODES. A type B code will be stored and the MIL will be turned on during the second consecutive trip, alerting the driver to the fact that a diagnostic test was performed and failed.

NOTE: Type A and B codes are emission-related codes that will cause the lighting of the malfunction indicator lamp (MIL), usually labeled "check engine" or "service engine soon."

TYPE C AND D CODES. Type C and D codes are for use with non-emission-related diagnostic tests; they will cause the lighting of a "service" lamp (if the vehicle is so equipped). Type C codes are also called type C1 codes and D codes are also called type C0 codes.

DIAGNOSTIC TROUBLE CODE PRIORITY CARB has also mandated that all diagnostic trouble codes (DTCs) be stored according to individual priority. DTCs with a higher priority overwrite those with a lower priority. The OBD-II System DTC Priority is listed below.

Priority 0—Non-emission-related codes

Priority 1—One-trip failure of two-trip fault for non-fuel, non-misfire codes

Priority 2—One-trip failure of two-trip fault for fuel or misfire codes

Priority 3—Two-trip failure or matured fault of non-fuel, non-misfire codes

Priority 4—Two-trip failure or matured fault for fuel or misfire codes

OBD-II FREEZE-FRAME

To assist the service technician, OBD II requires the computer to take a "snapshot" or freeze-frame of all data at the instant an emission-related DTC is set. A scan tool is required to retrieve this data.

? FREQUENTLY ASKED QUESTION

What Are Pending Codes?

Pending codes are set when operating conditions are met and the component or circuit is not within the normal range, yet the conditions have not yet been met to set a DTC. For example, a sensor may require two consecutive faults before a DTC is set. If a scan tool displays a pending code or a failure, a driveability concern could also be present. The pending code can help the technician to determine the root cause before the customer complains of a check engine light indication.

NOTE: Although OBD II requires that just one freeze-frame of data be stored, the instant an emission-related DTC is set, vehicle manufacturers usually provide expanded data about the DTC beyond that required. However, retrieving this enhanced data usually requires the use of the vehicle-specific scan tool.

Freeze-frame items include:

- Calculated load value
- Engine speed (RPM)
- Short-term and long-term fuel trim percent
- Fuel system pressure (on some vehicles)
- Vehicle speed (mph)
- Engine coolant temperature
- Intake manifold pressure
- Closed-open-loop status
- Fault code that triggered the freeze-frame
- If a misfire code is set, identify which cylinder is misfiring

A DTC should not be cleared from the vehicle computer memory unless the fault has been corrected and the technician is so directed by the diagnostic procedure. If the problem that caused the DTC to be set has been corrected, the computer will automatically clear the DTC after 40 consecutive warm-up cycles with no further faults detected. It requires 80 warm-up cycles to erase the pending fault if similar conditions cannot be met. The codes can also be erased by using a scan tool. ● **SEE CHART 87–1.**

NOTE: Disconnecting the battery may not erase OBD-II DTCs or freeze-frame data. Most vehicle manufacturers recommend using a scan tool to erase DTCs rather than disconnecting the battery, because the memory for the radio, seats, and learned engine operating parameters is lost if the battery is disconnected.

ENABLING CONDITIONS

These are the exact engine operating conditions required for a diagnostic monitor to run.

Example:

Specific RPM

Specific ECT, MAP, run time, etc.

CHART 87–1

PCM Determination of Faults Chart

PENDING Under some situations the PCM will not run a monitor if the MIL is illuminated and a fault is stored from another monitor. In these situations, the PCM postpones monitors pending a resolution of the original fault. The PCM does not run the test until the problem is remedied.

For example, when the MIL is illuminated for an oxygen sensor fault, the PCM does not run the catalyst monitor until the oxygen sensor fault is remedied. Since the catalyst monitor is based on signals from the oxygen sensor, running the test would produce inaccurate results.

CONFLICT There are also situations when the PCM does not run a monitor if another monitor is in progress. In these situations, the effects of another monitor running could result in an erroneous failure. If this conflict is present, the monitor is not run until the conflicting condition passes. Most likely, the monitor will run later after the conflicting monitor has passed.

For example, if the fuel system monitor is in progress, the PCM does not run the EGR monitor. Since both tests monitor changes in air–fuel ratio and adaptive fuel compensation, the monitors conflict with each other.

SUSPEND Occasionally, the PCM may not allow a two-trip fault to mature. The PCM will suspend the maturing fault if a condition exists that may induce erroneous failure. This prevents illuminating the MIL for the wrong fault and allows more precise diagnosis.

For example, if the PCM is storing a one-trip fault for the oxygen sensor and the EGR monitor, the PCM may still run the EGR monitor but will suspend the results until the oxygen sensor monitor either passes or fails. At that point, the PCM can determine if the EGR system is actually failing or if an oxygen sensor is failing.

PCM TESTS

RATIONALITY TEST While input signals to the PCM are constantly being monitored for electrical opens and shorts, they are also tested for rationality. This means that the input signal is compared against other inputs and information to see if it makes sense under the current conditions.

PCM sensor inputs that are checked for rationality include:

- MAP sensor
- O_2 sensor
- ECT
- Camshaft position sensor (CMP)
- VS sensor
- Crankshaft position sensor (CKP)
- IAT sensor
- TP sensor
- Ambient air temperature sensor
- Power steering switch
- O_2 sensor heater
- Engine controller
- Brake switch
- P/N switch (range switch)
- Transmission controls

FUNCTIONALITY TEST A functionality test refers to PCM inputs checking the operation of the outputs.

Example:

PCM commands the IAC open; expected change in engine RPM is not seen
IAC 60 counts
RPM 700 RPM

PCM outputs that are checked for functionality include:

- EVAP canister purge solenoid
- EVAP purge vent solenoid
- Cooling fan
- Idle air control solenoid
- Ignition control system
- Transmission torque converter clutch solenoid
- Transmission shift solenoids (A, B, 1–2, etc.)

ELECTRICAL TEST Refers to the PCM check of both input and outputs for the following:

- Open
- Shorts
- Ground

Example:

ECT

Shorted high (input to PCM) above capable voltage, i.e., 5-volt sensor with 12-volt input to PCM would indicate a short to voltage.

Monitor Type	Conditions to Set DTC and Illuminate MIL	Extinguish MIL	Clear DTC Criteria	Applicable DTC
Continuous 1-trip monitor	(See note below) Input and output failure—rationally, functionally, electrically	3 consecutive pass trips	40 warm-up cycles	P0123

NOTE: The number of times the comprehensive component monitor must detect a fault depends on the vehicle manufacturer. On some vehicles, the comprehensive component monitor will activate the MIL as soon as it detects a fault. On other vehicles, the comprehensive component monitor must fail two times in a row.

- Freeze-frame captured on first-trip failure.
- Enabling conditions: Many PCM sensors and output devices are tested at key-on or immediately after engine start-up. However, some devices (ECT, idle speed control) are only tested by the comprehensive component monitor after the engine meets particular engine conditions.
- Pending: No pending condition
- Conflict: No conflict conditions
- Suspend: No suspend conditions

GLOBAL OBD-II

All OBD-II vehicles must be able to display data on a global (also called *generic*) scan tool under nine different modes of operation. These modes include:

Mode One	Current powertrain data (**parameter identification** display or **PID**)
Mode Two	Freeze-frame data
Mode Three	Diagnostic trouble codes
Mode Four	Clear and reset diagnostic trouble codes (DTCs), freeze-frame data, and readiness status monitors for noncontinuous monitors only
Mode Five	Oxygen sensor monitor test results
Mode Six	Onboard monitoring of test results for noncontinuously monitored systems

FREQUENTLY ASKED QUESTION

How Can You Tell Generic from Factory?

When using a scan tool on an OBD-II-equipped vehicle, if the display asks for make, model, and year, then the factory or enhanced part of the PCM is being accessed. If the generic or global part of the PCM is being scanned, then there is no need to know the vehicle identification details.

Mode Seven	Onboard monitoring of test results for continuously monitored systems
Mode Eight	Bidirectional control of onboard systems
Mode Nine	Module identification

The global (generic) data is used by most state emission programs. Global OBD-II displays often use hexadecimal numbers, which use 16 numbers instead of 10. The numbers 0 to 9 (zero counts as a number) make up the first 10 and then capital letters A to F complete the 16 numbers. To help identify the number as being in a hexadecimal format, a dollar sign ($) is used in front of the number or letter. See the conversion chart below:

Decimal Number	Hexadecimal Code
0	$0
1	$1
2	$2
3	$3
4	$4
5	$5
6	$6
7	$7
8	$8
9	$9
10	$A
11	$B
12	$C
13	$D
14	$E
15	$F

Hexadecimal coding is also used to identify tests (**test identification [TID]** and **component identification [CID]**).

DIAGNOSING PROBLEMS USING MODE SIX

Mode six information can be used to diagnose faults by following three steps:

1. Check the monitor status before starting repairs. This step will show how the system failed.
2. Look at the component or parameter that triggered the fault. This step will help pin down the root cause of the failure.
3. Look to the monitor enable criteria, which will show what it takes to fail or pass the monitor.

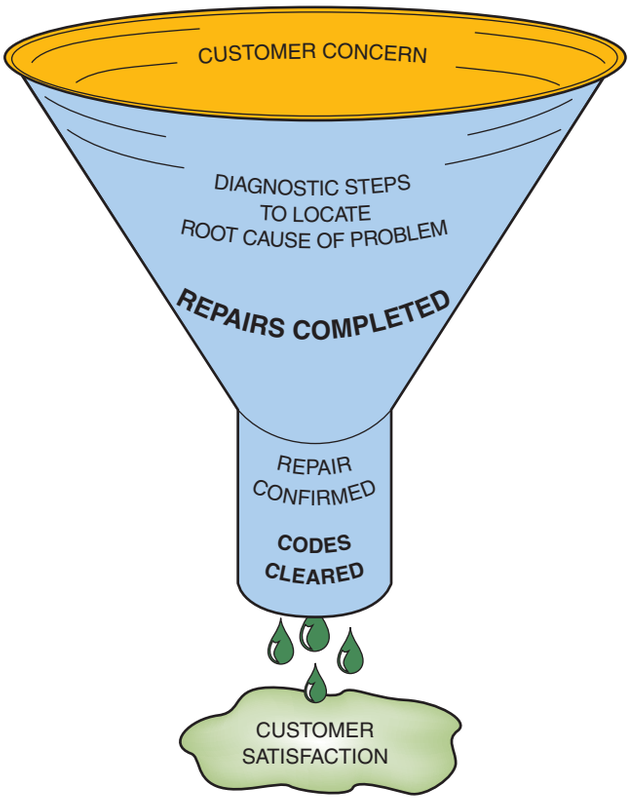

FIGURE 88–1 A funnel is one way to visualize the diagnostic process. The purpose is to narrow the possible causes of a concern until the root cause is determined and corrected.

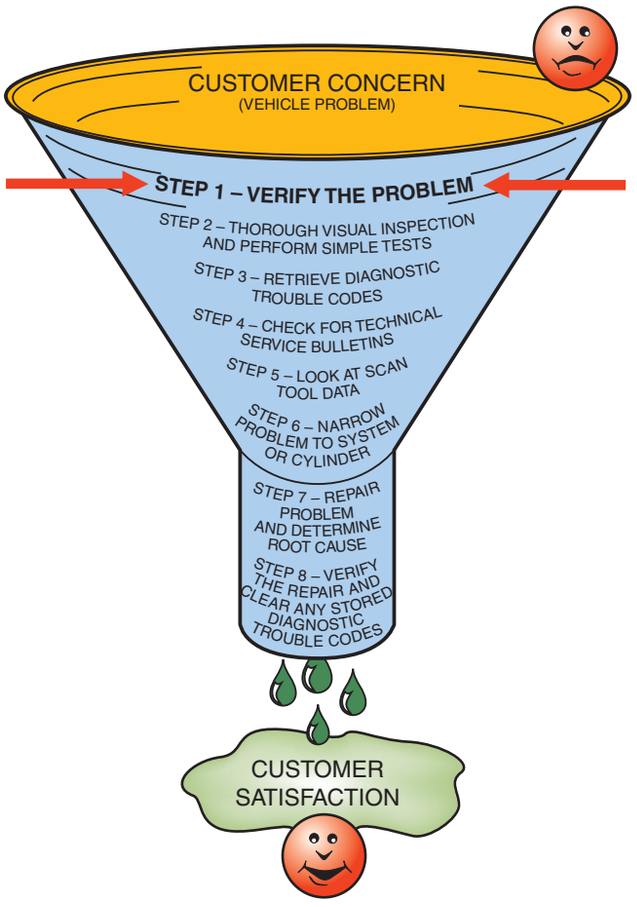

FIGURE 88–2 Step #1 is to verify the customer concern or problem. If the problem cannot be verified, then the repair cannot be verified.

THE EIGHT-STEP DIAGNOSTIC PROCEDURE

It is important that all automotive service technicians know how to diagnose and troubleshoot engine computer systems. The diagnostic process is a strategy that eliminates known-good components or systems in order to find the root cause of automotive engine performance problems. All vehicle manufacturers recommend a diagnostic procedure, and the plan suggested in this chapter combines most of the features of these plans plus additional steps developed over years of real-world problem solving.

Many different things can cause an engine performance problem or concern. The service technician has to narrow the possibilities to find the cause of the problem and correct it. A funnel is a way of visualizing a diagnostic procedure. ● **SEE FIGURE 88–1.** At the wide top are the symptoms of the problem; the funnel narrows as possible causes are eliminated until the root cause is found and corrected at the bottom of the funnel.

All problem diagnosis deals with symptoms that could be the result of many different causes. The wide range of possible solutions must be narrowed to the most likely and these must eventually be further narrowed to the actual cause. The following section describes eight steps the service technician can take to narrow the possibilities to one cause.

STEP 1 VERIFY THE PROBLEM (CONCERN) Before a minute is spent on diagnosis, be certain that a problem exists. If the problem cannot be verified, it cannot be solved or tested to verify that the repair was complete. ● **SEE FIGURE 88–2.**

The driver of the vehicle knows much about the vehicle and how it is driven. *Before* diagnosis, always ask the following questions:

- Is the malfunction indicator light (check engine) on?
- What was the temperature outside?
- Was the engine warm or cold?
- Was the problem during starting, acceleration, cruise, or some other condition?
- How far had the vehicle been driven?
- Were any dash warning lights on? If so, which one(s)?
- Has there been any service or repair work performed on the vehicle lately?

NOTE: This last question is very important. Many engine performance faults are often the result of something being knocked loose or a hose falling off during repair work. Knowing that the vehicle was just serviced before the problem began may be an indicator as to where to look for the solution to a problem.

After the nature and scope of the problem are determined, the complaint should be verified before further diagnostic tests are performed. A sample form that customers could fill out with details of the problem is shown in ● **FIGURE 88–3.**

NOTE: Because drivers differ, it is sometimes the best policy to take the customer on the test drive to verify the concern.

STEP 2 PERFORM A THOROUGH VISUAL INSPECTION AND BASIC TESTS The visual inspection is the most important aspect of diagnosis! Most experts agree that between 10%

and 30% of all engine performance problems can be found simply by performing a *thorough* visual inspection. The inspection should include the following:

- **Check for obvious problems (basics, basics, basics).**
  Fuel leaks
  Vacuum hoses that are disconnected or split
  Corroded connectors
  Unusual noises, smoke, or smell
  Check the air cleaner and air duct (squirrels and other small animals can build nests or store dog food in them). ● **SEE FIGURE 88–4.**
- **Check everything that does and does not work.** This step involves turning things on and observing that everything is working properly.

FIGURE 88–4 This is what was found when removing an air filter from a vehicle that had a lack-of-power concern. Obviously the nuts were deposited by squirrels or some other animal, blocking a lot of the airflow into the engine.

FIGURE 88–5 Using a bright light makes seeing where the smoke is coming from easier. In this case, smoke was added to the intake manifold with the inlet blocked with a yellow plastic cap and smoke was seen escaping past a gasket at the idle air control.

TECH TIP

"Original Equipment" Is Not a Four-Letter Word

To many service technicians, an original-equipment part is considered to be only marginal and to get the really "good stuff" an aftermarket (renewal market) part has to be purchased. However, many problems can be traced to the use of an aftermarket part that has failed early in its service life. Technicians who work at dealerships usually begin their diagnosis with an aftermarket part identified during a visual inspection. It has been their experience that simply replacing the aftermarket part with the factory original-equipment (OE) part often solves the problem.

Original equipment parts are *required* to pass quality and durability standards and tests at a level not required of aftermarket parts. The technician should be aware that the presence of a new part does not necessarily mean that the part is good.

TECH TIP

Smoke Machine Testing

Vacuum (air) leaks can cause a variety of driveability problems and are often difficult to locate. One good method is to use a machine that generates a stream of smoke. Connecting the outlet of the **smoke machine** to the hose that was removed from the vacuum brake booster allows smoke to enter the intake manifold. Any vacuum leaks will be spotted by observing smoke coming out of the leak. ● **SEE FIGURE 88–5.**

- **Look for evidence of previous repairs.** Any time work is performed on a vehicle, there is always a risk that something will be disturbed, knocked off, or left disconnected.
- **Check oil level and condition.** Another area for visual inspection is oil level and condition.

  Oil level. Oil should be to the proper level.

  Oil condition. Using a match or lighter, try to light the oil on the dipstick; if the oil flames up, gasoline is present in the engine oil. Drip some engine oil from the dipstick onto the hot exhaust manifold. If the oil bubbles or boils, coolant (water) is present in the oil. Check for grittiness by rubbing the oil between your fingers.

NOTE: Gasoline in the oil will cause the engine to run rich by drawing fuel through the positive crankcase ventilation (PCV) system.

- **Check coolant level and condition.** Many mechanical engine problems are caused by overheating. The proper operation of the cooling system is critical to the life of any engine.

NOTE: Check the coolant level in the radiator only if the radiator is cool. If the radiator is hot and the radiator cap is removed, the drop in pressure above the coolant will cause the coolant to boil immediately, which can cause severe burns because the coolant expands explosively upward and outward from the radiator opening.

- **Use the paper test.** A sound engine should produce even and steady exhaust flow at the tailpipe when running. For the paper test, hold a piece of paper (even a dollar bill works) or a 3-by-5-inch card within 1 inch (2.5 centimeters) of the tailpipe with the engine running at idle. The paper should blow evenly away from the end of the tailpipe without "puffing" or being drawn inward toward the end of the tailpipe. If the paper is at times drawn *toward* the tailpipe, the valves in one or more cylinders could be burned. Other reasons why the paper might be drawn toward the tailpipe include the following:

  1. The engine could be misfiring because of a lean condition that could occur normally when the engine is cold.
  2. Pulsing of the paper toward the tailpipe could also be caused by a hole in the exhaust system. If exhaust escapes through a hole in the exhaust system, air could be drawn—in the intervals between the exhaust puffs—from the tailpipe to the hole in the exhaust, causing the paper to be drawn toward the tailpipe.

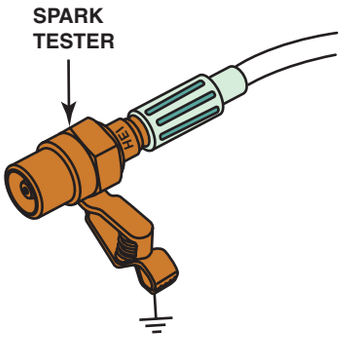

FIGURE 88–6 A spark tester connected to a spark plug wire or coil output. A typical spark tester will only fire if at least 25,000 volts is available from the coil, making a spark tester a very useful tool. Do not use one that just lights when a spark is present, because they do not require more than about 2,000 volts to light.

- **Ensure adequate fuel level.** Make certain that the fuel tank is at least one-fourth to one-half full; if the fuel level is low it is possible that any water or alcohol at the bottom of the fuel tank is more concentrated and can be drawn into the fuel system.
- **Check the battery voltage.** The voltage of the battery should be at least 12.4 volts and the charging voltage (engine running) should be 13.5 to 15.0 volts at 2,000 RPM. Low battery voltage can cause a variety of problems including reduced fuel economy and incorrect (usually too high) idle speed. Higher-than-normal battery voltage can also cause the PCM problems and could cause damage to electronic modules.
- **Check the spark using a spark tester.** Remove one spark plug wire and attach the removed plug wire to the spark tester. Attach the grounding clip of the spark tester to a good clean engine ground, start or crank the engine, and observe the spark tester. ● **SEE FIGURE 88–6.** The spark at the spark tester should be steady and consistent. If an intermittent spark occurs, then this condition should be treated as a no-spark condition. If this test does not show satisfactory spark, carefully inspect and test all components of the primary and secondary ignition systems.

  NOTE: Do not use a standard spark plug to check for proper ignition system voltage. An electronic ignition spark tester is designed to force the spark to jump about 0.75 inch (19 mm). This amount of gap requires between 25,000 and 30,000 volts (25 to 30 kV) at atmospheric pressure, which is enough voltage to ensure that a spark can occur under compression inside an engine.

- **Check the fuel-pump pressure.** Checking the fuel-pump pressure is relatively easy on many port-fuel-injected engines. Often the cause of intermittent engine performance is due to a weak electric fuel pump or clogged fuel filter. Checking fuel pump pressure early in the diagnostic process eliminates low fuel pressure as a possibility.

STEP 3 RETRIEVE THE DIAGNOSTIC TROUBLE CODES (DTCs)

If a diagnostic trouble code (DTC) is present in the computer memory, it may be signaled by illuminating a malfunction indicator lamp (MIL), commonly labeled "check engine" or "service engine soon." ● **SEE FIGURE 88–7.** Any code(s) that is displayed on a scan tool when the MIL is *not* on is called a **pending code.** Because the MIL is not on, this indicates that the fault has not repeated to cause the PCM to turn on the MIL. Although this pending code is helpful to the technician to know that a fault has, in the past, been detected, further testing will be needed to find the root cause of the problem.

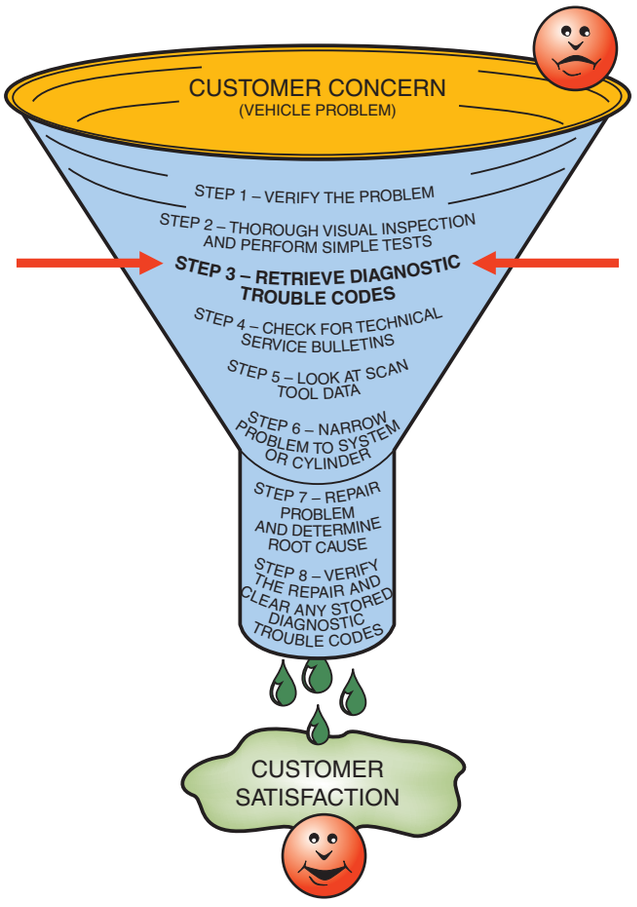

FIGURE 88–7 Step 3 in the diagnostic process is to retrieve any stored diagnostic trouble codes.

STEP 4 CHECK FOR TECHNICAL SERVICE BULLETINS (TSBs)

Check for corrections or repair procedures in **technical service bulletins (TSBs)** that match the symptoms. ● **SEE FIGURE 88–8.** According to studies performed by automobile manufacturers, as many as 30% of vehicles can be repaired following the information, suggestions, or replacement parts found in a service bulletin. DTCs must be known before searching for service bulletins, because bulletins often include information on solving problems that involve a stored diagnostic trouble code.

STEP 5 LOOK CAREFULLY AT SCAN TOOL DATA

Vehicle manufacturers have been giving the technician more and more data on a scan tool connected to the **data link connector (DLC).** ● **SEE FIGURE 88–9.** Beginning technicians are often observed scrolling through scan data without a real clue about what they are looking for. When asked, they usually reply that they are looking for something unusual, as if the screen will flash a big message "LOOK HERE—THIS IS NOT CORRECT." That statement does not appear on scan tool displays. The best way to look at scan data is in a definite sequence and with specific, selected bits of data that can tell the most about the operation of the engine, such as the following:

- Engine coolant temperature (ECT) is the same as intake air temperature (IAT) after the vehicle sits for several hours.
- Idle air control (IAC) valve is being commanded to an acceptable range.

FIGURE 88–8 After checking for stored diagnostic trouble codes (DTCs), the wise technician checks service information for any technical service bulletins that may relate to the vehicle being serviced.

- Oxygen sensor (O_2S) is operating properly:
  1. Readings below 200 mV at times
  2. Readings above 800 mV at times
  3. Rapid transitions between rich and lean

STEP 6 NARROW THE PROBLEM TO A SYSTEM OR CYLINDER Narrowing the focus to a system or individual cylinder is the hardest part of the entire diagnostic process.

- Perform a cylinder power balance test.
- If a weak cylinder is detected, perform a compression and a cylinder leakage test to determine the probable cause.

STEP 7 REPAIR THE PROBLEM AND DETERMINE THE ROOT CAUSE The repair or part replacement must be performed following vehicle manufacturer's recommendations and be certain that the root cause of the problem has been found. Also follow the manufacturer's recommended repair procedures and methods.

STEP 8 VERIFY THE REPAIR AND CLEAR ANY STORED DTCs ● **SEE FIGURE 88–10.**

- Test drive to verify that the original problem (concern) is fixed.
- Verify that no additional problems have occurred during the repair process.
- Check for and then clear all diagnostic trouble codes. (This step ensures that the computer will not make any changes based on a stored DTC, but should not be performed if the vehicle is going to be tested for emissions because all of the monitors will need to be run and pass.)
- Return the vehicle to the customer and double-check the following:
  1. The vehicle is clean.
  2. The radio is turned off.
  3. The clock is set to the right time and the radio stations have been restored if the battery was disconnected during the repair procedure.

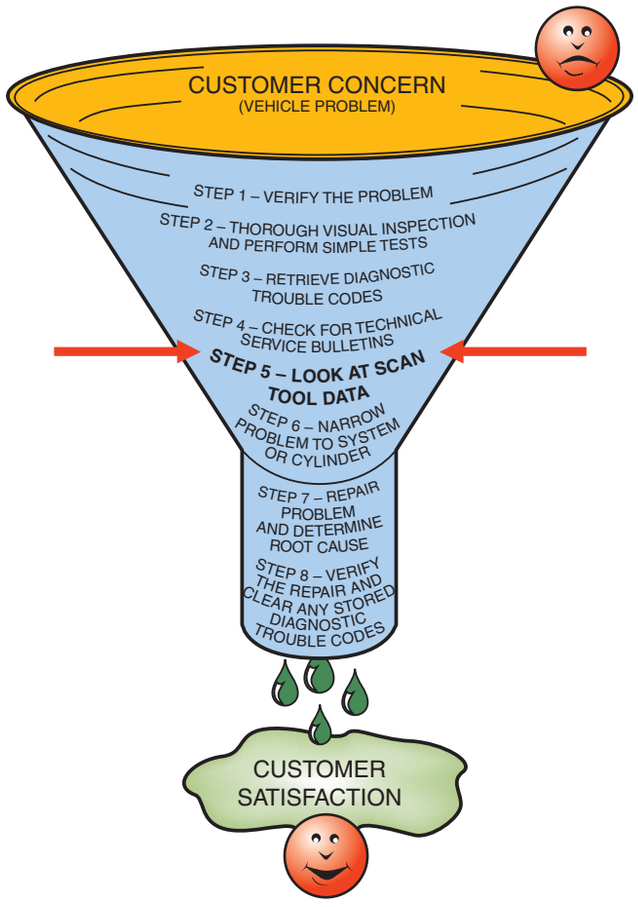

FIGURE 88–9 Looking carefully at the scan tool data is very helpful in locating the source of a problem.

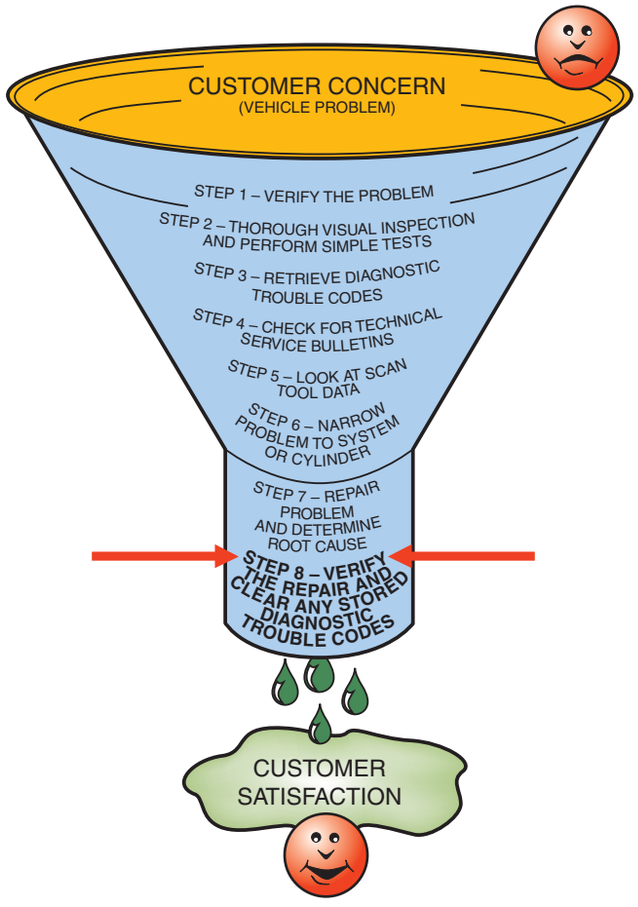

FIGURE 88–10 Step 8 is very important. Be sure that the customer's concern has been corrected.

FIGURE 88–11 A TECH 2 scan tool is the factory scan tool used on General Motors vehicles.

FIGURE 88–12 Some scan tools use pocket PCs which make it very convenient to use.

TECH TIP

One Test Is Worth 1,000 "Expert" Opinions

Whenever any vehicle has an engine performance or driveability concern, certain people always say:

"Sounds like it's a bad injector."
"I'll bet you it's a bad computer."
"I had a problem just like yours yesterday and it was a bad EGR valve."

Regardless of the skills and talents of those people, it is still more accurate to perform tests on the vehicle than to rely on feelings or opinions of others who have not even seen the vehicle. Even your own opinion should not sway your thinking. Follow a plan, perform tests, and the test results will lead to the root cause.

SCAN TOOLS

Scan tools are the workhorse for any diagnostic work on all vehicles. Scan tools can be divided into two basic groups:

1. **Factory scan tools.** These are the scan tools required by all dealers that sell and service the brand of vehicle. Examples of factory scan tools include:
   - **General Motors**—Tech 2. ● **SEE FIGURE 88–11.**
   - **Ford**—New Generation Star (NGS) and IDS (Integrated Diagnostic Software).
   - **Chrysler**—DRB-III or Star Scan (CAN-equipped vehicles)
   - **Honda**—HDS or Master Tech
   - **Toyota**—Master Tech

   All factory scan tools are designed to provide bidirectional capability which allows the service technician the opportunity to operate components using the scan tool thereby confirming that the component is able to work when commanded. Also all factory scan tools are capable of displaying all factory parameters.

2. **Aftermarket scan tools.** These scan tools are designed to function on more than one brand of vehicle. Examples of aftermarket scan tools include:
   - **Snap-on** (various models including the MT2500 and Modis)
   - **OTC** (various models including Pegasus, Genisys and Task Master)
   - **AutoEnginuity** and other programs that use a laptop or handheld computer for the display

While many aftermarket scan tools can display most if not all of the parameters of the factory scan tool, there can be a difference when trying to troubleshoot some faults. ● **SEE FIGURE 88–12.**

RETRIEVAL OF DIAGNOSTIC INFORMATION

To retrieve diagnostic information from the powertrain control module (PCM), a scan tool is needed. If a factory or factory-level scan tool is used, then all of the data can be retrieved. If a global (generic) only type scan tool is used, only the emissions-related data can be retrieved. To retrieve diagnostic information from the PCM, use the following steps:

STEP 1 Locate and gain access to the data link connector (DLC).

STEP 2 Connect the scan tool to the DLC and establish communication.

NOTE: If no communication is established, follow the vehicle manufacturer's specified instructions.

STEP 3 Follow the on-screen instructions of the scan tool to correctly identify the vehicle.

STEP 4 Observe the scan data, as well as any diagnostic trouble codes.

STEP 5 Follow vehicle manufacturer's instructions if any DTCs are stored. If no DTCs are stored, compare all sensor values with a factory acceptable range chart to see if any sensor values are out-of-range.

TROUBLESHOOTING USING DIAGNOSTIC TROUBLE CODES

Pinning down causes of the actual problem can be accomplished by trying to set the opposite code. For example, if a code indicates an open throttle position (TP) sensor (high resistance), clear the code and create a shorted (low-resistance) condition. This can be accomplished by using a jumper wire and connecting the signal terminal to the 5-volt reference terminal. This should set a diagnostic trouble code.

- **If the opposite code sets,** this indicates that the wiring and connector for the sensor is okay and the sensor itself is defective (open).
- **If the same code sets,** this indicates that the wiring or electrical connection is open (has high resistance) and is the cause of the setting of the DTC.

METHODS FOR CLEARING DIAGNOSTIC TROUBLE CODES

Clearing diagnostic trouble codes from a vehicle computer sometimes needs to be performed. There are three methods that can be used to clear stored diagnostic trouble codes.

CAUTION: Clearing diagnostic trouble codes (DTCs) also will clear all of the noncontinuous monitors.

- **Clearing codes—Method 1.** The preferred method of clearing codes is by using a scan tool. This is the method recommended by most vehicle manufacturers if the procedure can be performed on the vehicle. The computer of some vehicles cannot be cleared with a scan tool.
- **Clearing codes—Method 2.** If a scan tool is not available or a scan tool cannot be used on the vehicle being serviced, the power to the computer can be disconnected.
  1. Disconnect the fusible link (if so equipped) that feeds the computer.
  2. Disconnect the fuse or fuses that feed the computer.

  NOTE: The fuse may not be labeled as a computer fuse. For example, many Toyotas can be cleared by disconnecting the fuel-injection fuse. Some vehicles require that two fuses be disconnected to clear any stored codes.
- **Clearing codes—Method 3.** If the other two methods cannot be used, the negative battery cable can be disconnected to clear stored diagnostic trouble codes.

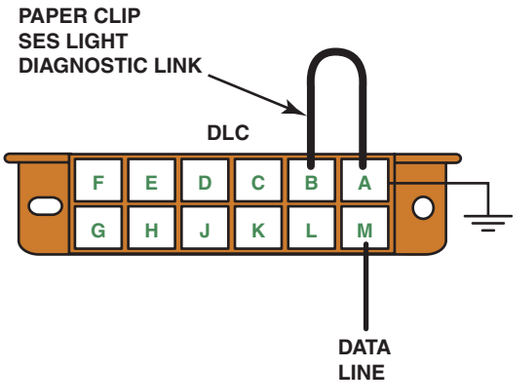

FIGURE 88–13 To retrieve flash codes from an OBD-I General Motors vehicle, without a scan tool, connect terminals A and B with the ignition on–engine off. The M terminal is used to retrieve data from the sensors to a scan tool.

NOTE: Because of the adaptive learning capacity of the computer, a vehicle may fail an exhaust emissions test if the vehicle is not driven enough to allow the computer to run all of the monitors.

CAUTION: By disconnecting the battery, the radio presets and clock information will be lost. They should be reset before returning the vehicle to the customer. If the radio has a security code, the code must be entered before the radio will function. Before disconnecting the battery, always check with the vehicle owner to be sure that the code is available.

FLASH CODE RETRIEVAL ON OBD-I GENERAL MOTORS VEHICLES

The GM system uses a "check engine" or "check engine soon" MIL to notify the driver of possible system failure. Under the dash (on most GM vehicles) is a data link connector (DLC) previously called an assembly line communications link (ALCL) or assembly line diagnostic link (ALDL).

Most General Motors diagnostic trouble codes can be retrieved by using a metal tool and contacting terminals A and B of the 12-pin DLC. ● **SEE FIGURE 88–13.** This method is called **flash code retrieval** because the MIL will flash to indicate diagnostic trouble codes. The steps are as follows:

1. Turn the ignition switch to on (engine off). The "check engine" light or "service engine soon" light should be on. If the amber malfunction indicator light (MIL) is not on, a problem exists within the light circuit.
2. Connect terminals A and B at the DLC.
3. Observe the MIL. A code 12 (one flash, then a pause, then two flashes) reveals that there is no engine speed indication to the computer. Because the engine is not running, this simply indicates that the computer diagnostic system is working correctly.

TECH TIP

Do Not Lie to a Scan Tool!

Because computer calibration may vary from year to year, using the incorrect year for the vehicle while using a scan tool can cause the data retrieved to be incorrect or inaccurate.

NOTE: Refer to service manual diagnostic procedures if the MIL is on and does not flash a code 12 when terminals A and B are connected.

4. After code 12 is displayed three times, the MIL will flash any other stored DTCs in numeric order starting with the lowest-number code. If only code 12 is displayed another three times, the computer has not detected any other faults.

NOTE: Trouble codes can vary according to year, make, model, and engine. Always consult the service literature or service manual for the exact vehicle being serviced. Check service information for the meaning and recommended steps to follow if a diagnostic trouble code is retrieved.

RETRIEVING FORD DIAGNOSTIC CODES

The best tool to use during troubleshooting of a Ford vehicle is a **self-test automatic readout (STAR)** tester, new generation STAR (NGS), WDS (Worldwide Diagnostic System), or another scan tool with Ford capabilities. If a STAR tester or scan tool is not available, a needle (analog) type of voltmeter can be used for all OBD-I (prior to 1996) systems. See the Tech Tip "Put a Wire in the Attic and a Light in the Basement!" to obtain flash codes. The test connector is usually located under the hood on the driver's side. ● **SEE FIGURE 88–14.**

KEY ON–ENGINE OFF TEST (ON-DEMAND CODES OR HARD FAULTS)

With the ignition key on (engine off), watch the voltmeter pulses, which should appear within 5 to 30 seconds. (Ignore any initial surge of voltage when the ignition is turned on.)

The computer will send a two-digit code that will cause the voltmeter to pulse or move from left to right. For example, if the voltmeter needle pulses two times, then pauses for 2 seconds, and then pulses three times, the code is 23. There is normally a 4-second pause between codes.

SEPARATOR PULSE. After all the codes have been reported, the computer will pause for about 6 to 9 seconds, then cause the voltmeter needle to pulse once, and then pause for another 6 to 9 seconds. This is the normal separation between current trouble codes and continuous memory codes (for intermittent problems). Code 11 is the normal pass code, which means that no fault has been stored in memory. Therefore, normal operation of the diagnostic procedure using a voltmeter should indicate the following if no codes are set: 1 pulse (2-second pause), 1 pulse (6- to 9-second pause), 1 pulse (6- to 9-second pause), 1 pulse (2-second pause), and finally, 1 pulse. These last two pulses that are separated by a 2-second interval represent a code 11, which is the code used between current and intermittent trouble codes.

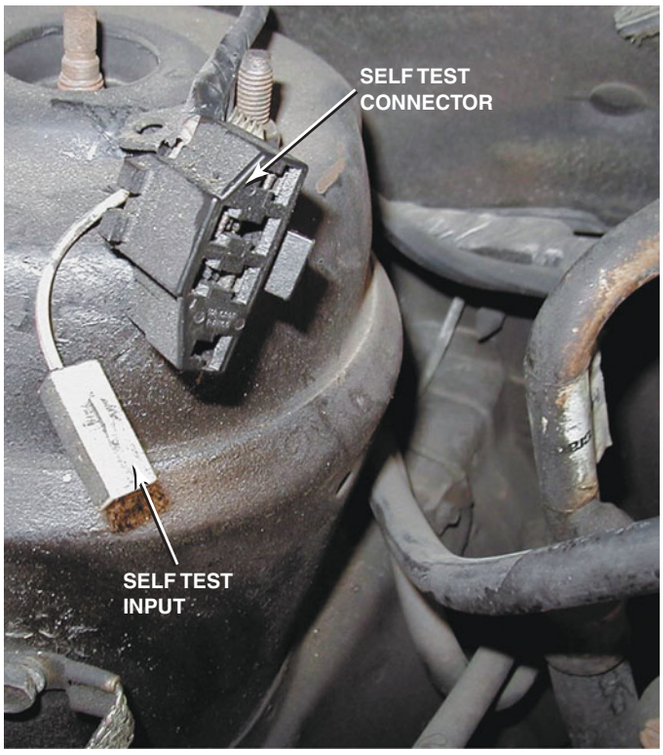

FIGURE 88–14 A Ford OBD-I self-test connector. The location of this connector can vary with model and year of vehicle.

TECH TIP

Put a Wire in the Attic and a Light in the Basement!

Retrieving DTCs from a Ford using low-cost test equipment is easier when you remember the following: "*Put a wire in the attic and a light in the basement.*"

After warming the engine to operating temperature, perform these simple steps:

1. Locate the data link connector (DLC) under the hood. Connect a jumper wire from the single-wire pigtail called the self-test input to terminal #2 at the top (attic) of the connector.
2. To read DTCs, connect a standard 12-volt test light (not a self-powered continuity light) to the positive battery terminal and the lower (basement) terminal (#4) of the DLC. ● **SEE FIGURE 88–15.** Turn the ignition to on (engine off). The DTCs will be displayed by means of the flashes of the test light.

To clear stored Ford DTCs, simply disconnect the jumper wire from the self-test input while the codes are being flashed. This interruption is the signal to the computer to clear any stored DTCs.

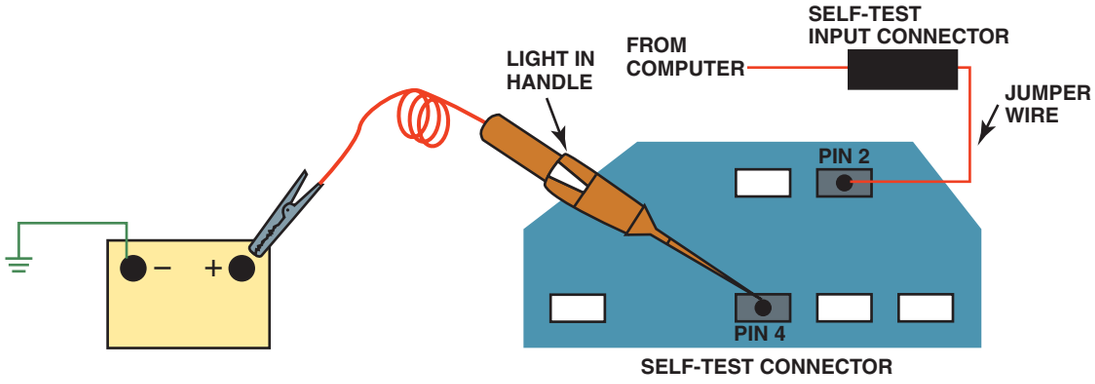

FIGURE 88–15 To retrieve Ford DTCs using a test light and a jumper wire, turn the ignition switch on (engine off) and make the connections shown. The test light will blink out the diagnostic trouble codes.

CONTINUOUS MEMORY CODES (SOFT CODES)

Continuous memory codes are set based on information stored while the vehicle was in normal operation. These codes represent an intermittent problem and should only be used for diagnosis if the **KOEO** test results in code 11 (no faults detected). Therefore, any codes displayed after the separation pulse represent failures that have been detected but may no longer be present.

KEY ON–ENGINE RUNNING (KOER) TEST

During the **KOER** self-test, the sensors are checked by the computer under actual operating conditions and the output devices (actuators) are operated and checked for expected results. Start the engine and raise the speed to 2500 to 3000 RPM to warm the oxygen sensor within 20 seconds of starting. Hold a steady high engine speed until the initial pulses appear (2 pulses for a four-cylinder engine, 3 pulses for a six-cylinder, and 4 pulses for an eight-cylinder). These codes are used to verify the proper processor (computer) is in the vehicle and that the self-test has been entered. Continue to hold a high engine speed until the code pulses begin (10 to 14 seconds).

STEERING, BRAKE, AND OVERDRIVE SWITCH TEST

To test the power steering pressure switch, the technician must turn the steering wheel one-half turn after the ID code has been displayed. The brake pedal and the overdrive cancel switch must also be cycled after the ID code to allow the system to detect a change of state of these switches.

DYNAMIC RESPONSE CHECK. The dynamic response test checks the throttle position (TP) mass air flow (MAF) and manifold absolute pressure (MAP) sensors during a brief wide-open throttle (WOT) test performed by the technician. The signal for the technician to depress the throttle briefly to wide open is a single pulse or a code 10 on a STAR tester.

If any hard (on-demand) faults appear, these should be repaired first and then any soft (continuous) codes next. Use the factory "pinpoint tests" to trace the problem. Refer to service information for a description of Ford-specific alphanumeric DTCs.

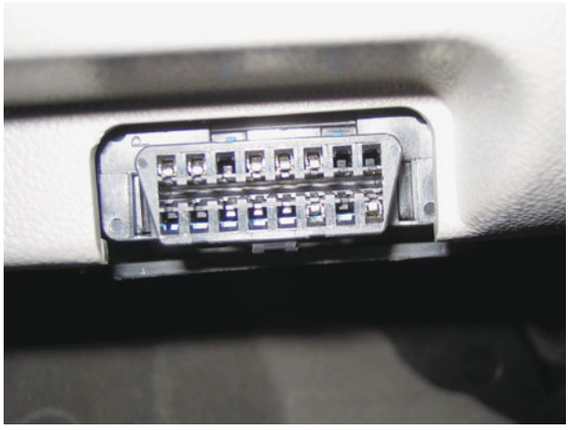

FIGURE 88–16 A typical OBD-II data link connector (DLC). The location varies with make and model and may even be covered, but a tool is not needed to gain access. Check service information for the exact location if needed.

FLASH CODE RETRIEVAL ON CHRYSLER VEHICLES

To put the computer into the self-diagnostic mode, the ignition switch must be turned on and off three times within a 5-second period (on-off-on-off-on). The computer will flash a series of fault codes. Older Chrysler brand products flash the "check engine" lamp on the dash.

NOTE: Unlike other manufacturers, most Chrysler brand vehicles equipped with OBD II will display the P-codes on the odometer display by cycling the ignition key as previously performed on older vehicles.

OBD-II DIAGNOSIS

Starting with the 1996 model year, all vehicles sold in the United States must use the same type of 16-pin data link connector (DLC) and must monitor emission-related components. ● **SEE FIGURE 88–16.**

RETRIEVING OBD-II CODES A scan tool is required to retrieve diagnostic trouble codes from most OBD-II vehicles. Every OBD-II scan tool will be able to read all generic Society of Automotive Engineers (SAE) DTCs from any vehicle.

OBD-II ACTIVE TESTS

The vehicle computer must run tests on the various emission-related components and turn on the malfunction indicator lamp (MIL) if faults are detected. OBD II is an *active* computer analysis system because it actually tests the operation of the oxygen sensors, exhaust gas recirculation system, and so forth whenever conditions permit. It is the purpose and function of the powertrain control module (PCM) to monitor these components and perform these active tests.

For example, the PCM may open the EGR valve momentarily to check its operation while the vehicle is decelerating. A change in the manifold absolute pressure (MAP) sensor signal will indicate to the computer that the exhaust gas is, in fact, being introduced into the engine. Because these tests are active and certain conditions must be present before these tests can be run, the computer uses its internal diagnostic program to keep track of all the various conditions and to schedule active tests so that they will not interfere with each other.

OBD-II DRIVE CYCLE The vehicle must be driven under a variety of operating conditions for all active tests to be performed. A **trip** is defined as an engine-operating drive cycle that contains the necessary conditions for a particular test to be performed. For example, for the EGR test to be performed, the engine has to be at normal operating temperature and decelerating for a minimum amount of time. Some tests are performed when the engine is cold, whereas others require that the vehicle be cruising at a steady highway speed.

TYPES OF OBD-II CODES

Not all OBD-II diagnostic trouble codes are of the same importance for exhaust emissions. Each type of DTC has different requirements for it to set, and the computer will only turn on the MIL for emissions-related DTCs.

TYPE A CODES. A type A diagnostic trouble code is emission related and will cause the MIL to be turned on at the *first trip* if the computer has detected a problem. Engine misfire or a very rich or lean air–fuel ratio, for example, would cause a type A diagnostic trouble code. These codes alert the driver to an emissions problem that may cause damage to the catalytic converter.

TYPE B CODES. A type B code will be stored as a pending code in the PCM and the MIL will be turned on only after the second consecutive trip, alerting the driver to the fact that a diagnostic test was performed and failed.

NOTE: Type A and Type B codes are emission related and will cause the lighting of the malfunction indicator lamp, usually labeled "check engine" or "service engine soon."

TYPE C AND D CODES. Type C and type D codes are for use with non-emission-related diagnostic tests. They will cause the lighting of a "service" lamp (if the vehicle is so equipped).

OBD-II FREEZE-FRAME

To assist the service technician, OBD II requires the computer to take a "snapshot" or freeze-frame of all data at the instant an emission-related DTC is set. A scan tool is required to retrieve this data. CARB and EPA regulations require that the controller store specific freeze-frame (engine-related) data when the first emission related fault is detected. The data stored in freeze-frame can only be replaced by data from a trouble code with a higher priority such as a trouble related to a fuel system or misfire monitor fault.

NOTE: Although OBD II requires that just one freeze-frame of data be stored, the instant an emission-related DTC is set, vehicle manufacturers usually provide expanded data about the DTC beyond that required. However, retrieving enhanced data usually requires the use of an enhanced or factory level scan tool.

The freeze-frame has to contain data values that occurred at the time the code was set (these values are provided in standard units of measurement). Freeze-frame data is recorded during the first trip on a two-trip fault. As a result, OBD-II systems record the data present at the time an emission-related code is recorded and the MIL activated. This data can be accessed and displayed on a scan tool. Freeze-frame data is one frame or one instant in time. Freeze-frame data is not updated (refreshed) if the same monitor test fails a second time.

REQUIRED FREEZE-FRAME DATA ITEMS.

- Code that triggered the freeze-frame
- A/F ratio, airflow rate, and calculated engine load
- Base fuel injector pulse width
- ECT, IAT, MAF, MAP, TP, and VS sensor data
- Engine speed and amount of ignition spark advance
- Open- or closed-loop status
- Short-term and long-term fuel trim values
- For misfire codes—identify the cylinder that misfired

NOTE: All freeze-frame data will be lost if the battery is disconnected, power to the PCM is removed, or the scan tool is used to erase or clear trouble codes.

DIAGNOSING INTERMITTENT MALFUNCTIONS

Of all the different types of conditions that you will see, the hardest to accurately diagnose and repair are intermittent malfunctions. These conditions may be temperature related (only occur when the vehicle is hot or cold), or humidity related (only occur when it is raining). Regardless of the conditions that will cause the malfunction to occur, you must diagnose and correct the condition.

When dealing with an intermittent concern, you should determine the conditions when the malfunction occurs, and then try to duplicate those conditions. If a cause is not readily apparent to you, ask the customer when the symptom occurs. Ask if there are any conditions that seem to be related to, or cause the concern.

Another consideration when working on an OBD-II-equipped vehicle is whether a concern is intermittent, or if it only occurs when a specific diagnostic test is performed by the PCM. Since OBD-II systems conduct diagnostic tests only under very precise conditions, some tests may only be run once during an ignition cycle. Additionally, if the requirements needed to perform the test are not met, the test will not run during an ignition cycle. This type of onboard diagnostics could be mistaken as "intermittent" when, in fact, the tests are only infrequent (depending on how the vehicle is driven). Examples of this type of diagnostic test are HO_2S heaters, evaporative canister purge, catalyst efficiency, and EGR flow. When diagnosing intermittent concerns on an OBD-II-equipped vehicle, a logical diagnostic strategy is essential. The use of stored freeze-frame information can also be very useful when diagnosing an intermittent malfunction if a code has been stored.

SERVICE/FLASH PROGRAMMING

Designing a program that allows an engine to meet strict air quality and fuel economy standards while providing excellent performance is no small feat. However, this is only part of the challenge facing engineers assigned with the task of developing OBD-II software. The reason for this is the countless variables involved with running the diagnostic monitors. Although programmers do their best to factor in any and all operating conditions when writing this complex code, periodic revisions are often required.

Reprogramming consists of downloading new calibration files from a scan tool, personal computer, or modem into the PCM's electronically erasable programmable read-only memory (EEPROM). This can be done on or off the vehicle using the appropriate equipment. Since reprogramming is not an OBD-II requirement however, many vehicles will need a new PCM in the event software changes become necessary. Physically removing and replacing the PROM chip is no longer possible.

The following are three industry-standard methods used to reprogram the EEPROM:

- Remote programming
- Direct programming
- Off-board programming

REMOTE PROGRAMMING. Remote programming uses the scan tool to transfer data from the manufacturer's shop PC to the vehicle's PCM. This is accomplished by performing the following steps:

- Connect the scan tool to the vehicle's DLC. ● **SEE FIGURE 88–17.**

FIGURE 88–17 The first step in the reprogramming procedure is to determine the current software installed using a scan tool. Not all scan tools can be used. In most cases using the factory scan tool is needed for reprogramming unless the scan tool is equipped to handle reprogramming.

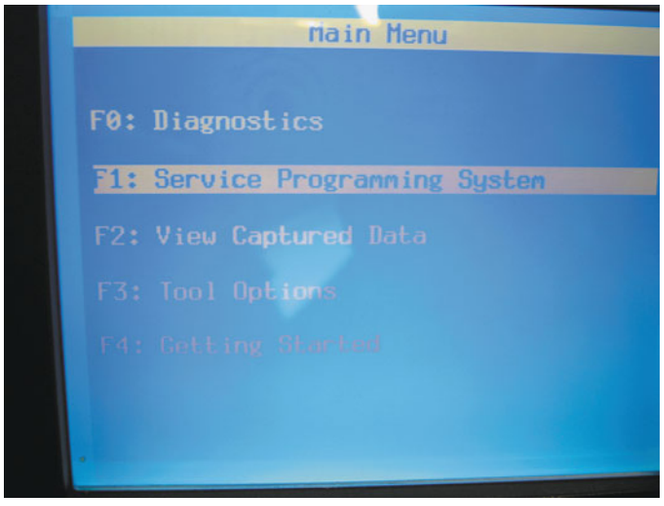

FIGURE 88–18 Follow the on-screen instructions.

- Enter the vehicle information into the scan tool through the programming application software incorporated in the scan tool. ● **SEE FIGURE 88–18.**
- Download VIN and current EEPROM calibration using a scan tool.
- Disconnect the scan tool from the DLC and connect the tool to the shop PC.
- Download the new calibration from the PC to the scan tool. ● **SEE FIGURE 88–19.**
- Reconnect the scan tool to the vehicle's DLC and download the new calibration into the PCM.

CAUTION: Before programming, the vehicle's battery must be between 11 and 14 volts. Do not attempt to program while charging the battery unless using a special battery charger which does not produce excessive ripple voltage such as the Midtronics PSC-300 (30 amp) or PSC-550 (55 amp) or similar as specified by the vehicle manufacturer.

DIRECT PROGRAMMING. Direct programming does utilize a connection between the shop PC and the vehicle DLC.

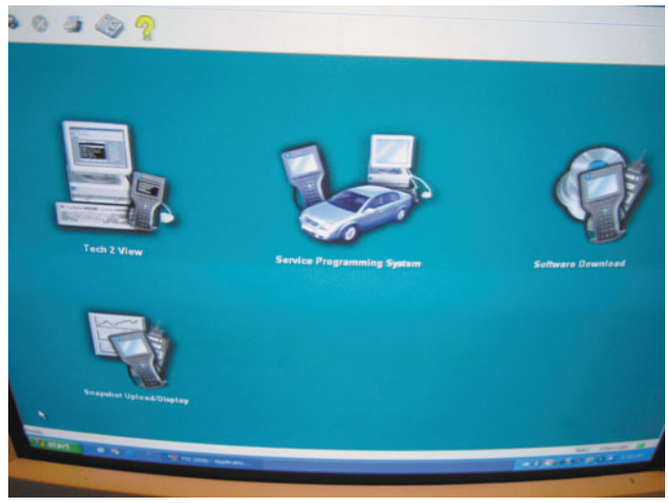

FIGURE 88–19 An Internet connection is usually needed to perform updates although some vehicle manufacturers use CDs which are updated regularly at a cost to the shop.

FIGURE 88–20 Connecting cables and a computer to perform off-board programming.

OFF-BOARD PROGRAMMING. Off-board programming is used if the PCM must be programmed away from the vehicle. This is performed using the off-board programming adapter. ● **SEE FIGURE 88–20.**

J2534 REPROGRAMMING

Legislation has mandated that vehicle manufacturers meet the SAE J2534 standards for all emissions-related systems on all new vehicles starting with model year 2004. This standard enables independent service repair operators to program or reprogram emissions-related ECMs from a wide variety of vehicle manufacturers with a single tool. ● **SEE FIGURE 88–21.** A J2534 compliant pass-through system is a standardized programming and diagnostic system. It uses a personal computer (PC) plus a standard interface to a software device driver, and a hardware vehicle communication interface. The interface connects to a PC, and to a programmable ECM on a vehicle through the J1962 data link connector (DLC). This system allows programming of all vehicle manufacturer ECMs using a single set of programming hardware. Programming software made available by the vehicle manufacturer must be functional with a J2534 compliant pass-through system.

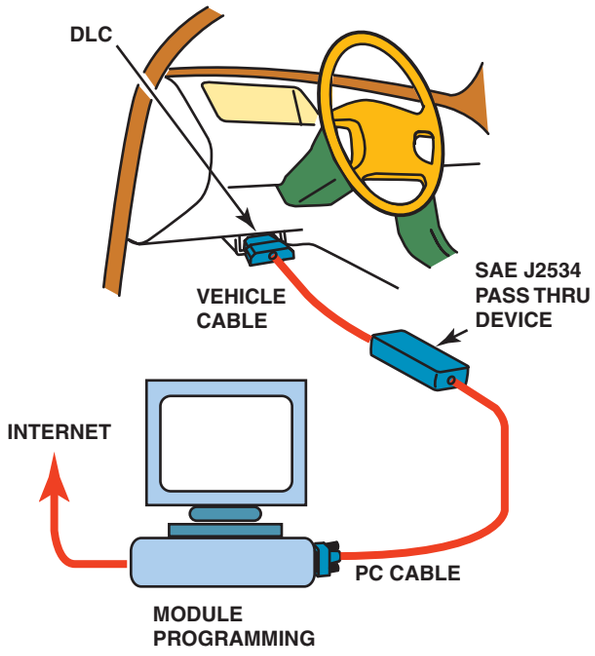

FIGURE 88–21 The J2534 pass-through reprogramming system does not need a scan tool to reflash the PCM on most 2004 and newer vehicles.

The software for a typical pass-through application consists of two major components including:

- The part delivered by the company that furnishes the hardware for J2534 enables the pass-through vehicle communication interface to communicate with the PC and provides for all Vehicle Communication Protocols as required by SAE J2534. It also provides for the software interface to work with the software applications as provided for by the vehicle manufacturers. ● **SEE FIGURE 88–22.**
- The second part of the pass-through enabling software is provided for by the vehicle manufacturers. This is normally a subset of the software used with their original equipment manufacturer (OEM) tools and their website will indicate how to obtain this software and under what conditions it can be used. Refer to the National Automotive Service Task Force (NASTF) website for the addresses for all vehicle manufacturers' service information and cost, *www.NASTF.org*.

Since the majority of vehicle manufacturers make this software available in downloadable form, having an Internet browser (Explorer/Netscape) and connection is a must.

MANUFACTURER'S DIAGNOSTIC ROUTINES

Each vehicle manufacturer has established their own diagnostic routines and they should be followed. Most include the following steps:

STEP 1 Retrieve diagnostic trouble codes.

STEP 2 Check for all technical service bulletins that could be related to the stored DTC.

STEP 3 If there are multiple DTCs, the diagnostic routine may include checking different components or systems instead of when only one DTC was stored.

FIGURE 88–22 A typical J2534 universal reprogrammer that uses the J2534 standards.

TECH TIP

The Brake Pedal Trick

If the vehicle manufacturer recommends that battery power be disconnected, first disconnect the negative battery cable and then depress the brake pedal. Because the brake lights are connected to battery power, depressing the brake pedal causes all of the capacitors in the electrical system and computer(s) to discharge through the brake lights.

STEP 4 Perform system checks.

STEP 5 Perform the necessary service or repair.

STEP 6 Perform a road test matching the parameters recorded in the freeze-frame to check that the repair has corrected the malfunction.

STEP 7 Repeat the road test to cause the MIL to be extinguished.

NOTE: Do not clear codes (DTCs) unless instructed by the service information.

Following the vehicle manufacturer's specific diagnostic routines will ensure that the root cause is found and the repair verified. This is important for customer satisfaction.

COMPLETING SYSTEM REPAIRS

After the repair has been successfully completed, the vehicle should be driven under similar conditions that caused the original concern. Verify that the problem has been corrected. To perform this test drive, it is helpful to have a copy of the freeze-frame parameters that were present when the DTC was set. By driving under similar conditions, the PCM may perform a test of the system and automatically extinguish the MIL. This is the method preferred by most vehicle manufacturers. The DTC can be cleared using a scan tool, but then that means that monitors will have to be run and the vehicle may fail an emission inspection if driven directly to the testing station.

PROCEDURES FOR RESETTING THE PCM

The PCM can be reset or cleared of previously set DTCs and freeze-frame data in the following ways:

1. **Driving the Vehicle.** Drive the vehicle under similar conditions that were present when the fault occurred. If the conditions are similar and the PCM performed the noncontinuous monitor test and it passed three times, then the PCM will extinguish the MIL. This is the method preferred by most vehicle manufacturers, however, this method could be time consuming. If three passes cannot be achieved, the owner of the vehicle will have to be told that even though the check engine light (MIL) is on, the problem has been corrected and the MIL should go out in a few days of normal driving.
2. **Clear DTCs Using a Scan Tool.** A scan tool can be used to clear the diagnostic trouble code (DTC), which will also delete all of the freeze-frame data. The advantage of using a scan tool is that the check engine (MIL) will be out and the customer will be happy that the problem (MIL on) has been corrected. Do not use a scan tool to clear a DTC if the vehicle is going to be checked soon at a test station for state-mandated emission tests.
3. **Battery Disconnect.** Disconnecting the negative battery cable will clear the DTCs and freeze-frame on many vehicles but not all. Besides clearing the DTCs, disconnecting the battery for about 20 minutes will also erase radio station presets and other memory items in many cases. Most vehicle manufacturers do not recommend that the battery be disconnected to clear DTCs and it may not work on some vehicles.

TECH TIP

Drive the Light Out

If working on a vehicle that is subject to state emission testing, it is best to not clear codes. When diagnostic trouble codes are cleared, all of the monitors have to be rerun and this can be a time consuming job. Instead of clearing the code, simply drive the vehicle until the PCM clears the code. This will likely take less time compared to trying to drive the vehicle under varying conditions to run all of the monitors.

ROAD TEST (DRIVE CYCLE)

Use the freeze-frame data and test-drive the vehicle so that the vehicle is driven to match the conditions displayed on the freeze-frame. If the battery has been disconnected, then the vehicle may have to be driven under conditions that allow the PCM to conduct monitor tests. This drive pattern is called a **drive cycle.** The drive cycle is different for each vehicle manufacturer but a universal drive cycle may work in many cases. In many cases performing a universal drive cycle will reset most monitors in most vehicles.

UNIVERSAL DRIVE CYCLE

PRECONDITIONING: Phase 1.

HYBRID VEHICLE

DEFINITION OF TERMS

A hybrid vehicle is one that uses two different methods to propel the vehicle. A hybrid electric vehicle, abbreviated **HEV** uses both an internal combustion engine and an electric motor to propel the vehicle. Most hybrid vehicles use a high-voltage battery pack and a combination electric motor and generator to help or assist a gasoline engine. The **internal combustion engine (ICE)** used in a hybrid vehicle can be either gasoline or diesel, although only gasoline-powered engines are currently used in hybrid vehicles. An electric motor is used to help propel the vehicle, and in some designs, is capable of propelling the vehicle alone without having to start the internal combustion engine.

BACKGROUND

In the early years of vehicle development, many different types of propulsion systems were used, including:

- steam engine powered
- gasoline engine powered
- electric motor powered

Early electric vehicles (**EVs**) were also called **battery electric vehicles (BEV).** These early electric vehicles used lead–acid batteries, an electric traction motor, and a mechanical controller. A traction motor is an electric motor used to rotate the drive wheels and propel vehicle. The vehicle moves as a result of the traction between the wheel and the road surface to transmit the torque needed to move the vehicle.

ELECTRIC VEHICLES

EARLY ELECTRIC VEHICLES

The controller was operated by the driver and allowed different voltages to be applied to the electric motor, depending on the needs of the driver. For an example, assume that an early electric vehicle used six 6-volt batteries. If the batteries are connected in series, the negative terminal of one battery is connected to the positive terminal of the second battery. Two 6-volt batteries connected in series result in 12 volts, but the same current as one of the batteries. If two 6-volt 500-amp hour batteries were connected in series, then the output would be 12 volts and 500-amp hours. If the batteries were connected in parallel, the current of each battery is increased, but the voltage remains the

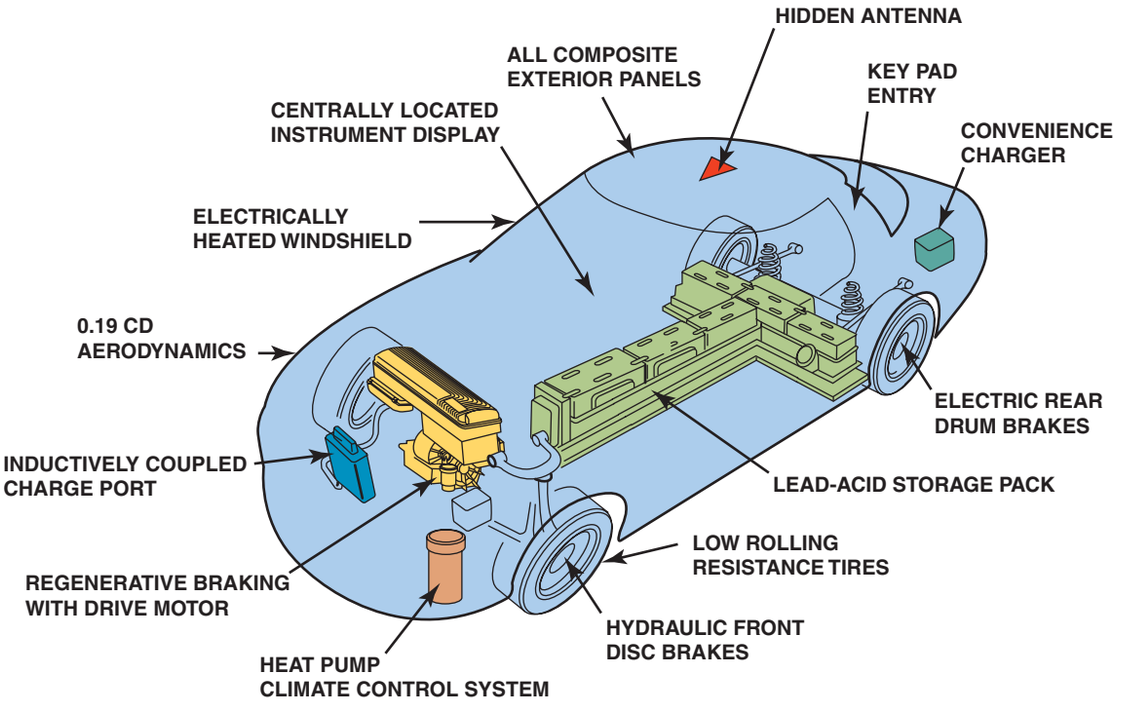

FIGURE 89–1 View of the components of the General Motors electric vehicle (EV1). Many of the features of this vehicle, such as regenerative braking, currently used on hybrid vehicles were first put into production on this vehicle.

same. If two 6-volt 500-amp hour batteries were connected in parallel, then the voltage would be six volts, but the capacity would be 1,000 amp hours.

The old electric vehicle mechanical controller was able to switch all six batteries in various combinations of series and parallel configurations to achieve lower voltage for slow speeds and higher voltages for higher speeds.

Electric vehicles did not have a long range and needed to have the batteries charged regularly, which meant that electric vehicles could only be used for short distances. In fact electric vehicles were almost more popular than steam power in 1900 when steam had 40% of the sales and electric had 38% of the sales. The gasoline-powered cars represented only 22% of the vehicles sold.

NOTE: Due to the oil embargo of 1973 and increased demand for alternative energy sources, Congress enacted Public Law 94-413, the *Electric and Hybrid Vehicle Research, Development, and Demonstration Act of 1976,* which was designed to promote new technologies.

NEWER ELECTRIC VEHICLES

In the late 1990s, several vehicle manufacturers produced electric vehicles, using electronic controllers to meet the demands for zero emission vehicles as specified by law in California at the time. Electric vehicles were produced by Ford, Toyota, Nissan, and General Motors. Legislation was passed in California that included the following revisions within the **zero emissions vehicle (ZEV)** mandate.

As a direct result of the California zero-emission vehicle mandate originally calling for 10% ZEV, General Motors developed the Electric Vehicle 1, known as EV1, and it was leased to customers in California and Arizona. ● **SEE FIGURE 89–1.**

By 2010, there were several electric vehicles for sale although often in limited parts of the country and in limited numbers. Electric vehicles include the Tesla, Nissan Leaf, and Chevrolet VOLT as well as plug-in hybrid electric vehicles such as the Toyota Prius. ● **SEE FIGURE 89–2.**

DRIVING AND OWNING A HYBRID ELECTRIC VEHICLE

DRIVING A HYBRID VEHICLE

Driving a hybrid electric vehicle is the same as driving any other conventional vehicle. In fact, many drivers and passengers are often not aware they are driving or riding in a hybrid electric vehicle. Some unique characteristics that the driver may or may not notice include:

- After the internal combustion engine has achieved normal operating temperature and other conditions are met, the engine will stop when the vehicle slows down and stops. This condition may cause some concern to some drivers who may think that the engine has stalled and then may try to restart it.
- The brake pedal may feel different, especially at slow speeds of about 5 mph and 15 mph when slowing to a stop. It is at about these speeds that the brake system switches from regenerative braking to actually applying brake force to the mechanical brakes. A slight surge or pulsation may be felt at this time. This may or may not be felt and is often not a concern to drivers.
- The power steering works even when the engine stops because all hybrid electric vehicles use an electric power steering system.
- Some hybrid electric vehicles are able to propel the vehicle using the electric motor alone, resulting in quiet, almost eerie operation.
- If a hybrid electric vehicle is being driven aggressively and at a high rate of acceleration, there is often a feeling that the vehicle is not going to slow down when the accelerator pedal is first released. This is caused by two factors:
  1. The inertia of the rotor of the electric motor attached to the crankshaft of the ICE results in the engine continuing to rotate after the throttle has been closed.

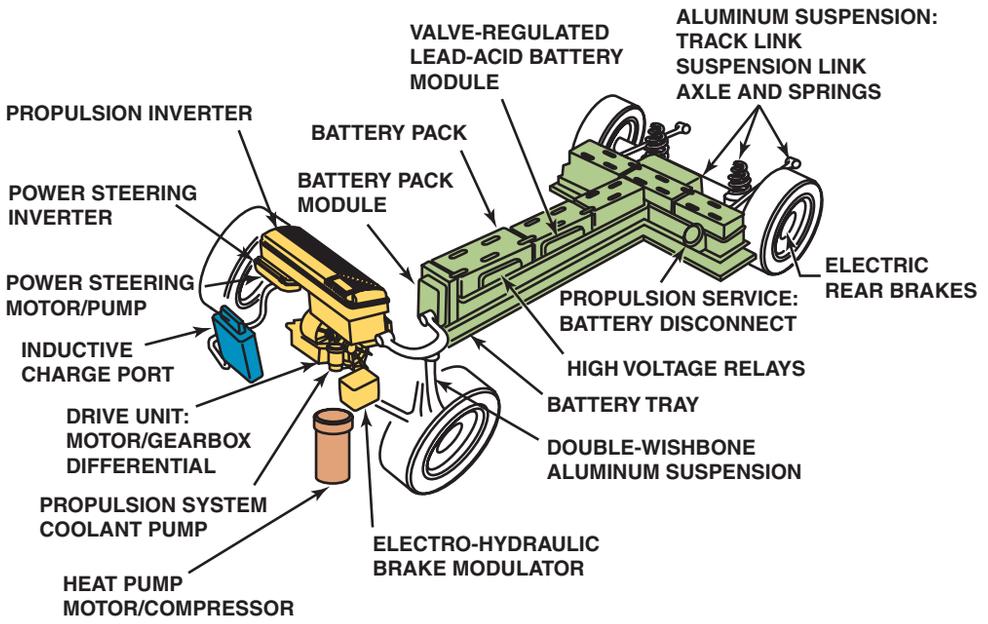

FIGURE 89–2 Using a standardized plug to recharge an electric vehicle or a plug-in hybrid electric vehicle such as this Toyota Prius takes many hours depending on the voltage of the charger.

2. The slight delay that occurs when the system switches the electric motor from powering the vehicle to generating (regenerative braking). While this delay would rarely be experienced, and is not at all dangerous, for a fraction of a second it gives a feeling that the accelerator pedal did not react to a closed throttle.

OWNING A HYBRID ELECTRIC VEHICLE

- The fuel economy will be higher compared to a similar-type vehicle, especially if driven in city-type driving conditions where engine stop and regenerative braking really add to the efficiency of a hybrid electric vehicle. However, the range of the hybrid version may be about the same as the conventional version of the same vehicle because the hybrid version usually has a smaller fuel tank capacity.
- A hybrid electric vehicle will cost and weigh more than a conventional vehicle. The increased cost is due to the batteries, electric motor(s), and controllers used plus the additional components needed to allow operation of the heating and air conditioning systems during idle stop periods. The cost is offset in part by returning improved fuel economy as well as government energy credits awarded at the time of purchase for some new-technology vehicles. It may take many years of operation before the extra cost is offset by cost savings from the improved fuel economy. However, many owners purchase a hybrid electric vehicle for other reasons besides fuel savings, including a feeling that they are helping the environment and love of the high technology involved.

CLASSIFICATIONS OF HYBRID ELECTRIC VEHICLES

SERIES HYBRID The types of hybrid electric vehicles include series, parallel, and series-parallel designs. In a **series-hybrid design,** sole propulsion is by a battery-powered electric motor, but the electric energy for the batteries comes from another on-board energy source, such as an internal combustion engine. In this design, the engine turns a generator and the generator can either charge the batteries or power an electric motor that drives the transmission. The internal combustion engine never powers the vehicle directly. **SEE FIGURES 89–3 AND 89–4.**

The engine is only operated to keep the batteries charged. Therefore, the vehicle could be moving with or without the internal combustion engine running. Series-hybrid vehicles also use regeneration braking to help keep the batteries charged. The Chevrolet VOLT is an example of a series-hybrid design.

The engine is designed to just keep the batteries charged, and therefore, is designed to operate at its most efficient speed and load. An advantage of a series-hybrid design is that no transmission, clutch, or torque converter is needed.

A disadvantage of a series-hybrid design is the added weight of the internal combustion engine to what is basically an electric

? FREQUENTLY ASKED QUESTION

How Fast Does the Motor-Generator Turn the Engine When Starting?

The typical starter motor used on a conventional gasoline or diesel engine rotates the engine from 100 to 300 revolutions per minute (RPM). Because the typical engine idles at about 600 to 700 RPM, the starter motor is rotating the engine at a speed slower than it operates. This makes it very noticeable when starting because the sound is different when cranking compared to when the engine actually starts and runs.

However, when the motor-generator of a hybrid electric vehicle rotates the engine to start it, the engine is rotated about 1,000 RPM, which is about the same speed as when it is running. As a result, engine cranking is just barely heard or felt. The engine is either running or not running, which is a truly unique sensation to those not familiar with the operation of hybrid electric vehicles (HEVs).

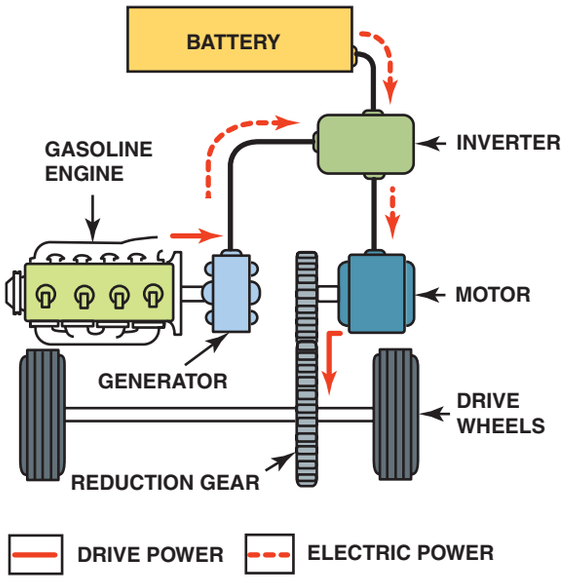

FIGURE 89–3 A drawing of the power flow in a typical series-hybrid vehicle.

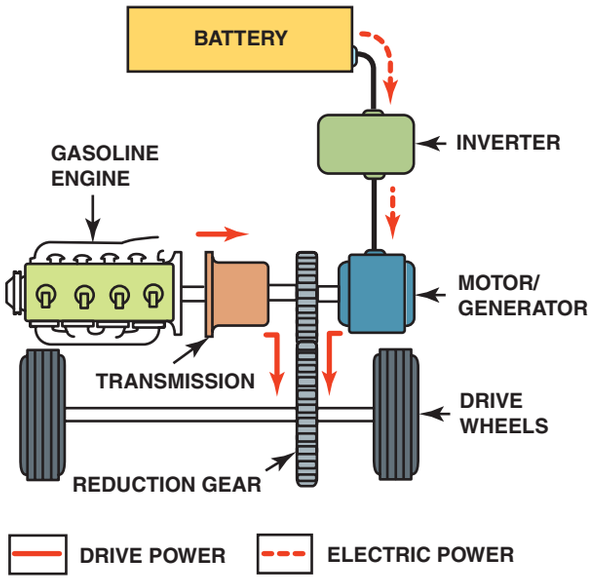

FIGURE 89–5 The power flow in a typical parallel-hybrid vehicle.

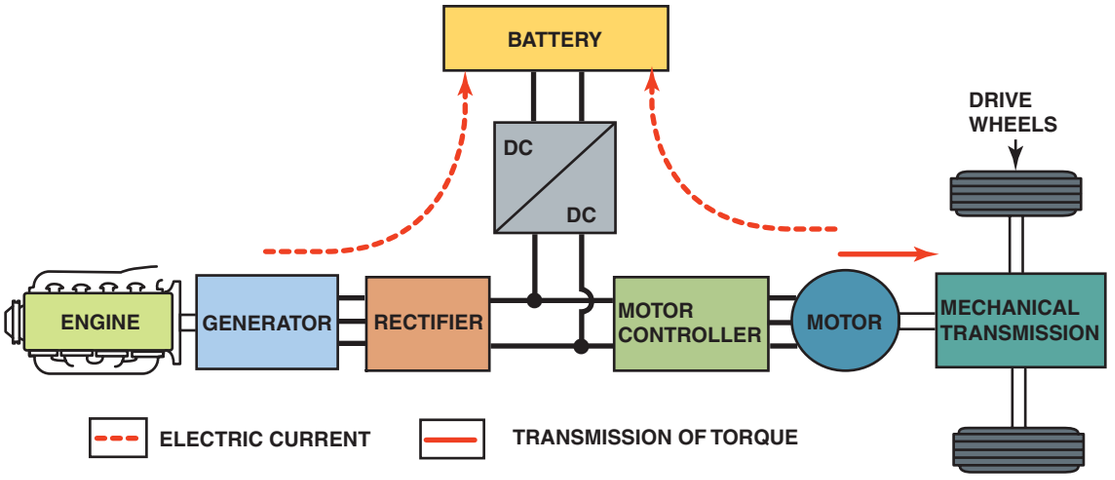

FIGURE 89–4 This diagram shows the components included in a typical series-hybrid design. The solid-line arrow indicates the transmission of torque to the drive wheels. The dotted-line arrows indicate the flow of electrical current.

vehicle. The engine is actually a heavy on-board battery charger. Also, the electric motor and battery capacity have to be large enough to power the vehicle under all operating conditions, including climbing hills.

All power needed for heating and cooling must also come from the batteries so using the air conditioning in hot weather and the heater in cold weather reduces the range that the vehicle can travel on battery power alone.

PARALLEL HYBRID

In a **parallel-hybrid design,** multiple propulsion sources can be combined, or one of the energy sources alone can drive the vehicle. In this design, the battery and engine are both connected to the transmission.

The vehicle using a parallel-hybrid design can be powered by the internal combustion engine alone, by the electric motor alone (full hybrids only), or by a combination of engine and electric motor propulsion. In most cases, the electric motor is used to assist the internal combustion engine. One of the advantages of using a parallel hybrid design is that by using an electric motor or motors to assist the internal combustion engine, the engine itself can be smaller than would normally be needed. ● **SEE FIGURES 89–5 AND 89–6.**

? FREQUENTLY ASKED QUESTION

Is a Diesel-Hybrid Electric Vehicle Possible?

Yes, using a diesel engine instead of a gasoline engine in a hybrid electric vehicle is possible. While the increased efficiency of a diesel engine would increase fuel economy, the extra cost of the diesel engine is the major reason this combination is not currently in production.

NOTE: A parallel-hybrid design could include additional batteries to allow for plug-in capability, which could extend the distance the vehicle can travel using battery power alone.

One disadvantage of a parallel-hybrid design is that complex software is needed to seamlessly blend electric and ICE power. Another concern about the parallel-hybrid design is that it had to be engineered to provide proper heating and air-conditioning system operation when the ICE stops at idle.

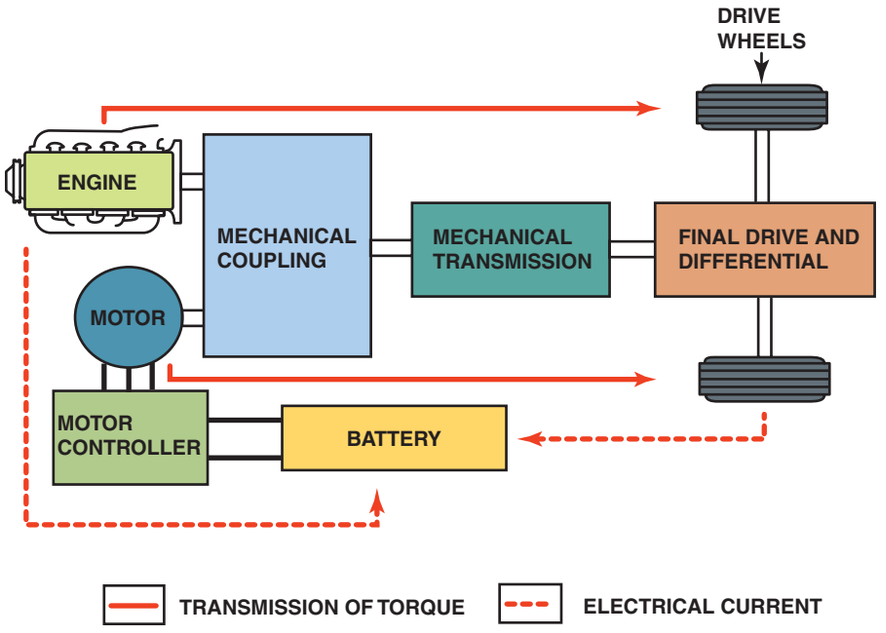

FIGURE 89–6 Diagram showing the components involved in a typical parallel-hybrid vehicle. The solid-line arrows indicate the transmission of torque to the drive wheels, and the dotted-line arrows indicate the flow of electrical current.

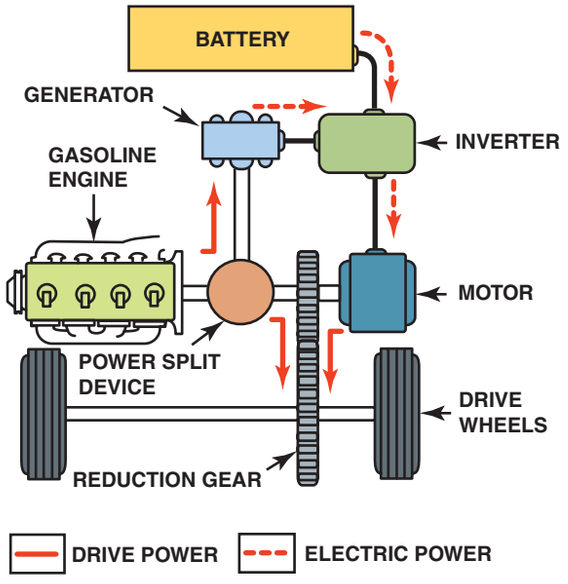

FIGURE 89–7 A series-parallel hybrid design allows the vehicle to operate in electric motor mode only or in combination with the internal combustion engine.

SERIES-PARALLEL HYBRID

The Toyota and Ford hybrids are classified as **series-parallel hybrids** because they can operate using electric motor power alone or with the assist of the ICE. Series-parallel hybrids combine the functions of both a series and a parallel design.

The internal combustion engine may be operating even though the vehicle is stopped if the electronic controller has detected that the batteries need to be charged. ● **SEE FIGURE 89–7.**

NOTE: The internal combustion engine may or may not start when the driver starts the vehicle depending on the temperature of the engine and other conditions. This can be confusing to some who are driving a hybrid electric vehicle for the first time and sense that the engine did not start when they tried to start the engine.

BELT ALTERNATOR STARTER SYSTEMS

PARTS AND OPERATION

The belt system, commonly called the **belt alternator starter (BAS),** is the least expensive system that can be used and still claim that the vehicle is a hybrid. For many buyers, cost is a major concern and the BAS system allows certain hybrid features without the cost associated with an entire redesign of the engine and powertrain. Consumers will be able to upgrade from conventional models to BAS hybrids at a reasonable cost and will get slightly better fuel economy.

The BAS concept is to replace the belt-driven alternator with an electric motor that serves as a generator and a motor. When the engine is running the motor, acting as a generator, it will charge a separate 36-volt battery (42-volt charging voltage). When the engine needs to be started again after the engine has been stopped at idle to save fuel (idle stop), the BAS motor is used to crank the engine by taking electrical power from the 36-volt battery pack and applies its torque via the accessory belt, and cranks the engine instead of using the starter motor.

NOTE: A BAS system uses a conventional starter motor for starting the ICE the first time, and only uses the high-voltage motor-generator to start the ICE when leaving idle stop mode.

The motor-generator is larger than a standard starter motor so more torque can be generated in the cranking mode, also referred to as the **motoring mode.** The fast rotation of the BAS allows for quicker starts of the engine, and makes the start/stop operation possible. Having the engine shut off when the vehicle is at a stop saves fuel. Of course, the stopping of the engine does create a sense that the engine has stalled, which is a common concern to drivers unfamiliar with the operation of hybrid vehicles.

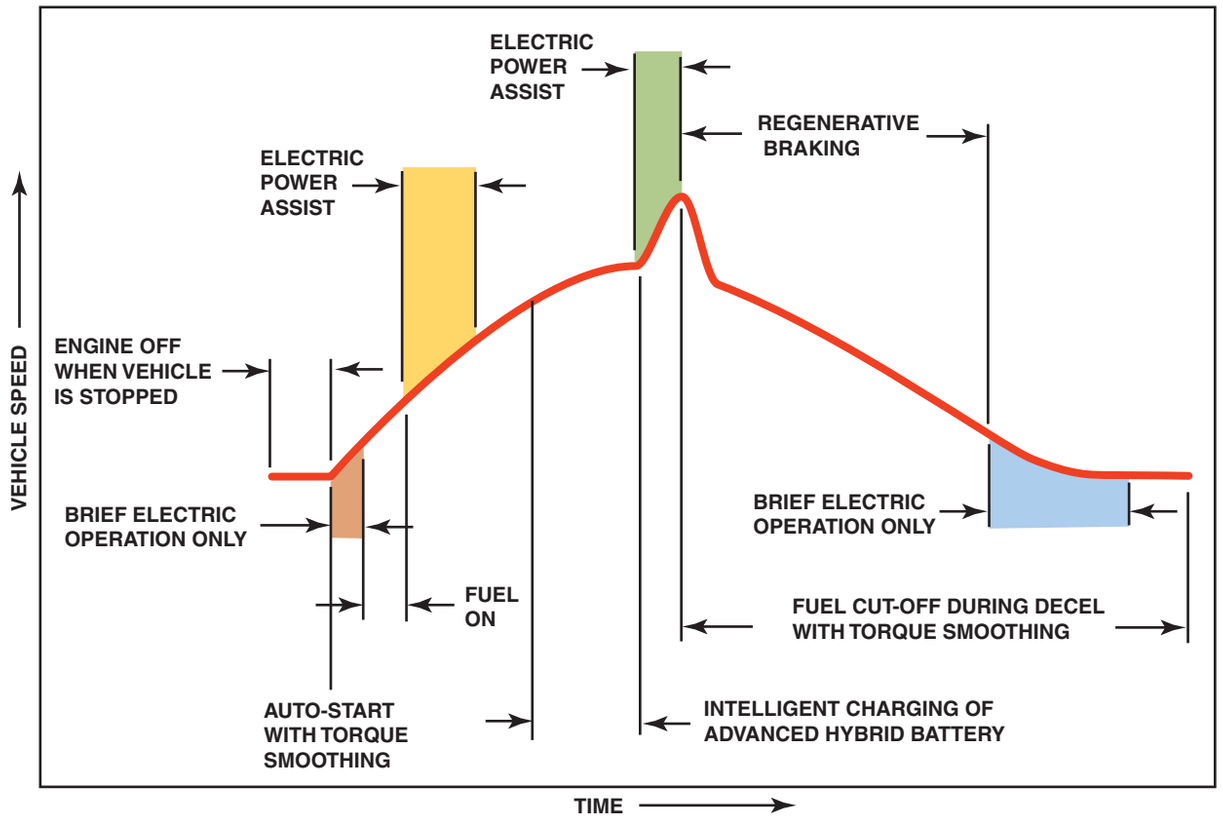

FIGURE 89–8 This chart shows what is occurring during various driving conditions in a BAS-type hybrid.

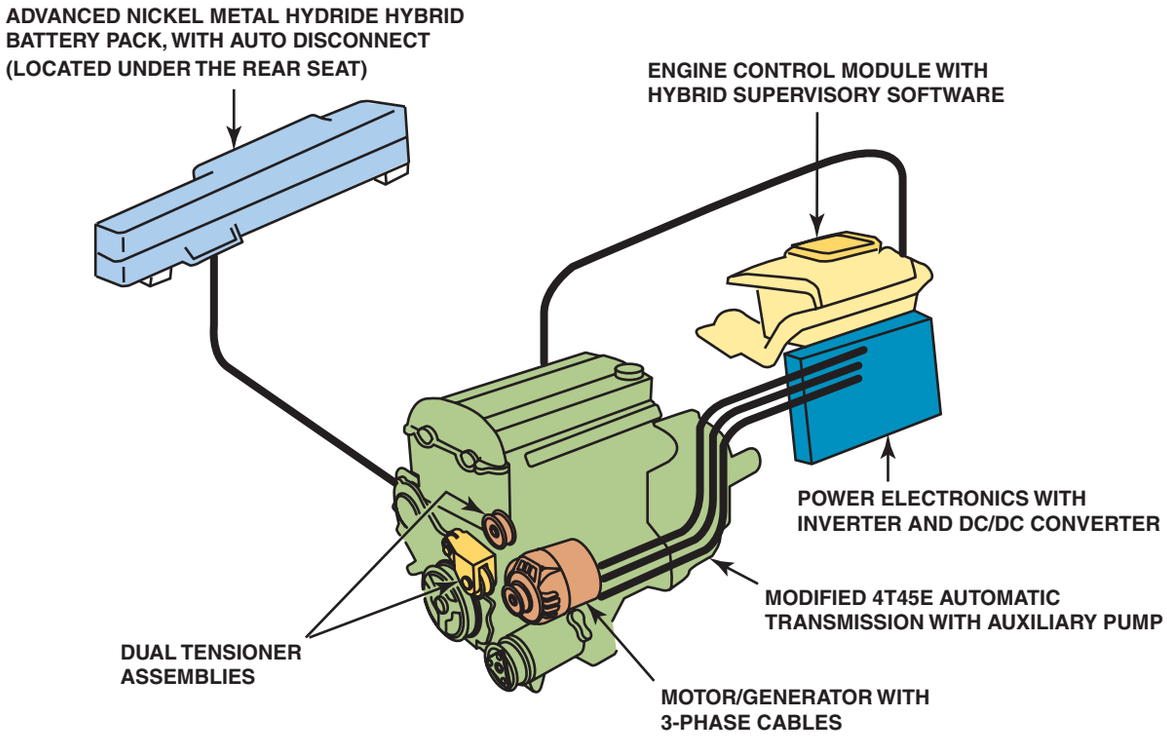

FIGURE 89–9 The components of a typical belt alternator-starter (BAS) system.

A typical BAS system will achieve a 8% to 15% increase in fuel economy, mostly affecting the city mileage with little, if any, effect on the highway mileage. On extremely small vehicles, the belt alternator starter might nudge a vehicle into the mild hybrid category. The BAS system is the type used in the Saturn VUE hybrid SUV. ● **SEE FIGURES 89–8 AND 89–9.**

MICRO-HYBRID DRIVE SYSTEM One of the major fuel-saving features of a hybrid electric vehicle is the idle stop mode, in which the internal combustion engine is stopped, instead of idling, while in traffic.

One simple system developed by Valeo uses a starter/alternator that is used as a conventional alternator when the engine is running,

FIGURE 89–10 This sticker on a hybrid vehicle allows the driver to use the high-occupancy vehicle (HOV) lanes even if there is only one person in the vehicle as a way to increase demand for hybrid vehicles in California.

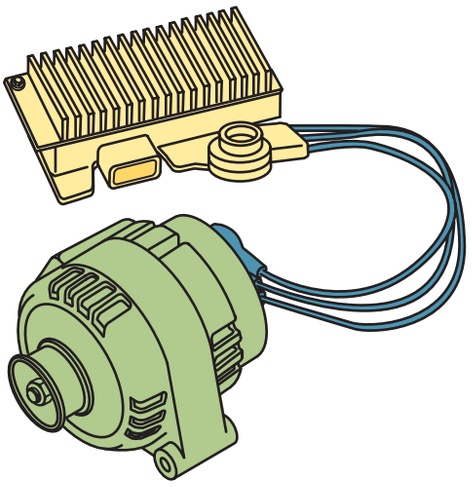

FIGURE 89–11 A combination starter/alternator is used to provide idle stop function to conventional vehicles. This very limited and low cost system is called a micro-hybrid drive.

? **FREQUENTLY ASKED QUESTION**

Can Hybrids Use the HOV Lane?

In most locations the answer is yes, but it depends on the type of hybrid vehicle. The **high-occupancy vehicle (HOV) lane** in many cities is reserved for use by vehicles that are carrying more than one occupant as a way to encourage carpooling and the use of public transportation. In California, only those hybrids classified as being high-fuel-economy models and those meeting certain emission ratings qualify. Those that do qualify, such as the Toyota Prius, are issued stickers that show that they are entitled to be in the HOV lane even if there is just the driver in the vehicle. High-performance hybrids, such as the Honda Accord hybrid, do not meet the specified fuel economy rating to allow the owners to be issued HOV stickers, which are also limited as to how many in the entire state can be issued.

● **SEE FIGURE 89–10.**

and as a starter to start the engine by transmitting power through the drive belt system. This type of system is often called a **micro-hybrid-drive system.** ● **SEE FIGURE 89–11.**

The only mechanical addition needed is a special belt tensioner that allows two-directional belt travel and can be fitted to almost any existing gasoline or diesel engine. The fuel and exhaust emission savings are proportional to the amount of idle time and can save up to 6% during city driving conditions.

COMMON FEATURES OF MOST HYBRIDS

The following are the most common features of hybrids that improve fuel economy:

Idle stop. The **idle stop mode** turns off the engine when the vehicle is stopped. When the brake is released, the engine immediately starts. This ensures that the vehicle is not using fuel, nor creating CO_2 emissions, when the engine is not required to propel the vehicle.

Regenerative braking. When decelerating, the braking system captures the energy from the vehicle's inertia and converts it to electrical energy which is stored in the battery or other device for later use. Regenerative braking helps keep the batteries charged.

Power assist. The electric motor provides extra power using electrical current drawn from the battery to assist the internal combustion engine during acceleration. This **power-assist mode** enables the vehicle to use a smaller, more fuel-efficient engine without giving up vehicle performance.

Engine-off drive-electric vehicle mode. The electric motor propels the vehicle at lower speeds. This mode is often called the motoring mode. Because the internal combustion engine is not being used during acceleration, no fuel is being used and no emissions are being released. When the hybrid is in this mode, it is essentially an electric vehicle.

LEVELS OF HYBRID VEHICLES

The term **hybrid** refers to a type of vehicle. However, there are different levels of "hybridization" among hybrids on the market. Different vehicle manufacturers use various hybrid technologies.

MILD HYBRID A **mild hybrid** will incorporate idle stop and regenerative braking but is not capable of using the electric motor to propel the vehicle on its own without help from the internal combustion engine. A mild hybrid system has the advantage of costing less, but saves less fuel compared to a full hybrid vehicle and usually uses a 42-volt electrical motor and battery package (36-volt batteries, 42-volt charging). An example of this type of hybrid is the General Motors Silverado pickup truck and the Saturn VUE. The fuel savings for a mild type of hybrid design is about 8% to 15%.

MEDIUM HYBRID A **medium hybrid** uses 144- to 158-volt batteries that provide for engine stop/start, regenerative braking, and power assist. Like a mild hybrid, a typical medium hybrid is not capable of propelling the vehicle from a stop using battery power alone. Examples of a medium hybrid vehicle include the Honda Insight, Civic, and Accord. The fuel economy savings are about 20% to 25% for medium hybrid systems.

TECH TIP

Watch Out for Motoring Mode

When a hybrid electric vehicle is operating at low speeds, it is often being propelled by the electric motor alone, sometimes called motoring mode. As a result, the vehicle is very quiet and is said to be operating in **quiet mode.**

During this time, the driver should be aware that the vehicle is not making any sound and should be careful when driving in congested areas. Service technicians should also be extremely careful when moving a hybrid electric vehicle around the shop due to the silence of the vehicle.

Honda Accord Civic Hybrid	✓	✓	✓	
Honda Insight	✓	✓	✓

FULL HYBRID A **full hybrid,** also called a **strong hybrid,** uses idle stop regenerative braking, and is able to propel the vehicle using the electric motor(s) alone.

Each vehicle manufacturer has made its decision on which hybrid type to implement based on its assessment of the market niche for a particular model. Examples of a full or strong hybrid include the Ford Escape SUV, Toyota Highlander, Lexus RX400h, Lexus GS450h, Toyota Prius, and Toyota Camry. The fuel economy savings are about 30% to 50% for full hybrid systems.

FREQUENTLY ASKED QUESTION

What Is an Assist Hybrid?

An **assist hybrid**-electric vehicle is a term used to describe a vehicle where the electric motor is not able to start moving the vehicle on electric power alone. This type of hybrid would include all mild hybrids (36 to 42 volts), as well as the medium hybrids that use 144- to 158-volt systems.

EFFICIENCIES OF ELECTRIC MOTORS AND INTERNAL COMBUSTION ENGINES

- An electric motor can have efficiency (including controller) of over 90%, while a gasoline engine only has efficiency of 35% or less.
- An ICE does not have the overload capability of an electric motor. That is why the rated power of an internal combustion engine is usually much higher than required for highway cruising. Operating smoothly at idle speed produces a much lower efficiency than operating at a higher speed.
- Maximum torque of an internal combustion engine is reached at intermediate speed and the torque declines as speed increases further.
- There is a maximum fuel efficiency point in the speed range for the ICE, and this speed is optimized by many hybrid vehicle manufacturers by using a transmission that keeps the engine speed within the most efficient range.

ELECTRIC MOTORS Electric motors offer ideal characteristics for use in a vehicle because of the following factors:

- Constant power over all speed ranges
- Constant torque at low speeds needed for acceleration and hill-climbing capability
- Constant torque below base speed
- Constant power above base speed
- Only single gear or fixed gear is needed in the electric motor transmission

HYBRID SAFETY AND SERVICE PROCEDURES

OBJECTIVES: **After studying Chapter 90, the reader will be able to:** • Safely de-power a hybrid electric vehicle. • Safely perform high-voltage disconnects. • Understand the unique service issues related to HEV high-voltage systems. • Correctly use appropriate personal protective equipment (PPE). • Perform routine vehicle service procedure on a hybrid electric vehicle. • Explain hazards while driving, moving, and hoisting a hybrid electric vehicle.

KEY TERMS: ANSI 992 • ASTM 992 • CAT III 993 • DMM 992 • Floating ground 994 • HV 991 • HV cables 991 • IEC 992 • Lineman's gloves 992 • NiMH 996 • OSHA 992 • Service plug 995

HIGH-VOLTAGE SAFETY

NEED FOR CAUTION There have been electrical systems on vehicles for over 100 years. Technicians have been repairing vehicle electrical systems without fear of serious injury or electrocution. However, when working with hybrid electric vehicles, this is no longer true. It is now possible to be seriously injured or electrocuted (killed) if proper safety procedures are not followed.

Hybrid electric vehicles and all electric vehicles use **high-voltage (HV)** circuits that if touched with an unprotected hand could cause serious burns or even death.

IDENTIFYING HIGH-VOLTAGE CIRCUITS **High-voltage cables** are identified by color of the plastic conduit and include:

- **Blue or yellow.** 42 volts (not a shock hazard but an arc will be maintained if a circuit is opened)
- **Orange.** 144 to 600 volts or higher

FIGURE 90–1 Rubber lineman's gloves protect the wearer from a shock hazard.

FIGURE 90–2 Wearing leather gloves over the lineman's gloves helps protect the rubber gloves from damage.

FIGURE 90–3 Checking rubber lineman's gloves for pinhole leaks.

carefully before each use. High voltage and current (amperes) in combination is fatal. ● **SEE FIGURES 90–1 AND 90–2.**

NOTE: The high-voltage insulated safety gloves must be recertified every six months to remain within Occupational Safety and Health Administration (OSHA) guidelines.

Before using the rubber gloves, they should be tested for leaks using the following procedure:

1. Roll the glove up from the open end until the lower portion of the glove begins to balloon from the resulting air pressure. Be sure to "lean" into the sealed glove to raise the internal air pressure. If the glove leaks any air, discard the gloves. ● **SEE FIGURE 90–3.**
2. The gloves should not be used if they show any signs of wear and tear.

WARNING

Touching circuits or wires containing high voltage can cause severe burns or death.

WARNING

Cables and wiring are orange in color. High-voltage insulated safety gloves and a face shield must be worn when carrying out any diagnostics involving the high-voltage systems or components.

HIGH-VOLTAGE SAFETY EQUIPMENT

RUBBER GLOVES

Before working on the high-voltage system of a hybrid electric vehicle, be sure that high-voltage **lineman's gloves** are available. Be sure that the gloves are rated at least 1,000 volts and class "0" by ANSI/ASTM. The **American National Standards Institute (ANSI)** is a private, nonprofit organization that administers and coordinates the U.S. voluntary standardization and conformity assessment system. ASTM International, originally known as the **American Society for Testing and Materials (ASTM),** was formed over a century ago, to address the need for component testing in industry. The **Occupational Safety and Health Administration (OSHA)** requirements specify that the HV gloves get inspected every six months by a qualified glove inspection laboratory. Use an outer leather glove to protect the HV rubber gloves. Inspect the gloves

CAT III-RATED DIGITAL MULTIMETER

Hybrid electric vehicles are equipped with electrical systems whose voltages can exceed 600 volts DC. A CAT III-certified **digital multimeter (DMM)** is required for making measurements on these high-voltage systems.

The **International Electrotechnical Commission (IEC)** has several categories of voltage standards for meter and meter leads. These categories are ratings for over-voltage protection and are rated CAT I, CAT II, CAT III, and CAT IV. The higher the category (CAT) rating, the greater the protection to the technician when measuring high-energy voltage. Under each category there are various voltage ratings.

CAT I Typically a CAT I meter is used for low-voltage measurements, such as voltage measurements at wall outlets in the home. Meters with a CAT I rating are usually rated at 300 to 800 volts. CAT I is for relatively low-energy levels, and while the voltage level to be high enough for use when working on a hybrid electric vehicle, the protective energy level is lower than what is needed.

FIGURE 90–4 Be sure to only use a meter that is CAT III-rated when taking electrical voltage measurements on a hybrid electric or electric vehicle.

? FREQUENTLY ASKED QUESTION

Is It the Voltage Rating that Determines the CAT Rating?

Yes and no. The voltages stated for the various CAT ratings are important but the potential harm to a technician due to the energy level is what is most important. For example some CAT II rated meters may have a stated voltage higher than a meter that has a CAT III rating. Always use a meter that has a CAT III rating when working on a hybrid electric vehicle. ● **SEE FIGURES 90–4 AND 90–5.**

CAT II A higher-rated meter that would be typically used for checking voltages at the circuit-breaker panel in the home. Meters with a CAT II rating are usually rated at 300 to 600 volts. CAT II rated meters have similar voltage ratings as the other CAT ratings, but the energy level of protection is higher with a CAT II compared to a CAT I.

CAT III **CAT III** is the minimum-rated meter that should be used for hybrid vehicles. Meters with a CAT III rating are usually rated at 600 to 1,000 volts and the highest energy level which is needed to protect the service technician.

CAT IV CAT IV meters are for clamp-on meters only. A clamp-on meter is used to measure current (amperes) in a circuit by placing the clamp around the wire carrying the current. If a clamp-on meter also has meter leads for voltage measurements, that part of the meter will be rated as CAT III.

INSULATION TESTER An electrical insulation tester, such as the Fluke 1587, is used to test for electrical continuity between the high-voltage wires or components and the body of the vehicle. If a hybrid electric vehicle has been involved in any type of collision or any other incident where damage could occur to the insulation, the high-voltage system should be checked. An insulation tester is more expensive than a digital meter. This means that an individual service technician often does not purchase one, but any technician or service shop that works on hybrid electric vehicles should have one available.

FIGURE 90–5 The meter leads should also be CAT III-rated when checking voltages on a hybrid electric vehicle.

EYE PROTECTION Eye protection should be worn when testing for high voltage, which is considered by many experts to be over 60 volts. Eye protection should include the following features:

1. Plastic frames (avoid metal frames as these are conductive and could cause a shock hazard)
2. Side shields
3. Meet the standard ANSI Z87.1

Most hybrid electric systems use voltages higher than this threshold. If the system has not been powered down or has not had the high-voltage system disabled, a shock hazard is always possible. Even when the high-voltage system has been disconnected, there is still high voltage in the HV battery box.

NOTE: Some vehicle manufacturers specify that full face shields be worn instead of safety glasses when working with high voltage circuits or components.

SAFETY CONES Ford requires that cones be placed at the four corners of any hybrid electric vehicle when service work on the high voltage system is being performed. They are used to establish a safety zone around the vehicles so that other technicians will know that a possible shock hazard may be present.

FIBERGLASS POLE Ford requires that a ten foot insulated fiberglass pole be available outside the safety zone to be used to pull a technician away from the vehicle in the unlikely event of an accident where the technician is shocked or electrocuted.

ELECTRIC SHOCK POTENTIAL

LOCATIONS WHERE SHOCKS CAN OCCUR Accidental and unprotected contact with any electrically charged ("hot" or "live") high-voltage component can cause serious injury or death. However, receiving an electric shock from a hybrid vehicle is highly unlikely because of the following:

1. Contact with the battery module or other components inside the battery box can occur only if the box is damaged and the contents are exposed, or the box is opened without following proper precautions.
2. Contact with the electric motor can occur only after one or more components are removed.

3. The high-voltage cables can be easily identified by their distinctive orange color, and contact with them can be avoided.
4. The system main relays (SMRs) disconnect power from the cables the moment the ignition is turned off.

LOCATIONS OF AUXILIARY BATTERIES

● SEE CHART 90–1 for a summary of the locations of auxiliary batteries.

As a rule of thumb, the auxiliary battery is usually a flood-type if it is located under the hood and an AGM-type if it is in the trunk area.

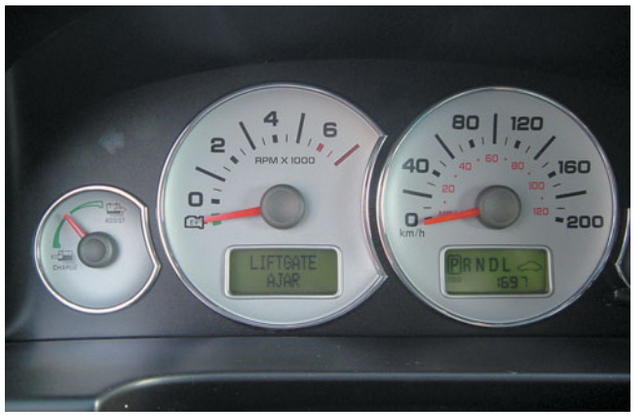

FIGURE 90–6 The Ford Escape Hybrid instrument panel showing the vehicle in park and the tachometer on "EV" instead of 0 RPM. This means that the gasoline engine could start at any time depending on the state-of-charge of the high-voltage batteries and other factors.

WARNING

Power remains in the high-voltage electrical system for up to 10 minutes after the HV battery pack is shut off. Never touch, cut, or open any orange high-voltage power cable or high-voltage component without confirming that the high-voltage has been completely discharged.

TECH TIP

Silence Is NOT Golden

Never assume the vehicle is shut off just because the engine is off. When working with a Toyota or Lexus hybrid electric vehicle, always look for the **READY** indicator status on the dash display. The vehicle is shut off when the **READY** indicator is off.

The vehicle may be powered by:

1. The electric motor only.
2. The gasoline engine only.
3. A combination of both the electric motor and the gasoline engine.

The vehicle computer determines the mode in which the vehicle operates to improve fuel economy and reduce emissions. The driver cannot manually select the mode.

● SEE FIGURE 90–6.

TECH TIP

High Voltage Is Insulated from the Vehicle Body

Both positive and negative high-voltage power cables are isolated from the metal chassis, so there is no possibility of shock by touching the metal chassis. This design is called a **floating ground.**

A ground fault monitor continuously monitors for high-voltage leakage to the metal chassis while the vehicle is running. If a malfunction is detected, the vehicle computer will illuminate the master warning light in the instrument cluster and the hybrid warning light in the LCD display. The HV battery pack relays will automatically open to stop electricity flow in a collision sufficient to activate the SRS airbags.

DE-POWERING THE HIGH-VOLTAGE SYSTEM

THE NEED TO DE-POWER THE HV SYSTEM

During routine vehicle service work there is no need to go through any procedures needed to de-power or to shut off the high-voltage circuits. However, if work is going to be performed on any of the following components then service information procedures must be followed to prevent possible electrical shock and personal injury.

- The high-voltage (HV) battery pack
- Any of the electronic controllers that use orange cables such as the inverter and converters
- The air-conditioning compressor if electrically driven and has orange cables attached

To safely de-power the vehicle always follow the instructions found in service information for the exact vehicle being serviced. The steps usually include:

STEP 1 Turn the ignition off and remove the key (if equipped) from the ignition.

CAUTION: If a push-button start is used, remove the key fob at least 15 feet (5 meters) from the vehicle to prevent the vehicle from being powered up.

STEP 2 Remove the 12-volt power source to the HV controller. This step could involve:

- Removing a fuse or a relay
- Disconnecting the negative battery cable from the auxiliary 12-volt battery

STEP 3 Remove the high-voltage (HV) fuse or **service plug** or switch.

WARNING

Even if all of the above steps are followed, there is still a risk for electrical shock at the high-voltage batteries. Always follow the vehicle manufacturer's instructions exactly and wear high-voltage gloves and other specified personal protective equipment (PPE).

FREQUENTLY ASKED QUESTION

When Do I Need to De-Power the High-Voltage System?

During routine service work, there is no need for a technician to de-power the high-voltage system. The only time when this process is needed is if service repairs or testing is being performed on any circuit that has an orange cable attached. These include:

- AC compressor if electrically powered
- High-voltage battery pack or electronic controllers

The electric power steering system usually operates on 12 volts or 42 volts and neither is a shock hazard. However, an arc will be maintained if a 42-volt circuit is opened. Always refer to service information if servicing the electric power steering system or any other system that may contain high voltage.

COLLISION AND REPAIR INDUSTRY ISSUES

JUMP STARTING

The 12-volt auxiliary battery may be jump started if the vehicle does not start. The 12-volt auxiliary battery is located under the hood or in the cargo (trunk) area of some HEVs. Using a jump box or jumper cable from another vehicle, make the connections to the positive and negative battery terminals. ● **SEE FIGURE 90–7.**

On the 2004+ Toyota Prius vehicles, there is a stud located under the hood that can be used to jump start the auxiliary battery, which is located in the truck. ● **SEE FIGURE 90–8.**

NOTE: The high-voltage HV battery pack cannot be jump started on most HEVs. One exception is the Ford Escape/Mercury Mariner hybrids that use a special "jump-start" button located behind the left kick panel. When this button is pushed, the auxiliary battery is used to boost the HV battery through a DC-DC converter.

FIGURE 90–9 Using a warning cover over the steering wheel helps others realize that work is being performed on the high-voltage system and that no one is to attempt to start or move the vehicle.

FIGURE 90–10 A lock box is a safe location to keep the ignition keys of a hybrid electric vehicle while it is being serviced.

FIGURE 90–11 Insulated tools, such as this socket set, would provide an additional margin of safety to the service technician when working around high-voltage components and systems.

FREQUENTLY ASKED QUESTION

Will the Heat from Paint Ovens Hurt the High-Voltage Batteries?

Nickel-metal hydride (NiMH) batteries may be damaged if exposed to high temperatures, such as in a paint oven. The warning labels on hybrid vehicles specify that the battery temperature not exceed 146°F (63°C). Therefore be sure to check the temperature of any paint oven before allowing a hybrid electric vehicle into one that may be hotter than specified. Check service information for details on the vehicle being repaired.

MOVING AND TOWING A HYBRID

TOWING If a disabled vehicle needs to be moved a short distance (to the side of the road, for example) and the vehicle can still roll on the ground, the easiest way is to shift the transmission into neutral and manually push the vehicle. To transport a vehicle away from an emergency location, a flatbed truck should be used if the vehicle might be repaired. If a flatbed is not available, the vehicle should be towed by wheel-lift equipment with the front wheels off the ground (FWD hybrid electric vehicles only). Do not use sling-type towing equipment. In the case of 4WD HEVs such as the Toyota Highlander, only a flatbed vehicle should be used.

MOVING THE HYBRID VEHICLE IN THE SHOP After an HEV has been serviced, it may be necessary to push the vehicle to another part of the shop or outside as parts are ordered. Make sure to tape any orange cable ends that were disconnected during the repair procedure. Permanent magnets are used in all the drive motors and generators and it is possible that a high-voltage arc could occur as the wheels turn and produce voltage. Another way to prevent this is to use wheel dollies. A sign that says "HIGH VOLTAGE—DO NOT TOUCH" could also be added to the roof of the vehicle. Remove the keys from the vehicle and keep in a safe location. ● **SEE FIGURES 90–9 AND 90–10.**

REMOVING THE HIGH-VOLTAGE BATTERIES

PRECAUTIONS The HV battery box should always be removed as an assembly, placed on a rubber-covered work bench, and handled carefully. Every other part, especially the capacitors, should be checked for voltage reading while wearing HV rubber gloves. Always check for voltage as the components become accessible before proceeding. When removing high-voltage components, it is wise to use insulated tools. ● **SEE FIGURE 90–11.**

STORING THE HIGH-VOLTAGE BATTERIES If a hybrid is to be stored for any length of time, the state of charge of the HV batteries must be maintained. If possible, start the vehicle every month and run it for at least 30 minutes to help recharge the HV batteries. This is necessary because NiMH batteries suffer from self-discharge over time. High-voltage battery chargers

FIGURE 90–12 The high-voltage wiring on this Honda hybrid is colored orange for easy identification.

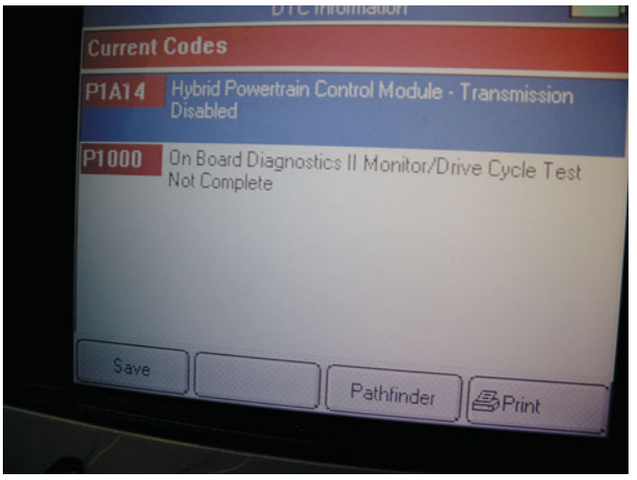

FIGURE 90–13 A scan tool display showing two hybrid-related faults in this Ford Escape hybrid.

TECH TIP

High-Voltage Battery SOC Considerations

NiMH batteries do not store well for long lengths of time. After a repair job, or when the HV system has been powered down by a technician and powered up again, do not be surprised if a warning lamp lights, diagnostic trouble codes are set, and the MIL are illuminated. If everything was done correctly, a couple road tests may be all that is required to reset the MIL. The HV battery indicator on the dash may also read zero charge level. After a road test, the HV battery level indicator will most likely display the proper voltage level.

are expensive and may be hard to find. If the HV battery SOC was over 60% when it was put into storage, the batteries may be stored for about a month without a problem. If, however, the SOC is less than 60%, a problem with a discharged HV battery may result.

HOISTING A HYBRID VEHICLE When hoisting or using a floor jack, pay attention to the lift points. Orange cables run under the vehicle just inside the fame rails on most hybrids. ● **SEE FIGURE 90–12.**

Some Honda hybrid vehicles use an aluminum pipe painted orange that includes three HV cables for the starter/generator and also three more cables for the HV air-conditioning compressor. If any damage occurs to any high-voltage cables, the MIL will light up and a no-start will result if the PCM senses a fault. The cables are not repairable and are expensive. The cables can be identified by an orange outer casing, but in some cases, the orange casing is not exposed until a black plastic underbelly shield is removed first.

HV BATTERY DISPOSAL The hybrid electric vehicle manufacturers are set up to ship NiMH battery packs to a recycling center. There is an 800 number located under the hood or on the HV battery pack that can be used to gain information on how to recycle these batteries.

Always follow the proper safety procedures, and then minor service to hybrid vehicles can be done with a reasonable level of safety.

ROUTINE SERVICE PROCEDURES

DIAGNOSIS PROCEDURES Hybrid electric vehicles should be diagnosed the same as any other type of vehicle. This means following a diagnostic routine, which usually includes the following steps:

STEP 1 Verify the customer concern.

STEP 2 Check for diagnostic trouble codes (DTCs). An enhanced or factory level scan tool may be needed to get access to codes and sub-codes.

STEP 3 Perform a thorough visual inspection. If a DTC is stored, carefully inspect those areas that might be the cause of the trouble code.

STEP 4 Check for technical service bulletins (TSBs) that may relate to the customer concern.

STEP 5 Follow service information specified steps and procedures. This could include checking scan tool data for sensors or values that are not within normal range.

STEP 6 Determine and repair the root cause of the problem.

STEP 7 Verify the repair and clear any stored diagnostic trouble codes unless in an emission testing area. If in an emission test area, drive the vehicle until the powertrain control module (PCM) passes the fault and turns off the malfunction indicator lamp (MIL) thereby allowing the vehicle to pass the inspection.

STEP 8 Complete the work order and record the "three Cs" (complaint, cause, and correction).

OIL CHANGE Performing an oil change is similar to changing oil in any vehicle equipped with an internal combustion engine. However, there are several items to know when changing oil in a hybrid electric vehicle including:

- **Use vehicle manufacturer's recommended hoisting locations.** Use caution when hoisting a hybrid electric vehicle and avoid placing the pads on or close to the orange high-voltage cables that are usually located under the vehicle.

FIGURE 90–14 Always use the specified viscosity of oil in a hybrid electric vehicle not only for best fuel economy but also because of the need for fast lubrication because of the engine (idle) stop feature.

- **Always use the specified oil viscosity.** Most hybrid electric vehicles require either:

  SAE 0W-20
  SAE 5W-20

  Using the specified oil viscosity is important because the engine stops and starts many times and using the incorrect viscosity not only can cause a decrease in fuel economy but also could cause engine damage. ● **SEE FIGURE 90–14.**
- **Always follow the specified procedures.** Be sure that the internal combustion engine (ICE) is off and that the "READY" lamp is off. If there is a smart key or the vehicle has a push-button start, be sure that the key fob is at least 15 feet (5 meters) away from the vehicle to help prevent the engine from starting accidentally.

COOLING SYSTEM SERVICE

Performing cooling system service is similar to performing this service in any vehicle equipped with an internal combustion engine. However, there are several items to know when servicing the cooling system on a hybrid electric vehicle including:

- **Always check service information for the exact procedure to follow.** The procedure will include the following:
  1. **The specified coolant.** Most vehicle manufacturers will recommend using premixed coolant because using water (half of the coolant) that has minerals could cause corrosion issues.
  2. **The specified coolant replacement interval.** While this may be similar to the coolant replacement interval for a conventional vehicle, always check to be sure that this service is being performed at the specified time or mileage interval.
  3. **The specified precautions.** Some Toyota Prius HEVs use a coolant storage bottle that keeps the coolant hot for up to three days. Opening a coolant hose could cause the release of this hot coolant and can cause serious burns to the technician.
  4. Always read, understand, and follow all of the service information instructions when servicing the cooling system on a hybrid electric vehicle.

REAL WORLD FIX

A Bad Day Changing Oil

A shop owner was asked by a regular customer who had just bought a Prius if the oil could be changed there. The owner opened the hood, made sure the filter was in stock (it is a standard Toyota filter used on other models), and said yes. A technician with no prior knowledge of hybrids drove the warmed-up vehicle into the service bay. The internal combustion engine never started, as it was in electric (stealth) mode at the time. Not hearing the engine running, the technician hoisted the vehicle into the air, removed the drain bolt, and drained the oil into the oil drain unit. When the filter was removed, oil started to fly around the shop. The engine was in "standby" mode during the first part of the oil change. When the voltage level dropped, the onboard computer started the engine so that the HV battery could recharge. The technician should have removed the key to keep this from happening. Be sure that the "ready" light is off before changing the oil or doing any other service work that may cause personal harm or harm to the vehicle if the engine starts.

AIR FILTER SERVICE

Performing air filter service is similar to performing this service in any vehicle equipped with an internal combustion engine. However, there are several items to know when servicing the air filter on a hybrid electric vehicle including:

1. Always follow the service information recommended air filter replacement interval.
2. For best results use the factory type and quality air filter.
3. Double-check that all of the air ducts are securely fastened after checking or replacing the air filter.

AIR-CONDITIONING SERVICE

Performing air-conditioning system service is similar to performing this service in any vehicle equipped with an internal combustion engine. However, there are several items to know when servicing the air-conditioning system on a hybrid electric vehicle including:

1. Many hybrid electric vehicles use an air-conditioning compressor that uses high voltage from the high-voltage (HV) battery pack to operate the compressor either all of the time, such as many Toyota/Lexus models, or during idle stop periods, such as on Honda hybrids.
2. If the system is electrically driven, then special refrigerant oil is used that is nonconductive. This means that a separate recovery machine should be used to avoid the possibility of mixing regular refrigerant oils in with the oil used in hybrids.
3. Always read, understand, and follow all of the service information instructions when servicing the air-conditioning system on a hybrid electric vehicle.

STEERING SYSTEM SERVICE Performing steering system service is similar to performing this service in any vehicle equipped with an internal combustion engine. However, there are several items to know when servicing the steering system on a hybrid electric vehicle including:

1. Check service information for any precautions that are specified to be followed when servicing the steering system on a hybrid electric vehicle.
2. Most hybrid electric vehicles use an electric power steering system. These can be powered by one of two voltages:
   - **12 volts**—These systems can be identified by the red or black wiring conduit and often use an inverter that increases the voltage to operate the actuator motor (usually to 42 volts). While this higher voltage is contained in the controller and should not create a shock hazard, always follow the specified safety precautions and wear protective high-voltage gloves as needed.
   - **42 volts**—These systems use a yellow or blue plastic conduit over the wires to help identify the possible hazards from this voltage level. This voltage level is not a shock hazard but can maintain an arc if a circuit carrying 42 volts is opened.

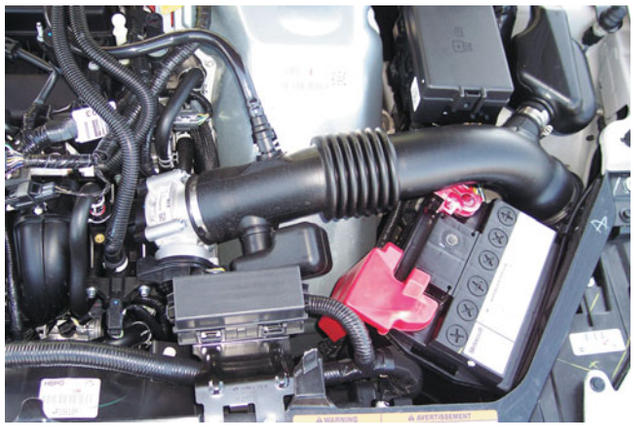
BRAKING SYSTEM SERVICE Performing braking system service is similar to performing this service in any vehicle equipped with an internal combustion engine. However, there are several items to know when servicing the braking system on a hybrid electric vehicle including:

1. Check service information for any precautions that are specified to be followed when servicing the braking system on a hybrid electric vehicle.
2. All hybrid electric vehicles use a regenerative braking system, which captures the kinetic energy of the moving vehicle and converts it to electrical energy and is sent to the high-voltage battery pack. The amount of current produced during hard braking can exceed 100 amperes. This current is stored in the high-voltage battery pack and is then used as needed to help power the vehicle.
3. The base brakes used on hybrid electric vehicles are the same as any other conventional vehicle except for the master cylinder and related control systems. There is no high-voltage circuits associated with the braking system as the regeneration occurs inside the electric drive (traction) motors and is controlled by the motor controller.
4. The base brakes on many hybrid vehicles are often found to be stuck or not functioning correctly because the brakes are not doing much work and can rust.

NOTE: Always check the base brakes whenever there is a poor fuel economy complaint heard from an owner of a hybrid vehicle. Often when a disc brake caliper sticks, the brakes drag but the driver is not aware of any performance problems but the fuel economy drops.

TIRES Performing tire-related service is similar to performing this service in any vehicle equipped with an internal combustion engine. However, there are several items to know when servicing tires on a hybrid electric vehicle including:

1. Tire pressure is very important to not only the fuel economy but also on the life of the tire. Lower inflation pressure increases rolling resistance and reduces load carrying capacity and tire life. Always inflate the tires to the pressure indicated on the door jamb sticker or found in service information or the owner's manual.
2. All tires create less rolling resistance as they wear. This means that even if the same identical tire is used as a replacement, the owner may experience a drop in fuel economy.
3. Tires can have a big effect on fuel economy. It is best to warn the owner that replacement of the tires can and often will cause a drop in fuel economy, even if low rolling resistance tires are selected.
4. Try to avoid using tires that are larger than used from the factory. The larger the tire, the heavier it is and it takes more energy to rotate, resulting in a decrease in fuel economy.
5. Follow normal tire inspections and tire rotation intervals as specified by the vehicle manufacturer.



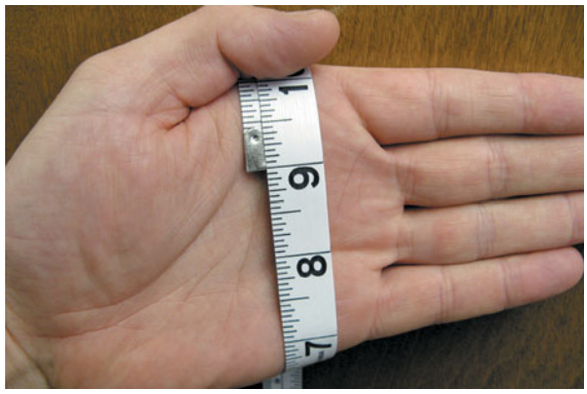


FIGURE 90–15 This 12 volt battery under the hood on a Ford Fusion hybrid is a flooded cell type auxiliary battery.

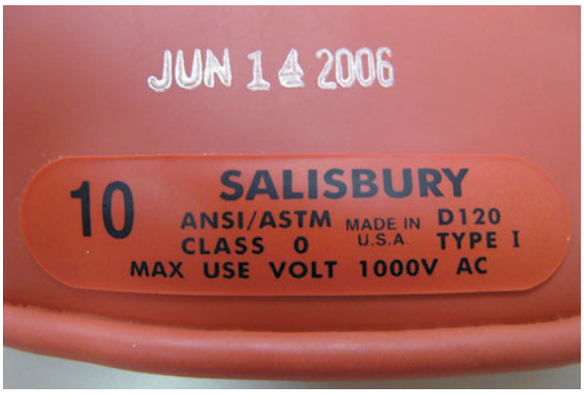
AUXILIARY BATTERY TESTING AND SERVICE Performing auxiliary battery service is similar to performing this service in any vehicle equipped with an internal combustion engine. However, there are several items to know when servicing the auxiliary battery on a hybrid electric vehicle including:



1. Auxiliary 12-volt batteries used in hybrid electric vehicles are located in one of two general locations.
   - **Under the hood**—If the 12-volt auxiliary battery is under the hood it is generally a flooded-type lead–acid battery and should be serviced the same as any conventional battery. ● **SEE FIGURE 90–15**.
   - **In the passenger or trunk area**—If the battery is located in the passenger or trunk area of the vehicle, it is usually of the absorbed glass mat (AGM) design. This type of battery requires that a special battery charger that limits the charging voltage be used.
2. The auxiliary 12-volt battery is usually smaller than a battery used in a conventional vehicle because it is not used to actually start the engine unless under extreme conditions on Honda hybrids only.
3. The 12-volt auxiliary battery can be tested and serviced the same as any battery used in a conventional vehicle.
4. Always read, understand, and follow all of the service information instructions when servicing the auxiliary battery on a hybrid electric vehicle.

1 The cuff of the rubber glove should extend at least 1/2 inch beyond the cuff of the leather protector.

2 To determine correct glove size, use a soft tape to measure around the palm of the hand. A measurement of 9 inches would correspond with a glove size of 9.

3 The glove rating and the date of the last test should be stamped on the glove cuff.

4 Start with a visual inspection of the glove fingertips, making sure that no cuts or other damage is present.

5 The damage on this glove was easily detected with a simple visual inspection. Note that the rubber glove material can be damaged by petroleum products, detergents, certain hand soaps, and talcum powder.

6 Manually inflate the glove to inspect for pinhole leaks. Starting at the cuff, roll up the glove and trap air at the finger end. Listen and watch carefully for deflation of the glove. If a leak is detected, the glove must be discarded.

7 Petroleum on the leather protector's surfaces will damage the rubber glove underneath.

8 Glove powder (glove dust) should be used to absorb moisture and reduce friction.

9 Put on the gloves and tighten the straps on the back of the leather protectors.

10 Technicians MUST wear HV gloves and leather protectors whenever working around the high-voltage areas of a hybrid electric vehicle.

11 HV gloves and leather protectors should be placed in a canvas storage bag when not in use. Note the ventilation hole at the bottom of this bag.

12 Make sure that the rubber gloves are not folded when placed in the canvas bag. Folding increases mechanical stress on the rubber and can lead to premature failure of the glove material.

FUEL-CELL TECHNOLOGY

WHAT IS A FUEL CELL?

A **fuel cell** is an electrochemical device in which the chemical energy of hydrogen and oxygen is converted into electrical energy. The principle of the fuel cell was first discovered in 1839 by Sir William Grove, a Welsh physician. In the 1950s, NASA put this principle to work in building devices for powering space exploration vehicles. In the present day, fuel cells are being developed to power homes and vehicles while producing low or zero emissions. ● **SEE FIGURE 91–1.**

The chemical reaction in a fuel cell is the opposite of **electrolysis.** Electrolysis is the process in which electrical current is passed through water in order to break it into its components, hydrogen and oxygen. While energy is required to bring about electrolysis, this same energy can be retrieved by allowing hydrogen and oxygen to reunite in a fuel cell. It is important to note that while hydrogen can be used as a fuel, it is **not** an energy source. Instead, hydrogen is only an **energy carrier,** as energy must be expended to generate the hydrogen and store it so it can be used as a fuel.

In simple terms, a fuel cell is a hydrogen-powered battery. Hydrogen is an excellent fuel because it has a very high **specific energy** when compared to an equivalent amount of fossil fuel. One kilogram (kg) of hydrogen has three times the energy content as one kilogram of gasoline. Hydrogen is the most abundant element on earth, but it does not exist by itself in nature. This is because its natural tendency is to react with oxygen in the atmosphere to form water (H_2O). Hydrogen is also found in many other compounds, most notably hydrocarbons, such as natural gas or crude oil. In order to store hydrogen for use as a fuel, processes must be undertaken to separate it from these materials. ● **SEE FIGURE 91–2.**

BENEFITS OF A FUEL CELL

A fuel cell can be used to move a vehicle by generating electricity to power electric drive motors, as well as powering the remainder of the vehicle's electrical system. Since they are powered by hydrogen and oxygen, fuel cells by themselves do not generate carbon emissions such as CO_2. Instead, their only emissions are water vapor and heat, and this makes the fuel cell an ideal candidate for a ZEV (zero-emission vehicle).

A fuel cell is also much more energy-efficient than a typical internal combustion engine. While a vehicle powered by an internal combustion engine (ICE) is anywhere from 15% to 20% efficient, a fuel-cell vehicle can achieve efficiencies upwards of 40%. Another major benefit of fuel cells is that they have very few moving parts and have the potential to be very reliable. A number of OEMs have spent many years and millions of dollars in order to develop a low-cost, durable, and compact fuel cell that will operate satisfactorily under all driving conditions. ● **SEE FIGURE 91–3.**

A **fuel-cell vehicle (FCV)** uses the fuel cell as its only source of power, whereas a **fuel-cell hybrid vehicle (FCHV)** would also have an electrical storage device that can be used to power the vehicle. Most new designs of fuel-cell vehicles are now based on a hybrid configuration due to the significant increase in efficiency and driveability that can be achieved with this approach. ● **SEE FIGURE 91–4.**

FUEL-CELL CHALLENGES

While major automobile manufacturers continue to build demonstration vehicles and work on improving fuel-cell system design, no vehicle powered by a fuel cell has been placed into mass production. There are a number of reasons for this, including:

- High cost
- Lack of refueling infrastructure
- Safety perception
- Insufficient vehicle range

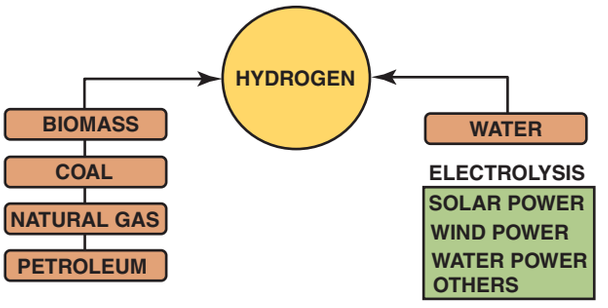

FIGURE 91–2 Hydrogen does not exist by itself in nature. Energy must be expended to separate it from other, more complex materials.

Fuel cell types and their temperature operating range.

FIGURE 91–4 The Toyota FCHV is based on the Highlander platform and uses much of Toyota's Hybrid Synergy Drive (HSD) technology in its design.

- Lack of durability
- Freeze starting problems

All of these problems are being actively addressed by researchers, and significant improvements are being made. Once cost and performance levels meet that of current vehicles, fuel cells will be adopted as a mainstream technology. ● **SEE CHART 91–1.**

TYPES OF FUEL CELLS There are a number of different types of fuel cells, and these are differentiated by the type of **electrolyte** that is used in their design. Some electrolytes operate best at room temperature, whereas others are made to operate at up to 1800°F. See the accompanying chart showing the various fuel-cell types and applications.

The fuel-cell design that is best suited for automotive applications is the **Proton Exchange Membrane (PEM).** A PEM fuel cell must have hydrogen for it to operate, and this may be stored on the vehicle or generated as needed from another type of fuel.

PEM FUEL CELLS

DESCRIPTION AND OPERATION The Proton Exchange Membrane fuel cell is also known as a **Polymer Electrolyte Fuel Cell (PEFC).** The PEM fuel cell is known for its lightweight and compact design, as well as its ability to operate at ambient temperatures. This means that a PEM fuel cell can start quickly and produce full power without an extensive warmup period. The PEM is a simple design based on a membrane that is coated on both sides with a catalyst such as platinum or palladium. There are two electrodes, one located on each side of the membrane. These are responsible for distributing hydrogen and oxygen over the membrane surface, removing waste heat, and providing a path for electrical current flow. The part of the PEM fuel cell that contains the membrane, catalyst coatings, and electrodes is known as the **Membrane Electrode Assembly (MEA).**

The negative electrode (anode) has hydrogen gas directed to it, while oxygen is sent to the positive electrode (cathode). Hydrogen is sent to the negative electrode as H_2 molecules, which break apart into H^+ ions (protons) in the presence of the catalyst. The electrons (e^-) from the hydrogen atoms are sent through the external circuit, generating electricity that can be utilized to perform work. These same electrons are then sent to the positive electrode where they rejoin the H^+ ions that have passed through the membrane and have reacted with oxygen in the presence of the catalyst. This creates H_2O and waste heat, which are the only emissions from a PEM fuel cell. ● **SEE FIGURE 91–5.**

NOTE: It is important to remember that a fuel cell generates direct current (DC) electricity as electrons only flow in one direction (from the anode to the cathode).

FUEL-CELL STACKS A single fuel cell by itself is not particularly useful, as it will generate less than 1 volt of electrical potential. It is more common for hundreds of fuel cells to be built together in a **fuel-cell stack.** In this arrangement, the fuel cells are connected in series so that total voltage of the stack is the sum of the individual cell voltages. The fuel cells are placed end-to-end in the stack, much

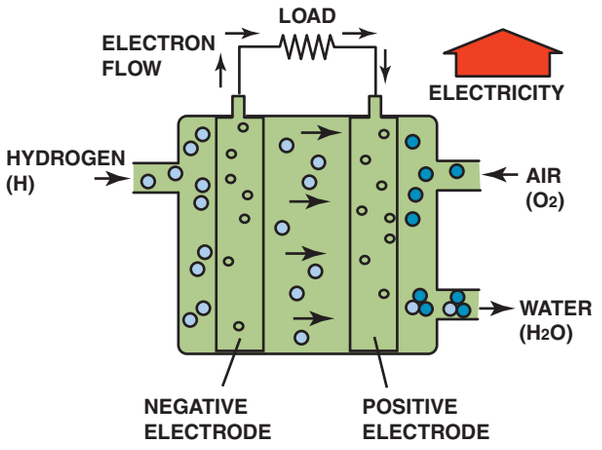

FIGURE 91–5 The polymer electrolyte membrane only allows H^+ ions (protons) to pass through it. This means that electrons must follow the external circuit and pass through the load to perform work.

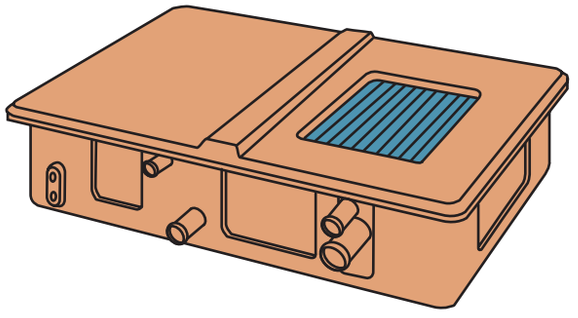

FIGURE 91–6 A fuel-cell stack is made up of hundreds of individual cells connected in series.

like slices in a loaf of bread. Automotive fuel-cell stacks contain upwards of 400 cells in their construction. ● **SEE FIGURE 91–6.**

The total voltage of the fuel-cell stack is determined by the number of individual cells incorporated into the assembly. The current-producing ability of the stack, however, is dependent on the surface area of the electrodes. Since output of the fuel-cell stack is related to both voltage and current (voltage × current = power), increasing the number of cells or increasing the surface area of the cells will increase power output. Some fuel-cell vehicles will use more than one stack, depending on power output requirements and space limitations.

DIRECT METHANOL FUEL CELLS High-pressure cylinders are one method of storing hydrogen onboard a vehicle for use in a fuel cell. This is a simple and lightweight storage method, but often does not provide sufficient vehicle driving range. Another approach has been to fuel a modified PEM fuel cell with liquid methanol instead of hydrogen gas. ● **SEE FIGURE 91–7.**

Methanol is most often produced from natural gas and has a chemical symbol of CH_3OH. It has a higher **energy density** than gaseous hydrogen because it exists in a liquid state at normal temperatures, and is easier to handle since no compressors or other high-pressure equipment is needed. This means that a fuel-cell vehicle can be refueled with a liquid instead of high-pressure gas, which makes the refueling process simpler and produces a greater vehicle driving range. ● **SEE FIGURE 91–8.**

Unfortunately, direct methanol fuel cells suffer from a number of problems, not the least of which is the corrosive nature of methanol itself. This means that methanol cannot be stored in existing

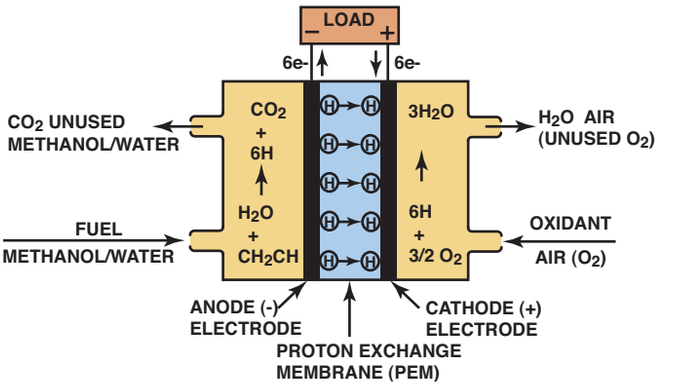

FIGURE 91–7 A direct methanol fuel cell uses a methanol/water solution for fuel instead of hydrogen gas.

FIGURE 91–8 A direct methanol fuel cell can be refueled similar to a gasoline-powered vehicle.

TECH TIP

CO Poisons the PEM Fuel-Cell Catalyst

Purity of the fuel gas is critical with PEM fuel cells. If more than 10 parts per million (ppm) of carbon monoxide is present in the hydrogen stream being fed to the PEM anode, the catalyst will be gradually poisoned and the fuel cell will eventually be disabled. This means that the purity must be "five nines" (99.999% pure). This is a major concern in vehicles where hydrogen is generated by reforming hydrocarbons such as gasoline, because it is difficult to remove all CO from the hydrogen during the reforming process. In these applications, some means of hydrogen purification must be used to prevent CO poisoning of the catalyst.

tanks and thus requires a separate infrastructure for handling and storage. Another problem is "fuel crossover," in which methanol makes its way across the membrane assembly and diminishes performance of the cell. Direct methanol fuel cells also require much greater amounts of catalyst in their construction, which leads to higher costs. These challenges are leading researchers to look for alternative electrolyte materials and catalysts to lower cost and improve cell performance.

NOTE: Direct methanol fuel cells are not likely to see service in automotive applications. However, they are well suited for low-power applications, such as cell phones or laptop computers.

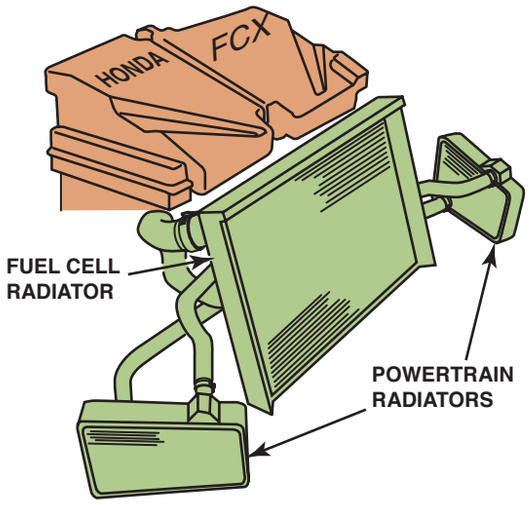

FIGURE 91–10 The Honda FCX uses one large radiator for cooling the fuel cell, and two smaller ones on either side for cooling drive train components.

FREQUENTLY ASKED QUESTION

What Is the Role of the Humidifier in a PEM Fuel Cell?

The polymer electrolyte membrane assembly in a PEM fuel cell acts as conductor of positive ions and as a gas separator. However, it can only perform these functions effectively if it is kept moist. A fuel-cell vehicle uses an air compressor to supply air to the positive electrodes of each cell, and this air is sometimes sent through a humidifier first to increase its moisture content. The humid air then comes in contact with the membrane assembly and keeps the electrolyte damp and functioning correctly.

FREQUENTLY ASKED QUESTION

When Is Methanol Considered to Be a "Carbon-Neutral" Fuel?

Most of the methanol in the world is produced by reforming natural gas. Natural gas is a hydrocarbon, but does not increase the carbon content of our atmosphere as long as it remains in reservoirs below the earth's surface. However, natural gas that is used as a fuel causes extra carbon to be released into the atmosphere, which is said to contribute to global warming. Natural gas is not a carbon-neutral fuel, and neither is methanol that is made from natural gas.

Fortunately, it is possible to generate methanol from biomass and wood waste. Methanol made from renewable resources is carbon neutral, because no extra carbon is being released into the earth's atmosphere than what was originally absorbed by the plants used to make the methanol.

FUEL-CELL VEHICLE SYSTEMS

HUMIDIFIERS Water management inside a PEM fuel cell is critical. Too much water can prevent oxygen from making contact with the positive electrode; too little water can allow the electrolyte to dry out and lower its conductivity. The amount of water and where it resides in the fuel cell is also critical in determining at how low a temperature the fuel cell will start, because water freezing in the fuel cell can prevent it from starting. The role of the humidifier is to achieve a balance where it is providing sufficient moisture to the fuel cell by recycling water that is evaporating at the cathode. The humidifier is located in the air line leading to the cathode of the fuel-cell stack. ● **SEE FIGURE 91–9.**

Some newer PEM designs manage the water in the cells in such a way that there is no need to pre-humidify the incoming reactant gases. This eliminates the need for the humidifier assembly and makes the system simpler overall.

FUEL-CELL COOLING SYSTEMS Heat is generated by the fuel cell during normal operation. Excess heat can lead to a breakdown of the polymer electrolyte membrane, so a liquid cooling system must be utilized to remove waste heat from the fuel-cell stack. One of the major challenges for engineers in this regard is the fact that the heat generated by the fuel cell is classified as **low-grade heat.** This means that there is only a small difference between the temperature of the coolant and that of the ambient air. Heat transfers very slowly under these conditions, so heat exchangers with a much larger surface area must be utilized. ● **SEE FIGURE 91–10.**

In some cases, heat exchangers may be placed in other areas of the vehicle when available space at the front of the engine compartment is insufficient. In the case of the Toyota FCHV, an auxiliary heat exchanger is located underneath the vehicle to increase the cooling system heat-rejection capacity. ● **SEE FIGURE 91–11.**

An electric water pump and a fan drive motor are used to enable operation of the fuel cell's cooling system. These and other support devices use electrical power that is generated by the fuel cell, and therefore tend to decrease the overall efficiency of the vehicle.

AIR SUPPLY PUMPS Air must be supplied to the fuel-cell stack at the proper pressure and flow rate to enable proper performance under all driving conditions. This function is performed by an onboard air supply pump that compresses atmospheric air and

FIGURE 91–11 Space is limited at the front of the Toyota FCHV engine compartment, so an auxiliary heat exchanger is located under the vehicle to help cool the fuel-cell stack.

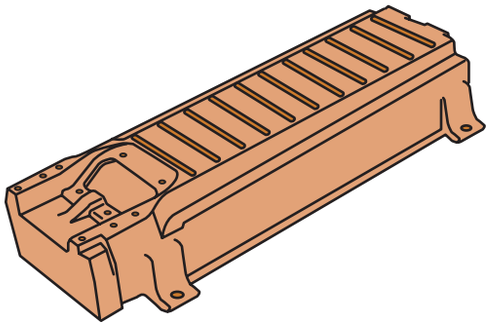

FIGURE 91–12 The secondary battery in a fuel-cell hybrid vehicle is made up of many individual cells connected in series, much like a fuel-cell stack.

supplies it to the fuel cell's positive electrode (cathode). This pump is often driven by a high-voltage electric drive motor.

FUEL-CELL HYBRID VEHICLES

Hybridization tends to increase efficiency in vehicles with conventional drive trains, as energy that was once lost during braking and otherwise normal operation is instead stored for later use in a high-voltage battery or **ultracapacitor.** This same advantage can be gained by applying the hybrid design concept to fuel-cell vehicles. Whereas the fuel cell is the only power source in a fuel-cell vehicle, the fuel-cell hybrid vehicle (FCHV) relies on both the fuel cell and an electrical storage device for motive power. Driveability is also enhanced with this design, as the electrical storage device is able to supply energy immediately to the drive motors and overcome any "throttle lag" on the part of the fuel cell.

SECONDARY BATTERIES. All hybrid vehicle designs require a means of storing electrical energy that is generated during regenerative braking and other applications. In most FCHV designs, a high-voltage nickel-metal hydride (NiMH) battery pack is used as a secondary battery. This is most often located near the back of the vehicle, either under or behind the rear passenger seat. ● **SEE FIGURE 91–12.** The secondary battery is built similar to a fuel-cell stack, because it is made up of many low-voltage cells connected in series to build a high-voltage battery.

ULTRACAPACITORS. An alternative to storing electrical energy in batteries is to use ultracapacitors. A capacitor is best known as an electrical device that will block DC current, but allow AC to pass. However, a capacitor can also be used to store electrical energy, and it is able to do this without a chemical reaction. Instead, a

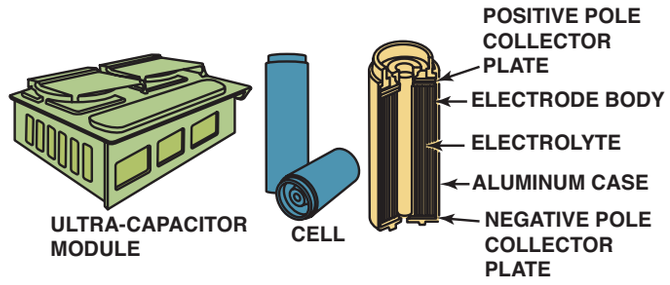

FIGURE 91–13 The Honda ultracapacitor module and construction of the individual cells.

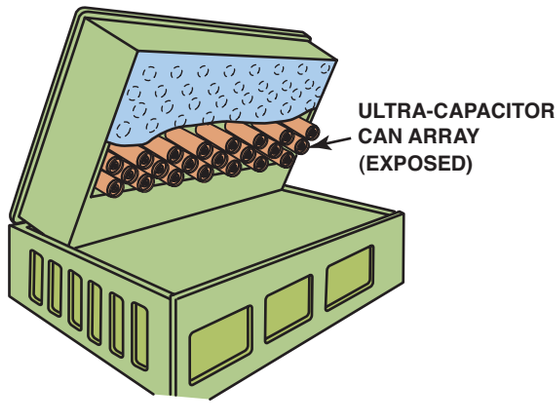

FIGURE 91–14 An ultracapacitor can be used in place of a high-voltage battery in a hybrid electric vehicle. This example is from the Honda FCX fuel-cell hybrid vehicle.

capacitor stores electrical energy using the principle of electrostatic attraction between positive and negative charges.

Ultracapacitors are built very different from conventional capacitors. Ultracapacitor cells are based on **double-layer technology,** in which two activated-carbon electrodes are immersed in an organic electrolyte. The electrodes have a very large surface area and are separated by a membrane that allows ions to migrate but prevents the electrodes from touching. ● **SEE FIGURE 91–13.** Charging and discharging occurs as ions move within the electrolyte but no chemical reaction takes place. Ultracapacitors can charge and discharge quickly and efficiently, making them especially suited for electric assist applications in fuel-cell hybrid vehicles.

Ultracapacitors that are used in fuel-cell hybrid vehicles are made up of multiple cylindrical cells connected in parallel. ● **SEE FIGURE 91–14.** This results in the total capacitance being the sum of the values of each individual cell. For example, ten 1.0-**farad** capacitors connected in parallel will have a total capacitance of 10.0 farads. Greater capacitance means greater electrical storage ability, and this contributes to greater assist for the electric motors in a fuel-cell hybrid vehicle.

Ultracapacitors have excellent cycle life, meaning that they can be fully charged and discharged many times without degrading their performance. They are also able to operate over a wide temperature range and are not affected by low temperatures to the same degree as many battery technologies. The one major downside of ultracapacitors is a lack of specific energy, which means that they are best suited for sudden bursts of energy as opposed to prolonged discharge cycles. Research is being conducted to improve this and other aspects of ultracapacitor performance.

FUEL-CELL TRACTION MOTORS. Much of the technology behind the electric drive motors being used in fuel-cell vehicles was developed during the early days of the California ZEV mandate. This was a period when battery-powered electric vehicles were being built by the

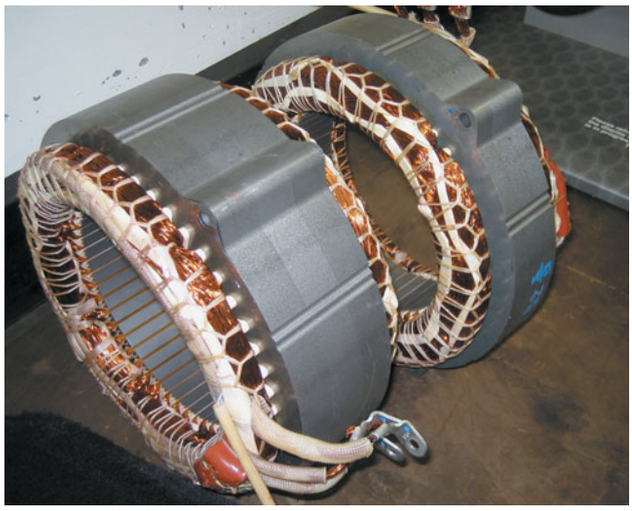

FIGURE 91–15 Drive motors in fuel-cell hybrid vehicles often use stator assemblies similar to ones found in Toyota hybrid electric vehicles. The rotor turns inside the stator and has permanent magnets on its outer circumference.

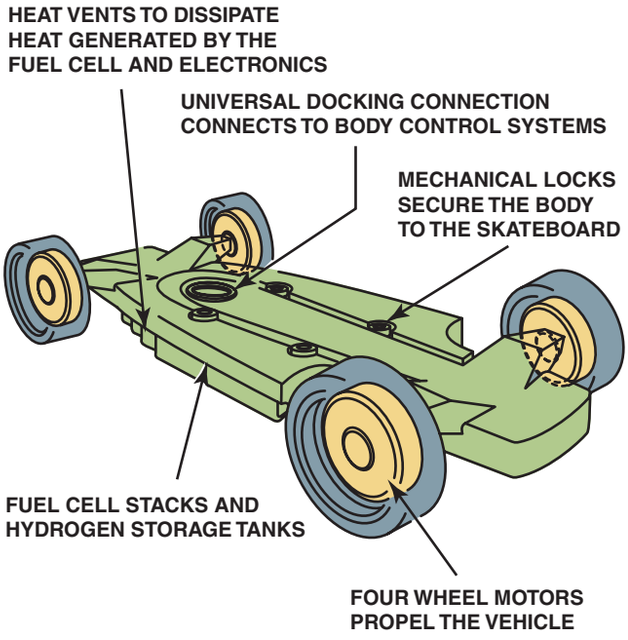

FIGURE 91–16 The General Motors "Skateboard" concept uses a fuel-cell propulsion system with wheel motors at all four corners.

major vehicle manufacturers in an effort to meet a legislated quota in the state of California. The ZEV mandate rules were eventually relaxed to allow other types of vehicles to be substituted for credit, but the technology that had been developed for pure electric vehicles was now put to work in these other vehicle designs.

The electric traction motors used in fuel-cell hybrid vehicles are very similar to those being used in current hybrid electric vehicles. The typical drive motor is based on an AC synchronous design, which is sometimes referred to as a DC brushless motor. This design is very reliable as it does not use a commutator or brushes, but instead has a three-phase stator and a permanent magnet rotor. ● **SEE FIGURE 91–15.** An electronic controller (inverter) is used to generate the three-phase high-voltage AC current required by the motor. While the motor itself is very simple, the electronics required to power and control it are complex.

Some fuel-cell hybrid vehicles use a single electric drive motor and a transaxle to direct power to the vehicle's wheels. It is also possible to use **wheel motors** to drive individual wheels. While this approach adds a significant amount of unsprung weight to the chassis, it allows for greater control of the torque being applied to each individual wheel. ● **SEE FIGURE 91–16.**

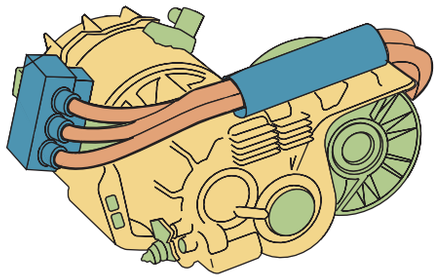

FIGURE 91–17 The electric drive motor and transaxle assembly from a Toyota FCHV. Note the three orange cables, indicating that this motor is powered by high-voltage three-phase alternating current.

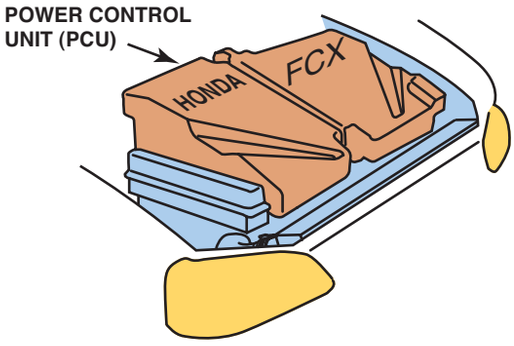

FIGURE 91–18 The power control unit (PCU) on a Honda FCX fuel-cell hybrid vehicle is located under the hood.

TRANSAXLES. Aside from the hydrogen fueling system, fuel-cell hybrid vehicles are effectively pure electric vehicles in that their drive train is electrically driven. Electric motors work very well for automotive applications because they produce high torque at low RPMs and are able to maintain a consistent power output throughout their entire RPM range. This is in contrast to vehicles powered by internal combustion engines, which produce very little torque at low RPMs and have a narrow range where significant horsepower is produced.

ICE-powered vehicles require complex transmissions with multiple speed ranges in order to accelerate the vehicle quickly and maximize the efficiency of the ICE. Fuel-cell hybrid vehicles use electric drive motors that require only a simple reduction in their final drive and a differential to send power to the drive wheels. No gear shifting is required and mechanisms such as torque converters and clutches are done away with completely. A reverse gear is not required either, as the electric drive motor is simply powered in the opposite direction. The transaxles used in fuel-cell hybrid vehicles are extremely simple with few moving parts, making them extremely durable, quiet, and reliable. ● **SEE FIGURE 91–17.**

POWER CONTROL UNITS. The drive train of a fuel-cell hybrid vehicle is controlled by a power control unit (PCU), which controls fuel-cell output and directs the flow of electricity between the various components. One of the functions of the PCU is to act as an **inverter,** which changes direct current from the fuel-cell stack into three-phase alternating current for use in the vehicle drive motor(s). ● **SEE FIGURE 91–18.**

Power to and from the secondary battery is directed through the power control unit, which is also responsible for maintaining the battery pack's state of charge and for controlling and directing the output of the fuel-cell stack. ● **SEE FIGURE 91–19.**

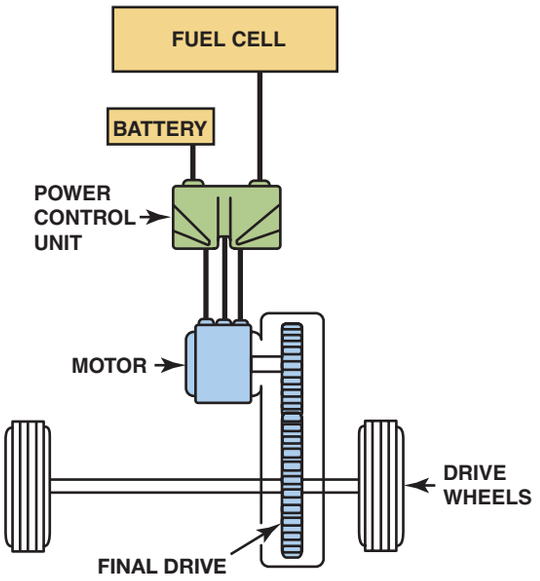

FIGURE 91–19 Toyota's FCHV uses a power control unit that directs electrical energy flow between the fuel cell, battery, and drive motor.

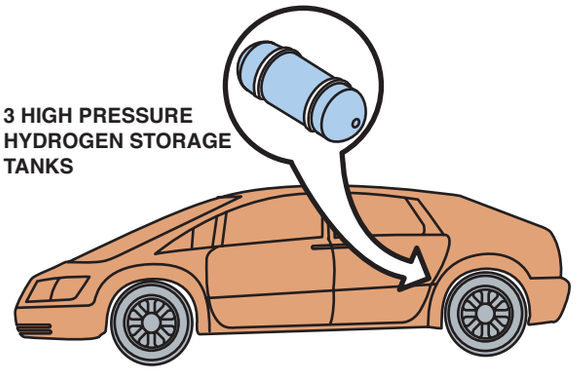

FIGURE 91–20 This GM fuel-cell vehicle uses compressed hydrogen in three high-pressure storage tanks.

During regenerative braking, the electric drive motor acts as a generator and converts kinetic (moving) energy of the vehicle into electricity for recharging the high-voltage battery pack. The PCU must take the three-phase power from the motor (generator) and convert (or *rectify*) this into DC voltage to be sent to the battery. DC power from the fuel cell will also be processed through the PCU for recharging the battery pack.

A DC-to-DC converter is used in hybrid-electric vehicles for converting the high voltage from the secondary battery pack into the 12 volts required for the remainder of the vehicle's electrical system. Depending on the vehicle, there may also be 42 volts required to operate accessories such as the electric-assist power steering. In fuel-cell hybrid vehicles, the DC-to-DC converter function may be built into the power control unit, giving it full responsibility for the vehicle's power distribution.

HYDROGEN STORAGE

One of the pivotal design issues with fuel-cell hybrid vehicles is how to store sufficient hydrogen onboard to allow for reasonable vehicle range. Modern drivers have grown accustomed to having a minimum of 300 miles between refueling stops, a goal that is extremely difficult to achieve when fueling the vehicle with hydrogen. Hydrogen has a very high energy content on a pound-for-pound basis, but its energy density is less than that of conventional liquid fuels. This is because gaseous hydrogen, even at high pressure, has a very low physical density (mass per unit volume). ● **SEE FIGURE 91–20.**

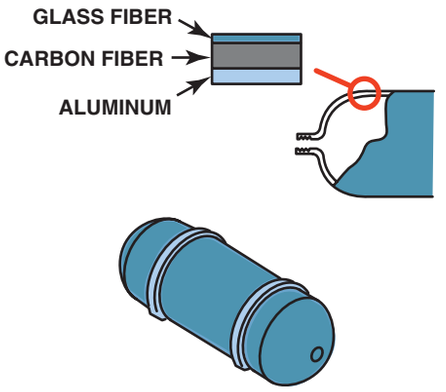

FIGURE 91–21 The Toyota FCHV uses high-pressure storage tanks that are rated at 350 bar. This is the equivalent of 5,000 pounds per square inch.

FIGURE 91–22 The high-pressure fitting used to refuel a fuel-cell hybrid vehicle.

A number of methods of hydrogen storage are being considered for use in fuel-cell hybrid vehicles. These include high-pressure compressed gas, liquefied hydrogen, and solid storage in metal hydrides. Efficient hydrogen storage is one of the technical issues that must be solved in order for fuel cells to be adopted for vehicle applications. Much research is being conducted to solve the issue of onboard hydrogen storage.

HIGH-PRESSURE COMPRESSED GAS. Most current fuel-cell hybrid vehicles use compressed hydrogen that is stored in tanks as a high-pressure gas. This approach is the least complex of all the storage possibilities, but also has the least energy density. Multiple small storage tanks are often used rather than one large one in order to fit them into unused areas of the vehicle. One drawback with this approach is that only cylinders can be used to store gases at the required pressures. This creates a good deal of unused space around the outside of the cylinders and leads to further reductions in hydrogen storage capacity. It is common for a pressure of 5000 psi (350 bar) to be used, but technology is available to store hydrogen at up to 10,000 psi (700 bar). ● **SEE FIGURE 91–21.**

The tanks used for compressed hydrogen storage are typically made with an aluminum liner wrapped in several layers of carbon fiber and an external coating of fiberglass. In order to refuel the compressed hydrogen storage tanks, a special high-pressure fitting is installed in place of the filler neck used for conventional vehicles. ● **SEE FIGURE 91–22.** There is also a special electrical connector

FIGURE 91–23 Note that high-pressure hydrogen storage tanks must be replaced in 2020.

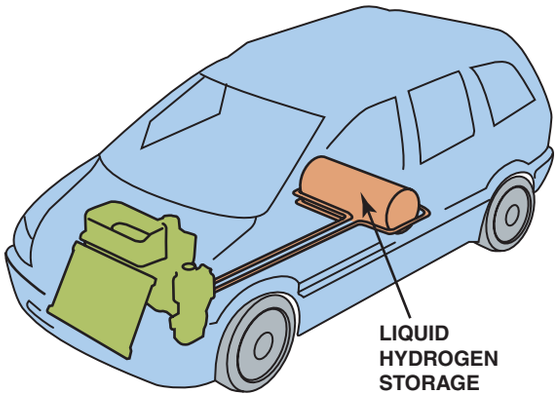

FIGURE 91–24 GM's Hydrogen3 has a range of 249 miles when using liquid hydrogen.

that is used to enable communication between the vehicle and the filling station during the refueling process. ● **SEE FIGURE 91–23.**

The filling station utilizes a special coupler to connect to the vehicle's high-pressure refueling fitting. The coupler is placed on the vehicle fitting, and a lever on the coupler is rotated to seal and lock it into place.

LIQUID HYDROGEN. Hydrogen can be liquefied in an effort to increase its energy density, but this requires that it be stored in cryogenic tanks at −423°F (−253°C). This increases vehicle range, but impacts overall efficiency, as a great deal of energy is required to liquefy the hydrogen and a certain amount of the liquid hydrogen will "boil off" while in storage.

One liter of liquid hydrogen only has one-fourth the energy content of 1 liter of gasoline. ● **SEE FIGURES 91–24 AND 91–25.**

SOLID STORAGE OF HYDROGEN. One method discovered to store hydrogen in solid form is as a metal hydride, similar to how a nickel-metal hydride (NiMH) battery works.

A demonstration vehicle features a lightweight fiber-wrapped storage tank under the body that stores 3 kg (about 6.6 pounds) of hydrogen as a metal hydride at low pressure. The vehicle can travel almost 200 miles with this amount of fuel. One kilogram of hydrogen is equal to 1 gallon of gasoline. Three gallons of water will generate 1 kilogram of hydrogen.

A metal hydride is formed when gaseous hydrogen molecules disassociate into individual hydrogen atoms and bond with the metal atoms in the storage tank. This process uses powdered metallic alloys capable of rapidly absorbing hydrogen to make this occur.

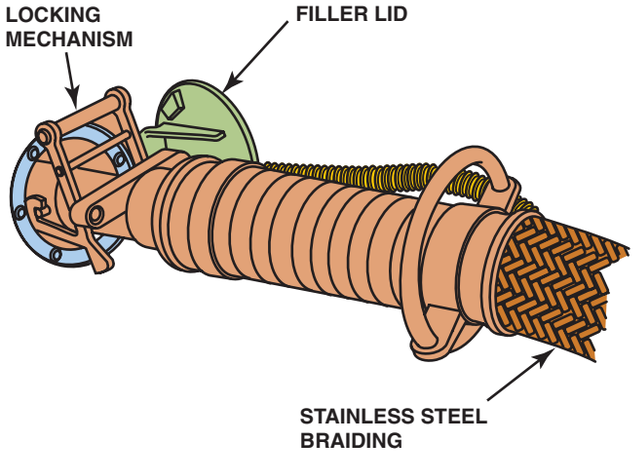

FIGURE 91–25 Refueling a vehicle with liquid hydrogen.

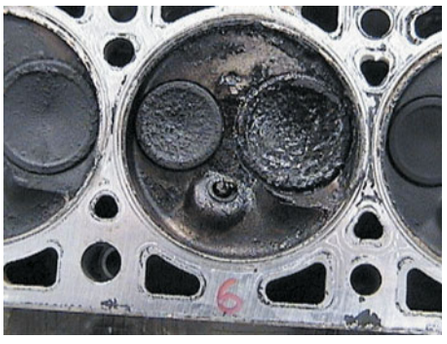

FIGURE 91–26 Carbon deposits, such as these, are created by incomplete combustion of a hydrocarbon fuel.

TECH TIP

Hydrogen Fuel = No Carbon

Most fuels contain hydrocarbons or molecules that contain both hydrogen and carbon. During combustion, the first element that is burned is the hydrogen. If combustion is complete, then all of the carbon is converted to carbon dioxide gas and exits the engine in the exhaust. However, if combustion is not complete, carbon monoxide is formed, plus leaving some unburned carbon to accumulate in the combustion chamber. ● **SEE FIGURE 91–26.**

HYDRAULIC HYBRID STORAGE SYSTEM

Ford Motor Co. is experimenting with a system it calls **Hydraulic Power Assist (HPA).** This system converts kinetic energy to hydraulic pressure, and then uses that pressure to help accelerate the vehicle. It is currently being tested on a four-wheel-drive (4WD) Lincoln Navigator with a 4.0-L V-8 engine in place of the standard 5.4-L engine.

A variable-displacement hydraulic pump/motor is mounted on the transfer case and connected to the output shaft that powers the front drive shaft. The HPA system works with or without 4WD engaged. A valve block mounted on the pump contains solenoid valves to control the flow of hydraulic fluid. A 14-gallon, high-pressure accumulator is mounted behind the rear axle, with a low-pressure accumulator right behind it to store hydraulic fluid. The master cylinder has a

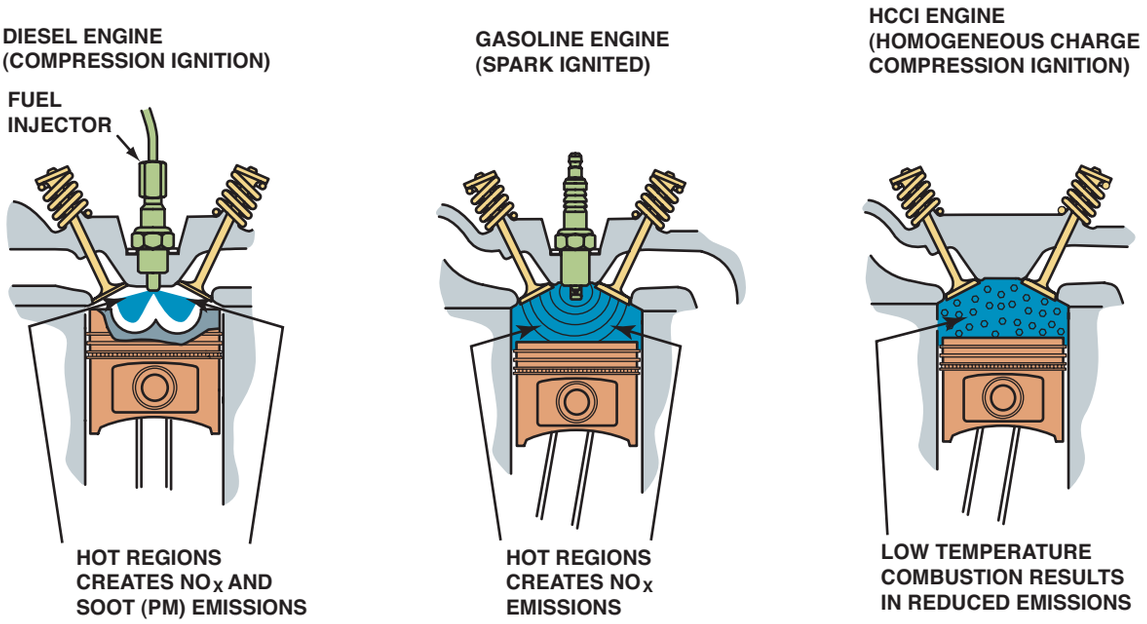

FIGURE 91–27 Both diesel and conventional gasoline engines create exhaust emissions due to high peak temperatures created in the combustion chamber. The lower combustion temperatures during HCCI operation result in high efficiency with reduced emissions.

"deadband," meaning the first few fractions of an inch of travel do not pressurize the brake system. When the driver depresses the brake pedal, a pedal movement sensor signals the control unit, which then operates solenoid valves to send hydraulic fluid from the low-pressure reservoir to the pump. The pumping action slows the vehicle, similar to engine compression braking, and the fluid is pumped into the high-pressure reservoir. Releasing the brake and pressing on the accelerator signals the control unit to send that high-pressure fluid back to the pump, which then acts as a hydraulic motor and adds torque to the drive line. The system can be used to launch the vehicle from a stop and/or add torque for accelerating from any speed.

While the concept is simple, the system itself is very complicated. Additional components include:

- Pulse suppressors
- Filters
- An electric circulator pump for cooling the main pump/motor

Potential problems with this system include leakage problems with seals and valves, getting air out of the hydraulic fluid system, and noise. In prototype stages the system demands different driving techniques. Still, this system was built to prove the concept, and the engineers believe that these problems can be solved and that a control system can be developed that will make HPA transparent to the driver. A 23% improvement in fuel economy and improvements in emissions reduction were achieved using a dynamometer set for a 7,000-pound vehicle. While the HPA system could be developed for any type of vehicle with any type of drive train, it does add weight and complexity, which would add to the cost.

HCCI

Homogeneous Charge Compression Ignition (HCCI) is a combustion process. HCCI is the combustion of a very lean gasoline air–fuel mixture without the use of a spark ignition. It is a low-temperature, chemically controlled (flameless) combustion process. ● **SEE FIGURE 91–27.**

HCCI combustion is difficult to control and extremely sensitive to changes in temperature, pressure, and fuel type. While the challenges of HCCI are difficult, the advantages include having a gasoline engine being able to deliver 80% of diesel efficiency (a 20% increase in fuel economy) for 50% of the cost. A diesel engine using HCCI can deliver gasoline-like emissions. Spark and injection timing are no longer a factor as they are in a conventional port-fuel injection system.

While much research and development needs to be performed using this combustion process, it has been shown to give excellent performance from idle to mid-load, and from ambient to warm operating temperatures as well as cold-start and run capability. Because an engine only operates in HCCI mode at light throttle settings, such as during cruise conditions at highway speeds, engineers need to improve the transition in and out of the HCCI mode. Work is also being done on piston and combustion chamber shape to reduce combustion noise and vibration that is created during operation in the HCCI operating mode.

Ongoing research is focusing on improving fuel economy under real-world operating conditions as well as controlling costs.

PLUG-IN HYBRID ELECTRIC VEHICLES

A **plug-in hybrid electric vehicle (PHEV)** is a hybrid electric vehicle that is designed to be plugged into an electrical outlet at night to charge the batteries. By charging the batteries in the vehicle, it can operate using electric power alone (stealth mode) for a longer time, thereby reducing the use of the internal combustion engine (ICE). The less the ICE is operating, the less fuel is consumed and the lower the emissions. At the present time, plug-in hybrids are not offered by any major manufacturer but many conventional HEVs are being converted to plug-in hybrids by adding additional batteries.

If a production plug-in hybrid is built, it should be able to get about twice the fuel economy of a conventional hybrid. The extra weight of the batteries will be offset, somewhat, by the reduced weight of a smaller ICE. At highway speeds, fuel efficiency is affected primarily by aerodynamics, and therefore the added weight of the extra batteries is equal to one or two additional passengers and thus would only slightly reduce fuel economy. Recharging will normally take place at night during cheaper off-peak hours. Counting fuel and service, the total lifetime cost of ownership will be lower than a conventional gasoline-powered vehicle.

FIGURE 91–28 A typical electric vehicle charging station on the campus of a college in southern California.

FIGURE 91–29 A conductive-type charging connector. This type of battery charging connector is sometimes called an AVCON connector, named for the manufacturer.

There are emissions related to the production of the electricity, which are called *well-to-wheel emissions.* These emissions, including greenhouse gases, are far lower than those of gasoline, even for the national power grid, which is 50% coal. Vehicles charging off-peak will use power from plants that cannot be turned off at night and often use cleaner sources such as natural gas and hydroelectric power. Plug-in hybrids could be recharged using rooftop photovoltaic systems, which would create zero emissions.

THE FUTURE FOR ELECTRIC VEHICLES

The future of electric vehicles depends on many factors, including:

1. The legislative and environmental incentives to overcome the cost and research efforts to bring a usable electric vehicle to the market.
2. The cost of alternative energy. If the cost of fossil fuels increases to the point that the average consumer cannot afford to drive a conventional vehicle, then electric vehicles (EVs) may be a saleable alternative.
3. Advancement in battery technology that would allow the use of lighter-weight and higher-energy batteries.

COLD-WEATHER CONCERNS Past models of electric vehicles such as the General Motors electric vehicle (EV1) were restricted to locations such as Arizona and southern California that had a warm climate, because cold weather is a major disadvantage to the use of electric vehicles for the following reasons:

- Cold temperatures reduce battery efficiency.
- Additional electrical power from the batteries is needed to heat the batteries themselves to be able to achieve reasonable performance.
- Passenger compartment heating is a concern for an electric vehicle because it would require the use of resistance units or other technology that would reduce the range of the vehicle.

HOT-WEATHER CONCERNS Batteries do not function well at high temperatures, and therefore some type of battery cooling must be added to the vehicle to allow for maximum battery performance. This would then result in a reduction of vehicle range due to the use of battery power needed just to keep the batteries working properly. Besides battery concerns, the batteries would also have to supply the power needed to keep the interior cool as well as all of the other accessories. These combined electrical loads represent a huge battery drain and reduce the range of the vehicle.

RECHARGING METHODS AND CONCERNS How far an electric vehicle can travel on a full battery charge is called its **range.** The range of an electric vehicle depends on many factors, including:

- Battery energy storage capacity
- Vehicle weight
- Outside temperature
- Terrain (driving in hilly or mountainous areas requires more energy from the battery)
- Use of air conditioning and other electrical devices

Because electric vehicles have a relatively short range, charging stations must be made available in areas where these vehicles are driven. For example, when the state of California mandated the sale of zero-emission vehicles (ZEV), charging stations were set up in many areas, usually in parking lots of businesses and schools. ● **SEE FIGURE 91–28.** The parking spaces near the charging stations were designated for electric vehicles only and could be used for free to recharge electric vehicles. If electric vehicles are going to become widely used, charging stations will have to be established to allow the necessary recharging for trips to work and back home.

CHARGING METHODS When the state of California set up electric vehicle charging stations, both a conductive- and inductive-type charger was made available at each station.

CONDUCTIVE CHARGING. Conductive charging uses an electrical plug that makes physical contact with terminals in the vehicle. The charger can be powered by 110-V AC, or most commonly 220-V AC. ● **SEE FIGURE 91–29.** This type of charger connection is used on some Ford and Honda electric vehicles.

INDUCTIVE CHARGING. Inductive charging is achieved by inserting a paddlelike probe into a charging receptacle (opening) in the vehicle. The charger is powered by 220-volt AC and does not make physical contact with the vehicle. ● **SEE FIGURE 91–30.**

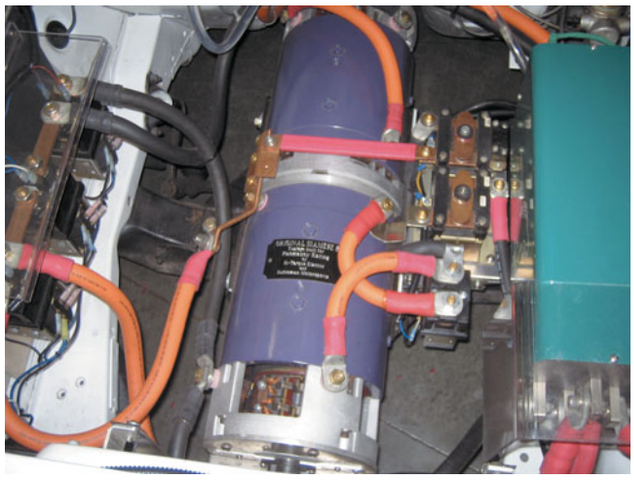
An inductive charger paddle contains a coil of wire and the AC current from the charger flows through the winding, which creates a moving magnetic field around the paddle. Inside the charging receptacle of the vehicle is another coil of wire. The alternating magnetic field induces an AC voltage in the coil winding.

FIGURE 91–30 An inductive-type electric vehicle battery charger connector. This type of connector fits into a charging slot in the vehicle, but does not make electrical contact.

FREQUENTLY ASKED QUESTION

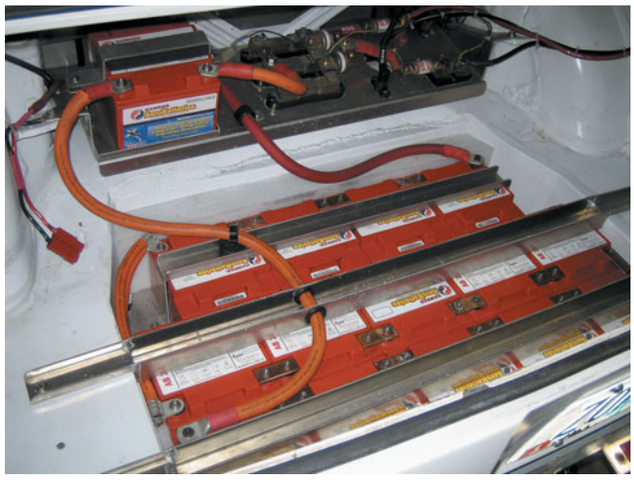
What Is NEDRA?

NEDRA is the **National Electric Drag Racing Association** that holds drag races for electric-powered vehicles throughout the United States. The association does the following:



1. Coordinates a standard rule set for electric vehicle drag racing, to balance the needs and interests of all those involved in the sport.
2. Sanctions electric vehicle drag racing events, to:
   - Make the events as safe as possible.
   - Record and maintain official records.
   - Maintain consistency on a national scale.
   - Coordinate and schedule electric vehicle drag racing events.
3. Promotes electric vehicle drag racing to:
   - Educate the public and increase people's awareness of electric vehicles while eliminating any misconceptions.
   - Have fun in a safe and silent drag racing environment.

● **SEE FIGURE 91–31.**



The electronics in the vehicle then changes the induced AC current into DC current to charge the batteries. Inductive-type chargers are used with the General Motors EV-1, as well as Nissan and Toyota electric vehicles.

WIND POWER

Wind power is used to help supplement electric power generation in many parts of the country. Because AC electricity cannot be stored, this energy source is best used to reduce the use of natural gas and coal to help reduce CO_2 emissions. Wind power is most economical if the windmills are located where the wind blows consistently above 8 miles per hour (13 km/h). Locations include the eastern slope of mountain ranges, such as the Rocky Mountains, or on high ground in many states. Often, wind power is used as supplemental power in the evenings when it is most needed, and is allowed to stop rotating in daylight hours when the power is not needed. Windmills are usually grouped together to form **wind farms,** where the product is electrical energy. Energy from wind farms can be used to charge plug-in hybrid vehicles, as well as for domestic lighting and power needs. ● **SEE FIGURES 91–32 AND 91–33.**

This 8-inch-diameter motor is controlled by an electronic controller that limits the voltage to 170 volts to prevent commutator flashover yet provides up to 2,000 amperes. This results in an amazing 340,000 watts or 455 Hp. (b) The batteries used for the compact drag car include twenty 12-volt absorbed glass mat (AGM) batteries connected in series to provide 240 volts.

HYDROELECTRIC POWER

Hydroelectric power is limited to locations where there are dammed rivers and hydroelectric plants. However, electricity can and is transmitted long distances—so that electricity generated at the Hoover Dam can be used in California and other remote locations. Electrical power from hydroelectric sources can be used to charge plug-in hybrid electric vehicles, thereby reducing emissions that would normally be created by burning coal or natural gas to create electricity. However, hydroelectric plants are limited as to the amount of power they can produce, and constructing new plants is extremely expensive. ● **SEE FIGURE 91–34.**

FUNDAMENTALS OF BRAKE SYSTEMS

Brakes are by far the most important mechanism on any vehicle because the safety and lives of those riding in the vehicle depend on proper operation of the braking system. It has been estimated that the brakes on the average vehicle are applied 50,000 times a year!

Brakes are an energy-absorbing mechanism that converts vehicle movement into heat while stopping the rotation of the wheels. All braking systems are designed to reduce the speed and stop a moving vehicle and to keep it from moving if the vehicle is stationary. **Service brakes** are the main driver-operated brakes of the vehicle. Service brakes are also called **base brakes** or **foundation brakes.** ● **SEE FIGURE 92–1.**

BRAKE SYSTEM PARTS

Most vehicles built since the late 1920s use a brake on each wheel. To stop a wheel, the driver exerts a force on a brake pedal. The force on the brake pedal pressurizes brake fluid in a master cylinder. This hydraulic force (liquid under pressure) is transferred through steel lines and flexible brake lines to a wheel cylinder or caliper at each wheel. Hydraulic pressure to each wheel cylinder or caliper is used to force friction materials against the brake drum or rotor. The friction between the stationary friction material and the rotating drum or rotor (disc) causes the rotating part to slow and eventually stop. Since the wheels are attached to the drums or rotors, the wheels of the vehicles also stop.

The heavier the vehicle and the higher the speed, the more heat the brakes have to be able to absorb. Long, steep hills can cause the brakes to overheat which results in the brakes not being able to produce the friction necessary to slow or stop a vehicle.

DRUM BRAKES. **Drum brakes** are used on the rear of many rear-wheel-drive, front-wheel-drive, and four-wheel-drive vehicles. When drum brakes are applied, brake shoes are moved outward against a rotating brake drum. The wheel studs for the wheels are attached to the drum. When the drum slows and stops, the wheels also slow and stop.

Drum brakes are economical to manufacture, service, and repair. Parts for drum brakes are generally readily available and reasonably priced. On some vehicles, an additional drum brake is used as a parking brake on vehicles equipped with rear disc brakes. ● **SEE FIGURE 92–2.**

DISC BRAKES. **Disc brakes** are used on the front of most vehicles built since the early 1970s and on the rear wheels of many vehicles.

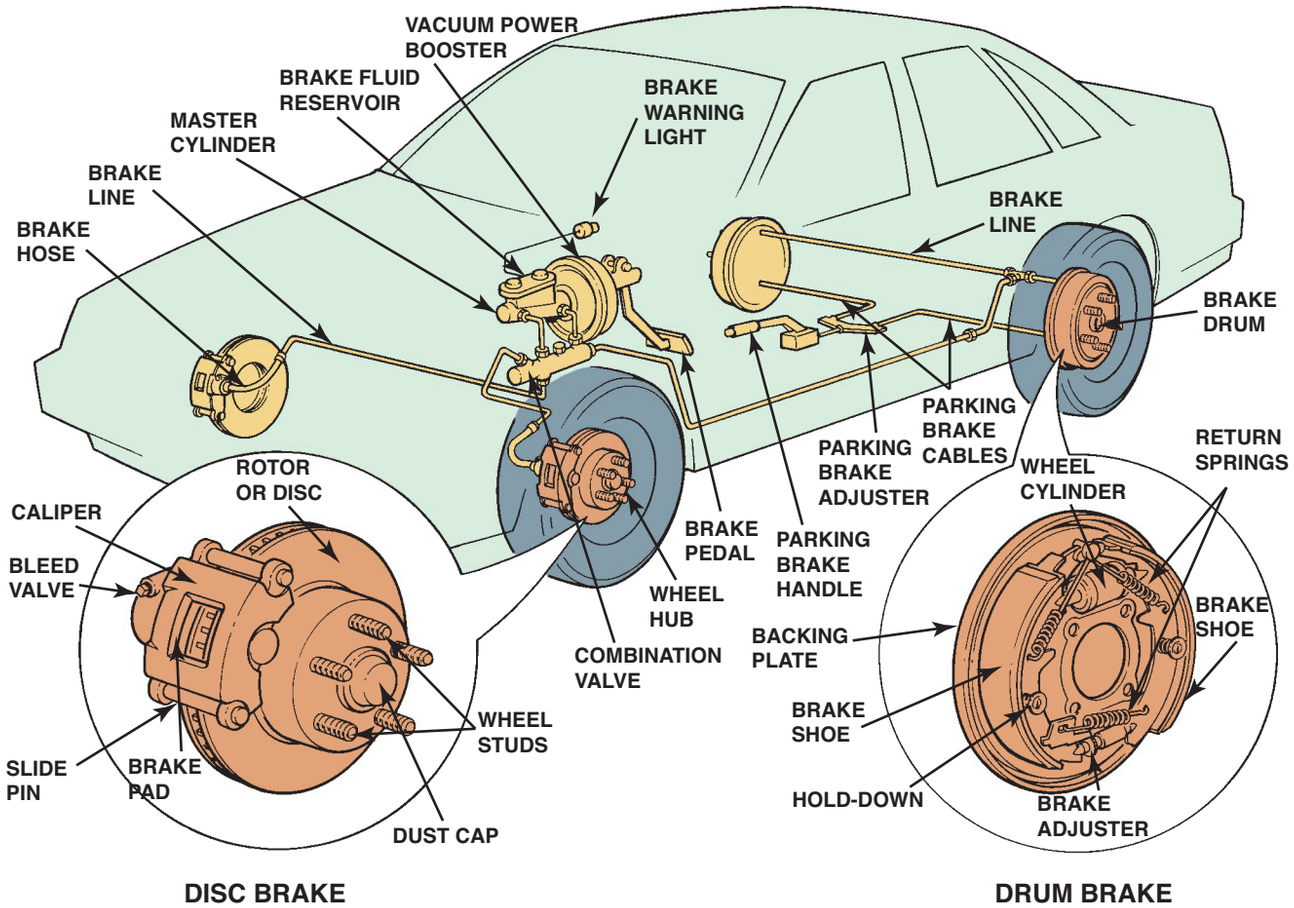

FIGURE 92–1 Typical vehicle brake system showing all typical components.

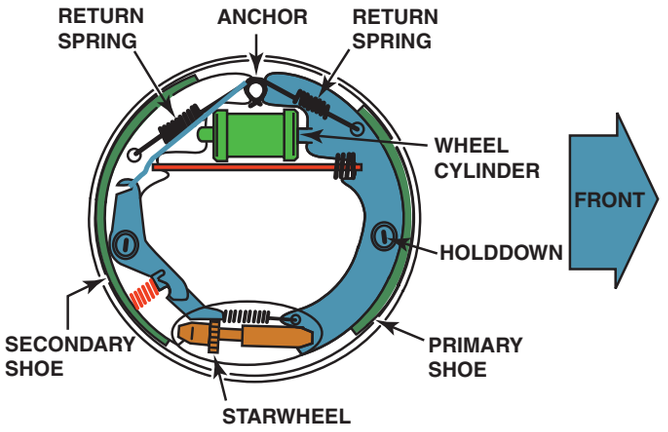

FIGURE 92–2 Typical drum brake assembly.

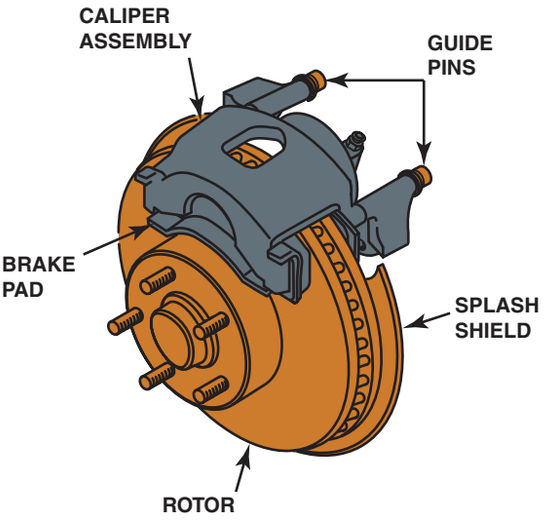

FIGURE 92–3 Typical disc brake assembly.

A disc brake operates by squeezing brake pads on both sides of a rotor or disc that is attached to the wheel. ● **SEE FIGURE 92–3.**

Type of Brake	Rotating Part	Friction Part
Drum brakes	Brake drum	Brake shoes
Disc brakes	Rotor or disc	Brake pads

Due to the friction between the road surface and the tires, the vehicle stops. To summarize, the sequence of events necessary to stop a vehicle include the following:

1. The driver presses on the brake pedal.
2. The brake pedal force is transferred hydraulically to a wheel cylinder or caliper at each wheel.
3. Hydraulic pressure inside the wheel cylinder or caliper presses friction materials (brake shoes or pads) against rotating brake drums or rotors.
4. The friction slows and stops the drum or rotor. Since the drum or rotor is bolted to the wheel of the vehicle, the wheel also stops.
5. When the wheels of the vehicle slow and stop, the tires must have friction (traction) with the road surface to stop the vehicle.

BRAKE DESIGN REQUIREMENTS

All braking forces must provide for the following:

- Equal forces must be applied to both the left and right sides of the vehicle to assure straight stops.
- Hydraulic systems must be properly engineered and serviced to provide for changes as vehicle weight shifts forward during braking. Hydraulic valves must be used in the hydraulic system to permit the maximum possible braking forces but still prevent undesirable wheel lockup. Antilock braking systems (ABS) are specifically designed to prevent wheel lockup under all driving conditions, including wet or icy road conditions.
- The hydraulic system must use a fluid that will not evaporate or freeze. The fluid has to withstand extreme temperatures without boiling and must not damage rubber or metal parts of the braking system.
- The friction material (brake shoes or brake pads) must be designed to provide adequate friction between the stationary shoes or pads and the rotating drum or rotor. The friction material should be environmentally safe. Nonasbestos lining is generally considered to be safe for the environment and the technician.
- The design of the braking system should secure the brake lining solidly to prevent the movement of the friction material during braking. It is this movement of the friction material that causes brake noise (squeal).
- Most braking systems incorporate a power assist unit that reduces the driver's effort but does not reduce stopping distance. The most commonly used brake booster is vacuum operated.

BRAKE SYSTEM CATEGORIES

Brake system components can be classified and placed into six subsystem categories, depending on their function. ● **SEE FIGURE 92–4** for an overall view of the entire braking system.

1. **Apply System.** The driver starts the operation of the braking system by pressing on the **brake pedal** or applying the **parking brake.** The apply system includes all the levers, pedals, or linkage needed to activate a braking force.
2. **Boost System.** The boost (power brake) system is used on most vehicles to reduce the force that the driver must exert on the brake pedal.
3. **Hydraulic System.** The brake pedal force is transferred to the hydraulic system, where the force is directed through lines and hoses to the wheel brakes.
4. **Wheel Brakes.** Hydraulic pressure from the hydraulic system moves a piston, in either a disc or drum brake system, which uses friction to press material against a rotating drum or rotor. The resulting friction slows the rotation of the wheels.
5. **Brake Balance Control System.** Mechanical, electrical, and hydraulic components are used to ensure that brakes are applied quickly and with balanced pressure for safe operation. Components in this category include metering valves, proportioning valves, and antilock braking system components.
6. **Brake warning lights.** There are two brake system-related warning lights.
   - The **red brake warning lamp (RBWL)** lights whenever a hydraulic system failure occurs. The red brake warning

lamp lights when the ignition is turned on as a bulb check then goes out unless a hydraulic fault has been detected. ● **SEE FIGURE 92–5.**

CAUTION: Do not test-drive a vehicle if the red brake warning light is on.

- The amber ABS warning lamp or dim red brake light indicates an ABS self-test and/or a possible problem in the ABS system. This warning light will usually flash several times during a self-test when the engine is first started and then go out unless a fault with the antilock braking system was detected.

FIGURE 92–5 The red brake warning light will remain on after a bulb test if there is a fault with the hydraulic part of the brake system.

ANTILOCK BRAKE SYSTEM OVERVIEW

The purpose of an **antilock braking system (ABS)** is to prevent the wheels from locking during braking, especially on low-friction surfaces such as wet, icy, or snowy roads. Remember, it is the friction between the tire tread and the road that does the actual stopping of the vehicle. Therefore, ABS does not mean that a vehicle can stop quickly on all road surfaces. ABS uses sensors at the wheels to measure the wheel speed. If a wheel is rotating slower than the others, indicating possible lockup (for example, on an icy spot), the ABS hydraulic controller will reduce the brake fluid pressure to that

wheel for a fraction of a second. *A locked wheel has less traction to the road surface than a rotating wheel.*

The ABS controller can reapply the pressure from the master cylinder to the wheel a fraction of a second later. Therefore, if a wheel starts to lock up, the purpose of the ABS system is to pulse the brakes on and off to maintain directional stability with maximum braking force. Many ABS units will cause the brake pedal to pulse if the unit is working in the ABS mode. The pulsating brake pedal is a cause for concern for some drivers. However, the pulsing brake pedal informs the driver that the ABS is being activated. Some ABS units use an isolator valve in the ABS unit to prevent brake pedal pulsations during ABS operation. With these types of systems, it is often difficult for the driver to know if and when the ABS unit is working to control a locking wheel. ● **SEE FIGURE 92–7** for an overview of a typical ABS on a rear-wheel-drive vehicle.

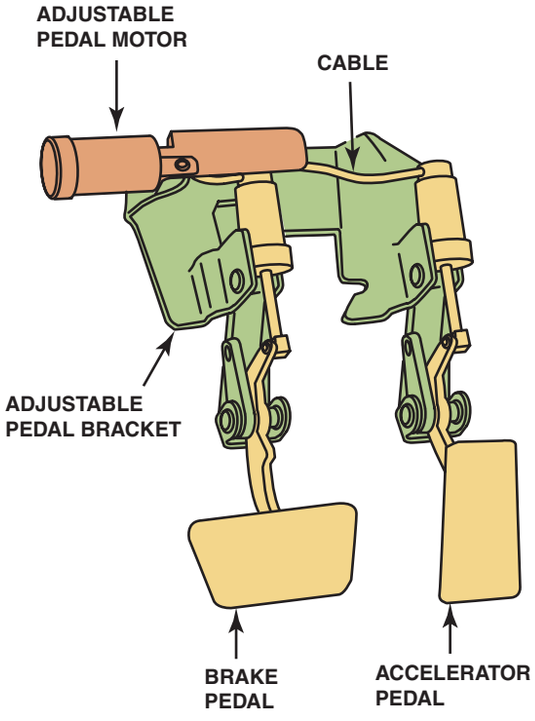

FIGURE 92–6 A typical adjustable pedal assembly. Both the accelerator and the brake pedal can be moved forward and rearward by using the adjustable pedal position switch.

FREQUENTLY ASKED QUESTION

How Do Adjustable Pedals Work?

Adjustable pedals, also called **electric adjustable pedals (EAP),** place the brake pedal and the accelerator pedal on movable brackets that are motor operated. A typical adjustable pedal system includes the following components:

- **Adjustable pedal position switch,** which allows the driver to position the pedals.
- **Adjustable pedal assembly,** which includes the motor, threaded adjustment rods, and a pedal position sensor. ● **SEE FIGURE 92–6.**

The position of the pedals, as well as the position of the seat system, is usually included as part of the memory seat function and can be set for two or more drivers.

Another symptom of normal ABS unit operation is the activation of the hydraulic pressure pump used by many ABS units. In some ABS units, the hydraulic pump is run every time the vehicle is started and moved. Other types of units operate randomly or whenever the pressure in the system calls for the pump to operate.

FEDERAL BRAKE STANDARDS

The statutes pertaining to automotive brake systems are part of the **Federal Motor Vehicle Safety Standards (FMVSS)** established by the United States **Department of Transportation (DOT).** Several standards apply to specific components within the brake system. The overall service and parking brake systems are dealt within standard 135.

FMVSS 135 was first mandated on September 1, 2000, for passenger vehicles, and September 1, 2002, for multipurpose vehicles, trucks, and buses with a gross vehicle weight rating (GVWR) of

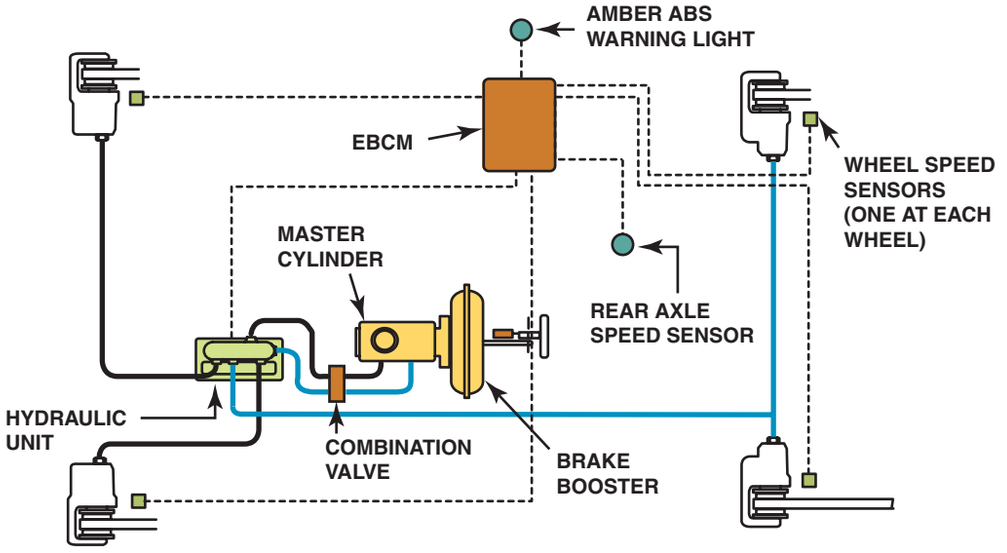

FIGURE 92–7 Typical components of an antilock braking system (ABS) used on a rear-wheel-drive vehicle.

7,716 pounds (3,500 kilograms). Its purpose is to "ensure safe braking performance under normal and emergency conditions." FMVSS 135 applies to "passenger vehicles, multipurpose passenger vehicles, trucks, and buses."

FMVSS 135 deals with brake system safety by establishing specific brake performance requirements. It does not dictate the *design* of the system, although some requirements may make older technologies impractical or obsolete. Only four parts of the brake system are specifically regulated:

- Fluid reservoir and labeling
- Dashboard warning lights
- A method of automatic adjustment
- A mechanically engaging, friction-type parking brake system

The FMVSS 135 tests are used by manufacturers to certify the braking performance of all new vehicles available for public purchase.

FMVSS 135 BRAKE TEST

The overall FMVSS 135 brake test procedure consists of up to 24 steps, depending on the vehicle's configuration and braking system. The actual performance tests are made with the vehicle loaded to both the manufacturer's specified **gross vehicle weight rating (GVWR)** and the **lightly loaded vehicle weight (LLVW),** with certain applied brake forces. There are precise instructions for every step of the test, including the number of times the tests must be repeated, the sequence of the testing, and the allowable stopping distance for the particular type of vehicle. Some highlights of the testing procedure include:

- **Burnish Procedure.** The brakes are burnished by making 200 stops from 50 mph (80 km/h) at a fixed rate of deceleration with a controlled cool-down period after each stop. This procedure conditions the friction material.
- **Adhesion Utilization (torque wheel method).** For vehicles not equipped with ABS, this test is to determine if the brake system will make adequate use of the road surface in stopping the vehicle.
- **Cold Effectiveness.** This test is performed to determine if the vehicle will have sufficient stopping power when the brake lining materials are not preheated by previous stops.
- **High Speed Effectiveness.** This test is performed to determine if the brake system will provide adequate stopping power for all loading conditions. The allowable stopping distance is calculated from the maximum speed the vehicle can attain.
- **Stops With the Engine Off.** This test is for vehicles equipped with brake power assist units. The vehicle, loaded to GVWR, must stop within 230 ft (70 m), from a speed of 62 mph (100 km/h). This test must be repeated six times.
- **Antilock Functional Failure.** This test ensures that service brakes will function correctly in the event of an antilock functional failure, and the brake system warning indicator is activated when an ABS electrical function failure occurs.
- **Variable Brake Proportioning System.** This test is performed on vehicles equipped with either a mechanical or an electrical variable proportioning system. It ensures that, in the event of a failure, the vehicle can still come to a stop in an acceptable distance.
- **Hydraulic Circuit Failure.** This test is performed to ensure that the driver will be alerted via the brake warning system indicator that a failure has occurred, and that the vehicle can still be stopped in an acceptable distance.

? **FREQUENTLY ASKED QUESTION**

Do the FMVSS 135 Standards Apply to Replacement Brake Part Performance?

No. The Federal Motor Vehicle Safety Standard 135 applies to new vehicles. Replacement parts used during a brake repair or replacement may or may not permit the vehicle to achieve the same standards as when new.

To help ensure like-new braking performance, the service technician should always use quality brake parts from a known manufacturer.

- **Brake Power Assist Unit Inoperative.** This test makes sure the service brake can stop the vehicle in an acceptable distance with the brake power assist unit in an inoperative state. It is performed on vehicles with brake power assist units turned off or inoperative.
- **Parking Brake.** The parking brake alone will hold the vehicle stationary in either the forward or reverse direction on a 20% grade for a period of at least 5 minutes.
- **Brake Heat Test.** This procedure heats the brake system by making a series of 15 stops from a high speed. The vehicle is loaded to GVWR, with rapid acceleration between each stop to minimize cooling the brakes.
- **Hot Performance.** After the brake system has been heated by a series of controlled stops, the hot performance test is immediately performed. The vehicle is loaded to GVWR and two stops are made. The stopping distance must be within acceptable limits as specified in the test. This test ensures that the brake system on the vehicle will not fade following a series of high-speed stops at GVWR.

Although these tests may seem extreme, these tests are only a minimum standard of performance. Any brake repair work should also leave the brake system capable of meeting FMVSS 135.

BRAKE REPAIR AND THE LAW

Once an automobile leaves the factory, the responsibility for maintaining the designed-in level of braking performance falls on the owner of the vehicle. Owners look to trained automotive technicians to service their brake systems. Many states have laws that regulate brake work to help ensure safe repairs. These laws vary from one area to another, but they may require special licensing for brake technicians, or special business practices when selling brake work. In some cases, the laws provide the consumer with specific warranties and the right to outside arbitration in cases of defective or substandard repairs.

Regardless of whether there are specific laws governing brake repair, a technician is always liable for damage or injuries resulting from repairs performed in an unprofessional or unworkman-like manner. Considering the lives and property that depend on good brakes, there is only one acceptable goal when making brake system repairs: to restore the system and its component parts so they perform to original specifications. In other words, *the purpose of any repair is to restore like-new performance.*

ENERGY PRINCIPLES

Energy is the ability to do work. There are many forms of energy, but chemical, mechanical, and electrical energy are the most familiar kinds involved in the operation of an automobile. ● **SEE FIGURE 93–1.**

For example, when the ignition key is turned to the "Start" position, chemical energy in the battery is converted into electrical energy to operate the starter motor. The starter motor then converts the electrical energy into mechanical energy that is used to crank the engine.

In the example above, energy is being used to perform work. **Work** is the transfer of energy from one physical system to another—especially the transfer of energy to an object through the application of force. This is precisely what occurs when a vehicle's brakes are applied: The *force* of the actuating system *transfers* the energy of the vehicle's motion to the brake drums or rotors where friction *converts* it into heat energy and stops the vehicle.

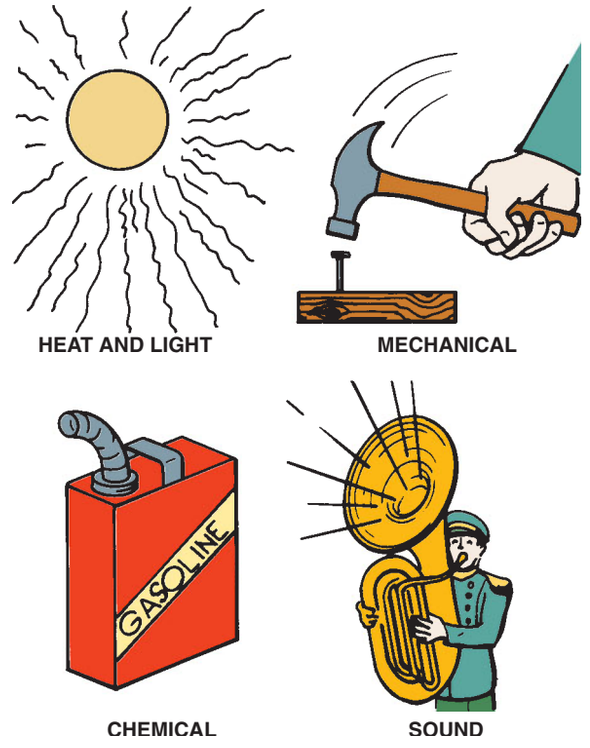

FIGURE 93–1 Energy which is the ability to perform work exists in many forms.

KINETIC ENERGY

Kinetic energy is a fundamental form of mechanical energy. It is the energy of mass in motion. Every moving object possesses kinetic energy, and the amount of that energy is determined by the object's mass and speed. The greater the mass of an object and the faster it moves, the more kinetic energy it possesses. Even at low speeds, a moving vehicle has enough kinetic energy to cause serious injury and damage. The job of the brake system is to dispose of that energy in a safe and controlled manner.

Engineers calculate kinetic energy using the following formula:

$$\frac{mv^2}{29.9} = E_k$$

where:

m = mass or weight of the vehicle in pounds (lb)
v = velocity of the vehicle in miles per hour
E_k = kinetic energy in foot-pounds (ft-lb)
29.9 = a constant

Another way to express this equation is as follows.

$$\frac{\text{weight} \times \text{speed}^2}{29.9} = \text{kinetic energy}$$

If a 3,000-lb vehicle traveling at 30 mph is compared with a 6,000-lb vehicle also traveling at 30 mph as shown in ● **FIGURE 93–2,** the equations for computing their respective kinetic energies look like this:

$$\frac{3{,}000 \text{ lb} \times 30^2 \text{ mph}}{29.9} = 90{,}301 \text{ ft-lb}$$

$$\frac{6{,}000 \text{ lb} \times 30^2 \text{ mph}}{29.9} = 180{,}602 \text{ ft-lb}$$

The results show that when the weight of a vehicle is doubled from 3,000 to 6,000 lb, its kinetic energy is also doubled from 90,301 ft-lb to 180,602 ft-lb. In mathematical terms, kinetic energy increases *proportionally* as weight increases. In other words, if the weight of a moving object doubles, its kinetic energy also doubles. If the weight quadruples, the kinetic energy becomes four times as great.

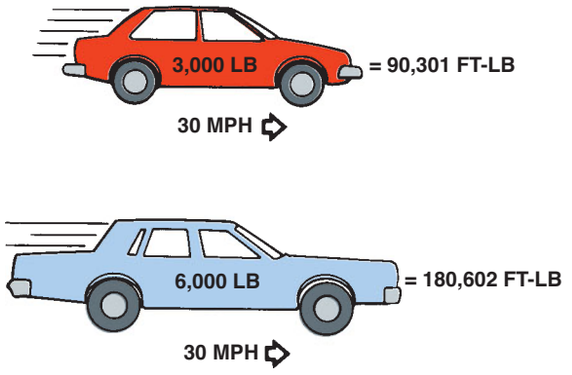

FIGURE 93–2 Kinetic energy increases in direct proportion to the weight of the vehicle.

If a 3,000-lb vehicle traveling at 30 mph is compared with the same vehicle traveling at 60 mph (● **FIGURE 93–3**), the equations for computing their respective kinetic energies look like this:

$$\frac{3{,}000 \text{ lb} \times 30^2 \text{ mph}}{29.9} = 90{,}301 \text{ ft-lb}$$

$$\frac{3{,}000 \text{ lb} \times 60^2 \text{ mph}}{29.9} = 361{,}204 \text{ ft-lb}$$

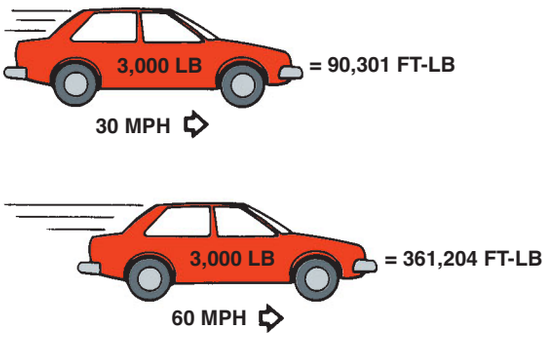

FIGURE 93–3 Kinetic energy increases as the square of any increase in vehicle speed.

The results show that the vehicle traveling at 30 mph has over 90,000 ft-lb of kinetic energy, but at 60 mph the figure increases to over 350,000 ft-lb. In fact, at twice the speed, the vehicle has exactly four times as much kinetic energy. If the speed were doubled again to 120 mph, the amount of kinetic energy would grow to almost 1,500,000 ft-lb! In mathematical terms, kinetic energy increases as the *square of its speed.* In other words, if the speed of a moving object doubles (2), the kinetic energy becomes four times as great ($2^2 = 4$). And if the speed quadruples (4), say from 15 to 60 mph, the kinetic energy becomes 16 times as great ($4^2 = 16$). This is the reason speed has such an impact on kinetic energy.

KINETIC ENERGY AND BRAKE DESIGN

The relationships between weight, speed, and kinetic energy have significant practical consequences for the brake system engineer. If vehicle A weighs twice as much as vehicle B, it needs a brake system that is twice as powerful. But if vehicle C has twice the speed potential of vehicle D, it needs brakes that are, not twice, but four times more powerful.

INERTIA

Although brake engineers take both weight and speed capability into account when designing a brake system, these are not the only factors involved. Another physical property, inertia, also affects the braking process and the selection of brake components. **Inertia** is defined by Isaac Newton's first law of motion, which states that a body at rest tends to remain at rest, and a body in motion tends to remain in motion in a straight line unless acted upon by an outside force.

WEIGHT TRANSFER AND BIAS

Inertia, in the form of **weight transfer,** plays a major part in a vehicle's braking performance. Newton's first law of motion dictates that a moving vehicle will remain in motion unless acted upon by an outside force. The vehicle brakes provide that outside force, but when the brakes are applied at the wheel friction assemblies, only the wheels and tires begin to slow immediately. The rest of the vehicle, all of the weight carried by the suspension, attempts to remain in forward motion. The result is that the front suspension compresses, the rear suspension extends, and the weight is transferred toward the front of the vehicle. ● **SEE FIGURE 93–4.**

The total weight of the vehicle does not change, only the amount supported by each axle. To compound the problem of weight transfer, most vehicles also have a forward **weight bias,** which means that even when stopped, more than 50% of their weight is supported by the front wheels. This occurs because the engine, transmission, and most other heavy parts are located toward the front of the vehicle. ● **SEE FIGURE 93–5.**

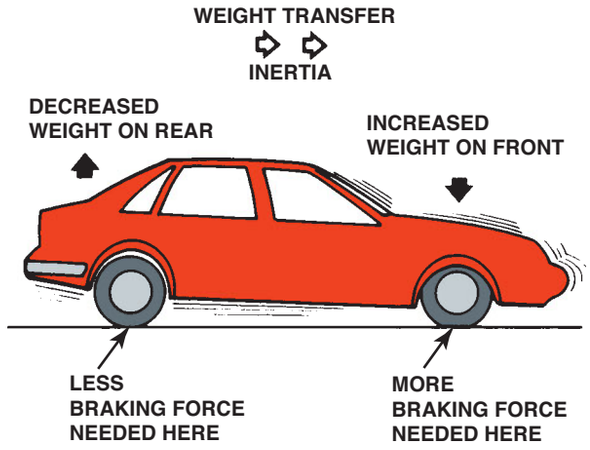

FIGURE 93–4 Inertia creates weight transfer that requires the front brakes to provide most of the braking force.

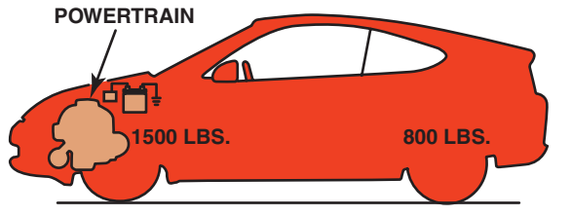

FIGURE 93–5 Front wheel drive vehicles have most of their weight over the front wheels.

TECH TIP

Brakes Cannot Overcome the Laws of Physics

No vehicle can stop on a dime. The energy required to slow or stop a vehicle must be absorbed by the braking system. All drivers should be aware of this fact and drive at a reasonable speed for the road and traffic conditions.

Front-wheel-drive (FWD) vehicles, in particular, have a forward weight bias. Whenever the brakes are applied, weight transfer and weight bias greatly increase the load on the front wheels, while the load on the rear wheels is substantially reduced. This requires the front brakes to provide 80% to 90% of the total braking force. To deal with the extra load, the front brakes are much more powerful than the rear brakes. They are able to convert more kinetic energy into heat energy.

MECHANICAL PRINCIPLES

LEVERS

The primary mechanical principle used to increase application force in every brake system is **leverage.** In the science of mechanics, a lever is a simple machine that consists of a rigid object, typically a metal bar that pivots about a fixed point called a **fulcrum.**

LEVERS IN BRAKING SYSTEMS

The levers in brake systems are used to increase force, so they are either first- or second-class. Second-class levers are the most common, and the service brake pedal is a good example. In a typical suspended brake pedal, the pedal arm is the lever, the pivot point is the fulcrum, and the force is applied at the foot pedal pad. ● **SEE FIGURE 93–6.**

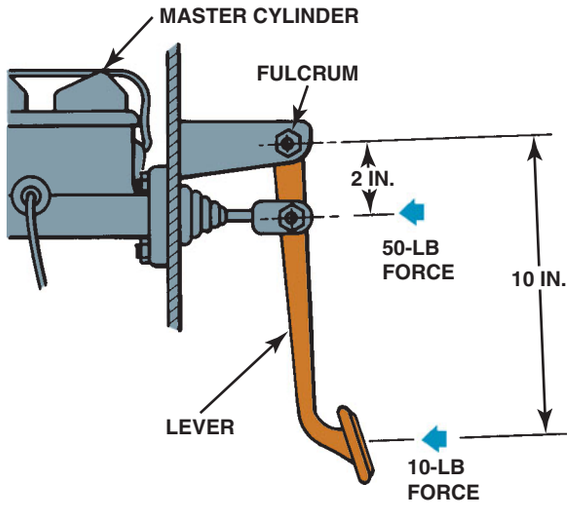

FIGURE 93–6 A brake pedal assembly is a second-class lever design that provides a 5 to 1 mechanical advantage.

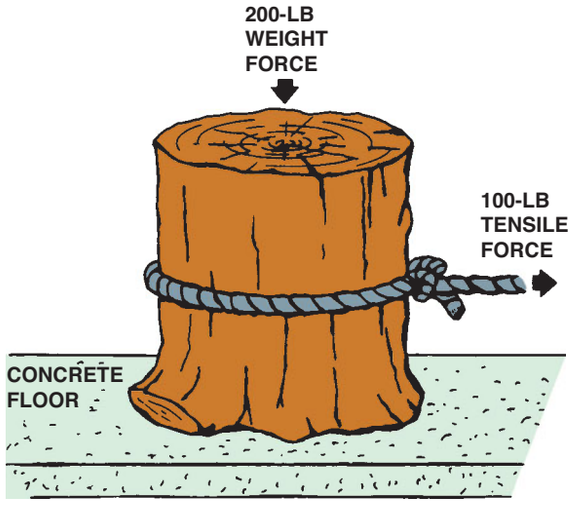

FIGURE 93–7 The coefficient of friction in this example is 0.5.

The force applied to the master cylinder by the pedal pushrod attached to the pivot is much greater than the force applied at the pedal pad, but the pushrod does not travel nearly as far.

MECHANICAL ADVANTAGE

Leverage creates a **mechanical advantage** that, at the brake pedal, is called the **pedal ratio.** For example, a pedal ratio of 5 to 1 is common for manual brakes, which means that a force of 10 lb at the brake pedal will result in a force of 50 lb at the pedal pushrod. In practice, leverage is used at many points in both the service and parking brake systems to increase braking force while making it easier for the driver to control the amount of force applied.

FRICTION PRINCIPLES

The wheel brakes use friction to convert kinetic energy into heat energy. **Friction** is the resistance to movement between two surfaces in contact with one another. Brake performance is improved by increasing friction (at least to a point), and brakes that apply enough friction to use all the grip the tires have to offer will always have the potential to stop a vehicle faster than brakes with less ability to apply friction.

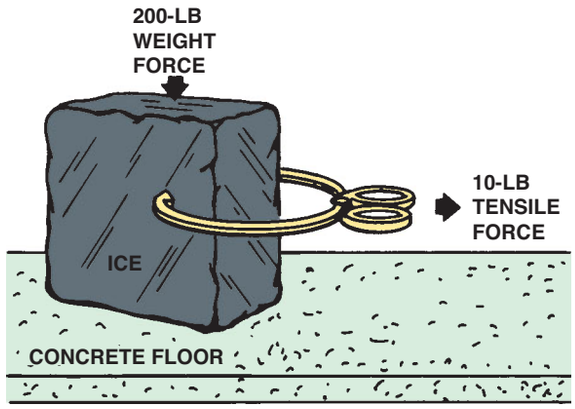

FIGURE 93–8 The type of friction material affects the coefficient of friction which is just 0.05 in this example.

COEFFICIENT OF FRICTION

The amount of friction between two objects or surfaces is commonly expressed as a value called the **coefficient of friction** and is represented by the Greek letter mu (μ).

$$\frac{F_t}{G} = \mu$$

$$\frac{\text{Tensile force}}{\text{Weight force}} = \text{Coefficient of friction}$$

SURFACE FINISH EFFECTS

The effect of surface finish on the friction coefficient can be seen in ● **FIGURE 93–7.**

In this case, 100 lb of tensile force is required to pull a 200-lb block of wood across a concrete floor. The equation for computing the coefficient of friction is as follows.

$$\frac{100 \text{ lb}}{200 \text{ lb}} = 0.5$$

The friction coefficient in this instance is 0.5. Now take the same example, except assume that the block of wood has been sanded smooth, which improves its surface finish and reduces the force required to move it to only 50 lb. In this case the equation reads as follows.

$$\frac{50 \text{ lb}}{200 \text{ lb}} = 0.25$$

The friction coefficient drops by half, and it would decrease even further if the surface finish of the floor were changed from rough concrete to smooth marble.

It is obvious that the *surface finish* of two connecting surfaces has a major effect on their coefficient of friction.

FRICTION MATERIAL EFFECTS

Taking the example above one step further, consider the effect if a 200-lb block of ice, a totally different type of material, is substituted for the wood block. In this case, it requires only a 10-lb force to pull the block across the concrete. ● **SEE FIGURE 93–8.**

The equation reads as follows.

$$\frac{10 \text{ lb}}{200 \text{ lb}} = 0.05$$

The coefficient of friction in this example decreases dramatically to only 0.05, and once again, even further reductions would be seen if the floor surface were changed to polished marble or some other similar smooth surface.

It is obvious that the *type* of materials being rubbed together have a very significant effect on the coefficient of friction. The choice of

materials for brake drums and rotors is limited. Iron and steel are used most often because they are relatively inexpensive and can stand up under the extreme friction brake drums and rotors must endure.

The brake lining material, however, can be replaced relatively quickly and inexpensively, and therefore does not need to have as long a service life. Brake shoe and pad friction materials play a major part in determining coefficient of friction. There are several fundamentally different materials to choose from, and each has its own unique friction coefficient and performance characteristics.

FRICTION CONTACT AREA For *sliding* surfaces, such as those in wheel friction assemblies, the amount of contact area has no effect on the amount of friction generated. This fact is related to the earlier statement that brake friction materials always have a friction coefficient of less than 1.0. To have a friction coefficient of 1.0 or more, material must be *transferred* between the two friction surfaces. The amount of contact area does not affect the coefficient of friction, but it does have significant effects on lining life and the dissipation of heat that can lead to brake fade.

Tires are an example where contact area makes a difference. All other things being equal, a wide tire with a large contact area on the road has a higher coefficient of friction than a narrow tire with less contact area. This occurs because the tire and road *do not* have a sliding relationship. A tire conforms to and engages the road surface, and during a hard stop, a portion of the breaking force comes from shearing or tearing away the tire tread rubber. The rubber's tensile strength, its internal resistance to being pulled apart, adds to the braking efforts of friction. A racing tire making a hard stop on dry pavement, for example, has a friction coefficient of 1.0 or better. The transfer of material between the two surfaces can be seen as skid marks on the pavement.

STATIC AND KINETIC FRICTION There are actually two measurements of the coefficient of friction, the **static friction** coefficient and the **kinetic friction** coefficient. The static value is the coefficient of friction with the two friction surfaces at rest. The kinetic value is the coefficient of friction while the two surfaces are sliding against one another.

The coefficient of static friction is always higher than that of kinetic friction, which explains why it is harder to *start* an object moving than to *keep* it moving. In the example shown in ● **FIGURE 93–9,** it takes 100 lb of tensile force to start the wooden block sliding, but once in motion, it takes only 50 lb to keep it sliding.

The relatively high static friction is harder to overcome than the somewhat lower kinetic friction. The static and kinetic friction coefficients for several combinations of materials are shown in ● **CHART 93–1.**

The difference between static and kinetic friction explains why parking brakes, although much less powerful than service brakes, are still able to hold a vehicle in position on a hill. The job of the parking brakes is relatively easy because the stationary vehicle has no kinetic energy, and the brake lining and drum or disc are not moving when they are applied. To start the vehicle moving, enough force would have to be applied to overcome the relatively high static friction of the parking brakes. The service brakes, however, have a much more difficult job. The moving vehicle has a great deal of kinetic energy, and the fact that the brake friction surfaces are in relative motion means that kinetic friction makes them less efficient.

FRICTION AND HEAT

The function of the brake system is to convert kinetic energy into heat energy through friction.

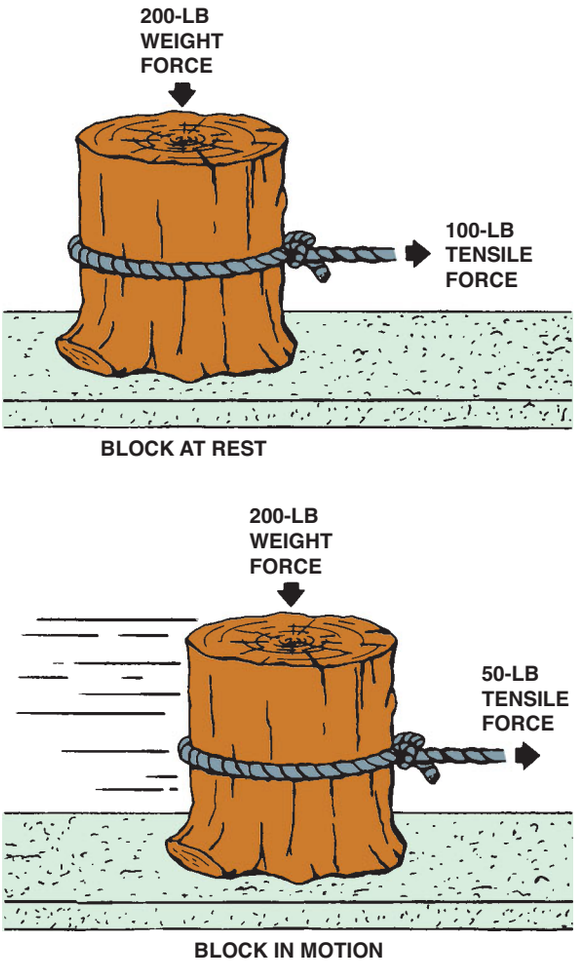

FIGURE 93–9 The static coefficient of friction of an object at rest is higher than the kinetic (dynamic) friction coefficient once in motion.

CHART 93–1

Every combination of materials has different static and kinetic friction coefficients.

It is the *change* in kinetic energy that determines the amount of temperature increase, and kinetic energy increases proportionately with increases in weight, and as the square of any increase in speed. If the weight of the vehicle is doubled to 6,000 lb, the change in kinetic energy required to bring it to a full stop will be 180,602 ft-lb.

The thicker and heavier the brake rotors and drums, the more heat they can absorb. Some of the heat is absorbed by the brake drums and rotors, some goes into the shoes and pads, and some is conducted into the wheel cylinders, calipers, and brake fluid. In addition, the front

brakes provide 60% to 80% of the total braking force and they receive a similar percentage of the average temperature increase. The increase at each axle is divided evenly between the two wheel friction assemblies unless there is unequal traction from one side to the other, or there is a problem within the brake system itself.

DECELERATION RATES

Deceleration rates are measured in units of "feet per second per second" (No, this is not a misprint). What it means is that the vehicle will change in velocity during a certain time interval divided by the time interval. Deceleration is abbreviated "ft/sec^2" (pronounced "feet per second per second" or "feet per second squared") or meters per sec^2 (m/sec^2) in the metric system. Typical deceleration rates include the following.

- Comfortable deceleration is about 8.5 ft/sec^2 (3 m/sec^2).
- Loose items in the vehicle will "fly" above 11 ft/sec^2 (3.5 m/sec^2).
- Maximum deceleration rates for most vehicles and light trucks range from 16 to 32 ft/sec^2 (5 to 10 m/sec^2).

An average deceleration rate of 15 ft/sec^2 (3 m/sec^2) can stop a vehicle traveling at 55 mph (88 km/h) in about 200 ft (61 m) in less than 4 seconds. During a standard brake system test, a vehicle is braked at this rate 15 times. Temperatures at the front brake pads can reach 1,300°F (700°C) or higher, sometimes reaching as high as 1,800°F (980°C). Brake fluid and rubber components may reach 300°F (150°C) or higher.

HYDRAULIC PRINCIPLES

In addition to the mechanical advantage provided by leverage, all vehicles use hydraulic pressure to help increase brake application force.

All braking systems require that a driver's force is transmitted to the drum or rotor attached to each wheel. ● **SEE FIGURE 94–1.**

The force that can be exerted on the brake pedal varies due to the strength and size of the driver. Engineers design braking systems to require less than 150 lb of force (68 kg) from the driver, yet provide the force necessary to stop a heavy vehicle from high speed.

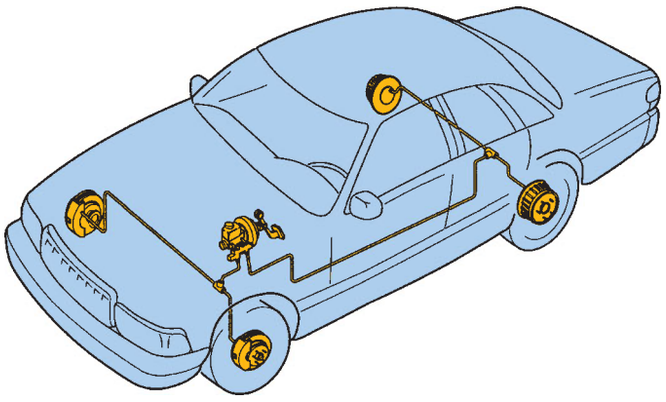

FIGURE 94–1 Hydraulic brake lines transfer the brake effort to each brake assembly attached to all four wheels.

NONCOMPRESSIBILITY OF LIQUIDS

Hydraulic systems use liquids to transmit motion. For all practical purposes, a liquid cannot be compressed. No matter how much pressure or force is placed on a quantity of liquid, its volume will remain the same. This fact enables liquids in a closed system to transmit motion. ● **SEE FIGURE 94–2.**

If piston A is moved a distance of 1 in., the liquid will be displaced ahead of it and piston B will move 1 in. as well.

Liquids cannot be compressed, but any air trapped in the system can be compressed. For example, the simple hydraulic system has been contaminated with air. ● **SEE FIGURE 94–3.**

Even though piston A is moved a distance of 1 in., piston B will not move if the load on it is greater than the pressure of the air in the system. For example, if the load on piston B is 50 pounds per square inch (PSI), the movement of piston A must compress the air in the system to that same pressure before piston B will begin to move. A brake hydraulic system must be air free or the brakes will not operate correctly and the driver will feel a spongy brake pedal that is also often lower than normal.

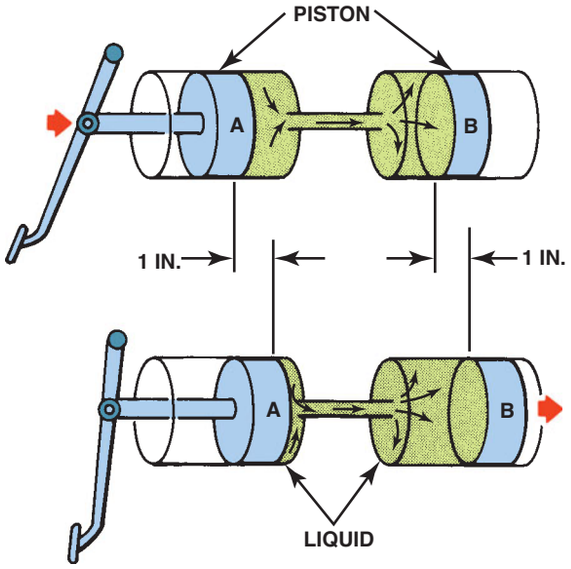

FIGURE 94–2 Because liquids cannot be compressed, they are able to transmit motion in a closed system.

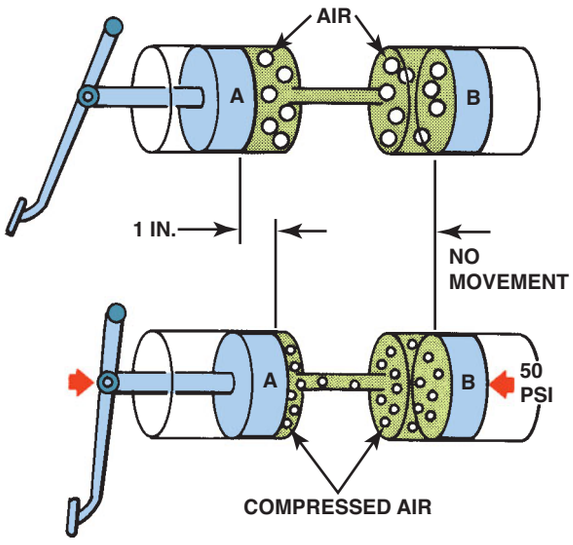

FIGURE 94–3 Hydraulic system must be free of air to operate properly. If air is in the system, the air is compressed when the brake pedal is depressed and the brake fluid does not transmit the force to the wheel brakes.

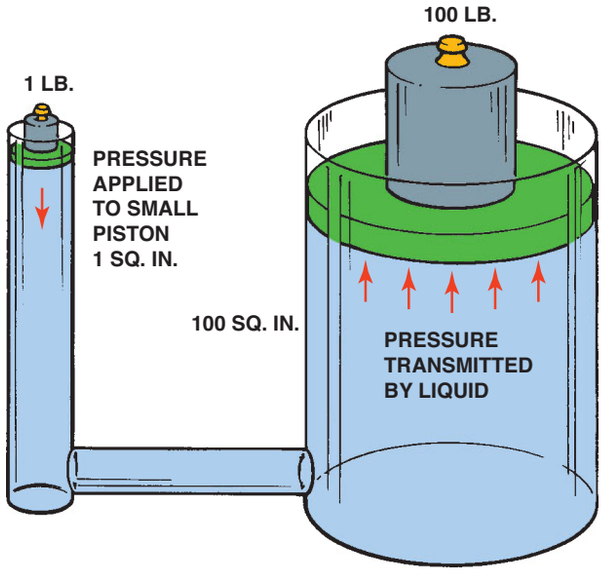

FIGURE 94–4 A one-pound force exerted on a small piston in a sealed system transfers the pressure to each square inch throughout the system. In this example, the 1-lb force is able to lift a 100-lb weight because it is supported by a piston that is 100 times larger in area than the small piston.

PASCAL'S LAW

The hydraulic principles that permit a brake system to function were discovered by a French physicist, Blaise Pascal (1632–1662). **Pascal's law** states that "when force is applied to a liquid confined in a container or an enclosure, the pressure is transmitted equal and undiminished in every direction." To help understand this principle, assume that a force of 10 lb is exerted on a piston with a surface area of 1 square inch (sq. in.). Since this *force* measured in lb or Newtons (N) is applied to a piston with an area measured in square inches (sq. in.), the *pressure* is the force divided by the area or "10 pounds per square inch (PSI)." It is this "pressure" that is transmitted, without loss, throughout the entire hydraulic system. ● **SEE FIGURE 94–4.**

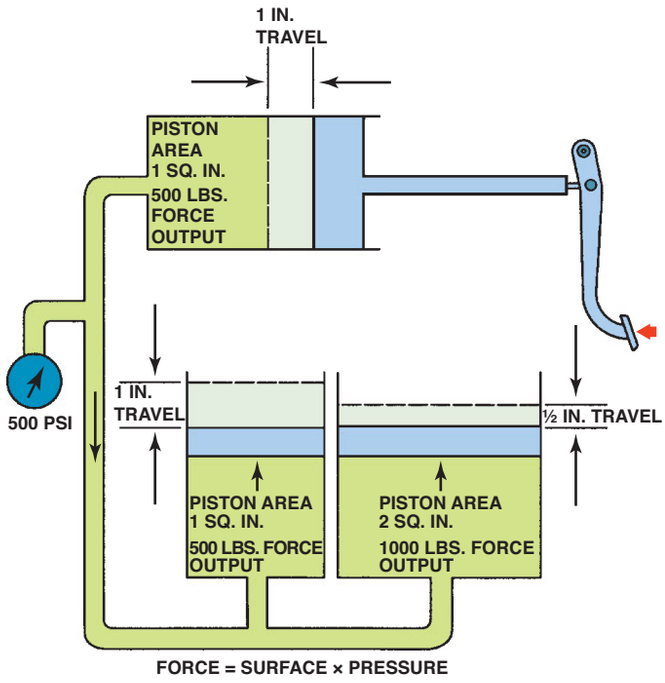

FIGURE 94–5 The amount of force (F) on the piston is the result of pressure (P) multiplied by the surface area (A). In this example, the driver is applying a force of 150 pounds but through the mechanical advantage of the brake pedal (3.3 to 1 ratio), the force is increased to 500 pounds into the master cylinder.

If two out of the three factors are known, then the other one can be calculated by using this formula.

***F* = *P* × *A* (force is equal to the pressure multiplied by the area)**

***P* = *F* ÷ *A* (pressure is equal to the force divided by the area)**

***A* = *F* ÷ *P* (area is equal to the force divided by the pressure)**

where the capital letters mean:

***F* = force (lb) (Newtons)**
***P* = pressure in lb per sq. in. (kilo Pascals [kPa])**
***A* = area in sq. in. (cm^2)**

A practical example involves a master cylinder with a piston area of 1 sq. in., and one wheel cylinder with an area of 1 sq. in., and one wheel cylinder with a piston area of 2 sq. in. ● **SEE FIGURE 94–5.**

The real "magic" of a hydraulic brake system is the fact that different forces can be created at different wheel cylinders. More force is necessary for front brakes than for rear brakes because, as the brakes are applied, the weight of the vehicle moves forward.

Larger (area) pistons are used in brake calipers on the front wheels to increase the force used to apply the front brakes.

Not only can hydraulics act as a "force machine" (by varying piston size), but the hydraulic system also can be varied to change piston stroke distances.

On a typical vehicle, a driver-input force of 150 lb (660 Newtons) is boosted both mechanically (through the brake pedal linkage) and by the power booster to a fluid pressure of about 1,700 PSI (11,700 kPa). With a drum brake, the wheel cylinder expands and pushes the brake shoes against a brake drum. *The distance the shoes move is only about 0.005–0.012 in. (5 to 12 thousandths of an inch) (0.015–0.30 mm).* ● **SEE FIGURE 94–6.**

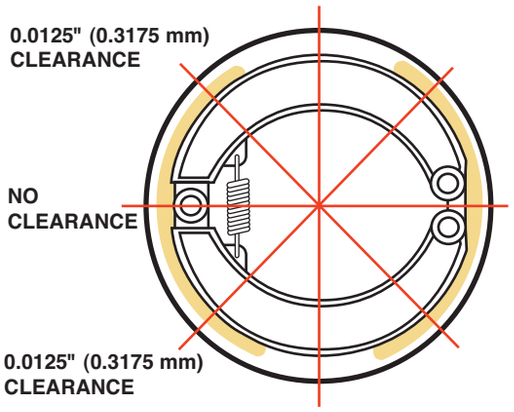

FIGURE 94–6 Drum brake illustrating the typical clearance between the brake shoes (friction material) and the rotating brake drum represented as the outermost black circle.

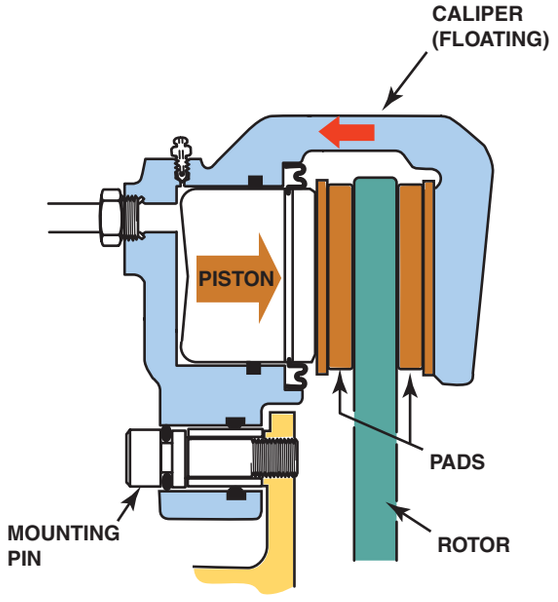

FIGURE 94–7 The brake pad (friction material) is pressed on both sides of the rotating rotor by the hydraulic pressure of the caliper.

FREQUENTLY ASKED QUESTION

How Much Brake Fluid Is Moved When the Brake Pedal Is Depressed?

During a typical brake application, only about *1 teaspoon (5 ml or cc) of brake fluid* actually is moved from the master cylinder and into the hydraulic system to cause the pressure buildup to occur.

With a disc brake, brake fluid pressure pushes on the piston in the caliper a small amount and causes a clamping of the disc brake pads against both sides of a rotor (disc). ● **SEE FIGURE 94–7.** *The typical distance the pads move is only about 0.001–0.003 in. (1 to 3 thousandths of an inch) (0.025–0.076 mm).*

HYDRAULIC PRESSURE AND PISTON SIZE

If a mechanical force of 100 lb is exerted by the brake pedal pushrod onto a master cylinder piston with 1 sq. in. of surface area, the equation reads as follows.

$$\frac{\text{100 lb}}{\text{1 sq. in.}} = \text{100 PSI}$$

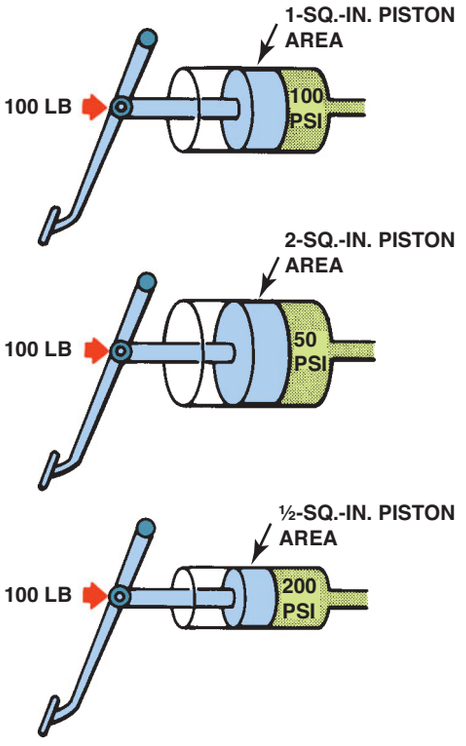

FIGURE 94–8 Mechanical force and the master cylinder piston area determine the hydraulic pressure in the brake system.

The result in this case is 100 PSI of brake system hydraulic pressure. ● **SEE FIGURE 94–8.** However, if the same 100-lb force is applied to a master cylinder piston with twice the area (2 sq. in.) the equation will read as follows.

$$\frac{\text{100 lb}}{\text{2 sq. in.}} = \text{50 PSI}$$

Doubling the area of the master cylinder piston cuts the hydraulic system pressure in half. Conversely, if the same 100-lb force is applied to a master cylinder piston with only half the area (0.5 or 1/2 sq. in.), the equation will show that the system pressure is doubled:

$$\frac{\text{100 lb}}{\text{0.5 sq. in.}} = \text{200 PSI}$$

APPLICATION FORCE AND PISTON SIZE

While the size of the master cylinder piston affects the hydraulic pressure of the entire brake system, weight shift and bias require that the heavily loaded front brakes receive much higher application force than the lightly loaded rear brakes. These differences in force are obtained by using different-sized pistons in the wheel cylinders and brake calipers. Pascal's law states that a pressurized liquid in a confined space acts with equal pressure on equal *areas* and as long as the pistons in a hydraulic system have the same area, 100 PSI from the master cylinder will result in 100 PSI of braking force. ● **SEE FIGURE 94–9.** However, when equal pressure acts on *unequal* areas, as with different-sized pistons, the brake application force will differ as well.

The mechanical *force(f)* at the brake pedal pushrod is applied to the master cylinder piston *area(a)* and converted into brake system hydraulic *pressure(p).* Brake calipers and wheel cylinders perform exactly the opposite. Hydraulic *pressure* applied to the wheel cylinder or brake caliper piston *area* is converted back into mechanical *force* that is used to apply the wheel friction assemblies. Because the variables are identical, the same equation can

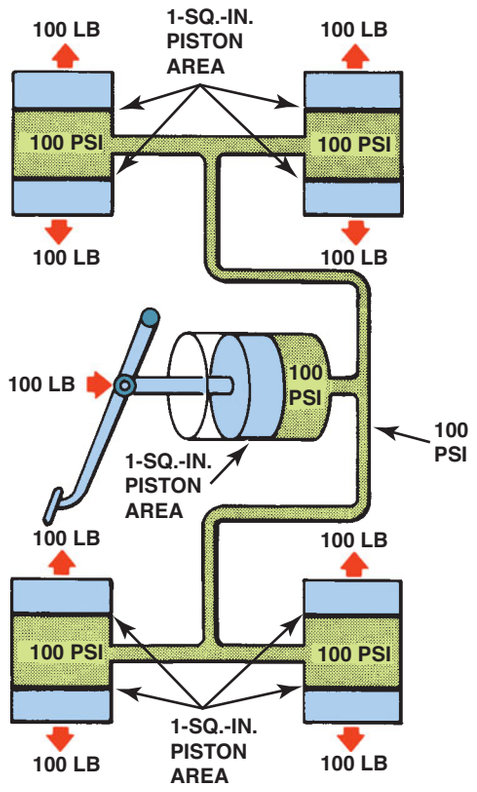

FIGURE 94–9 Hydraulic pressure is the same throughout a closed system and acts with equal force on equal areas.

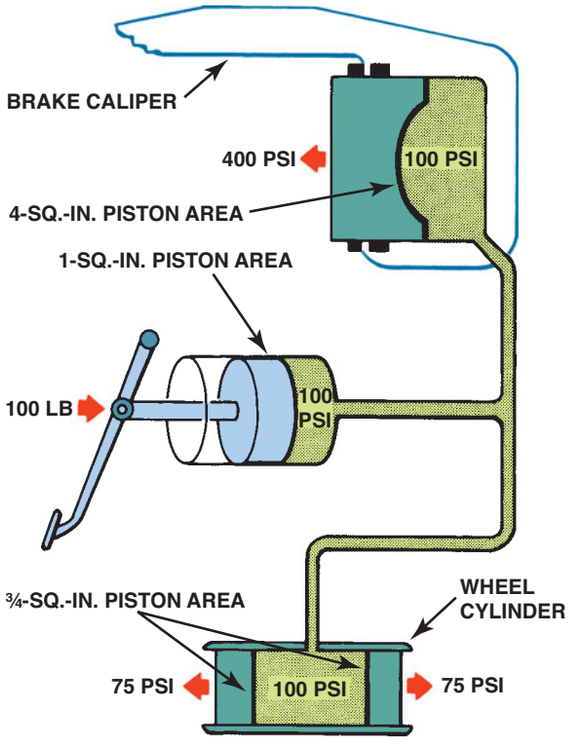

FIGURE 94–10 Differences in brake caliper and wheel cylinder piston area have a major effect on brake application force.

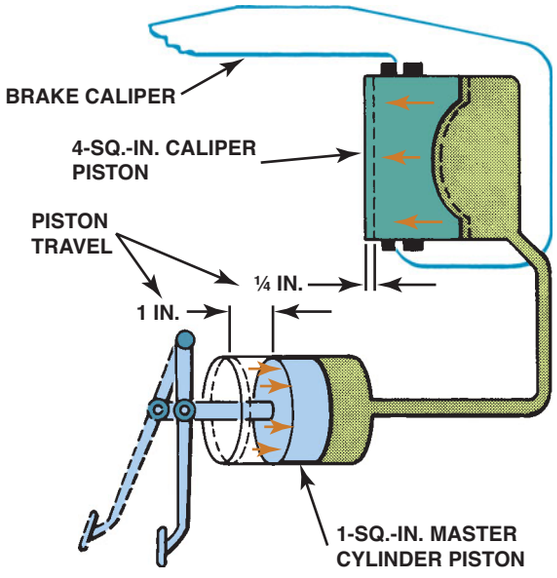

FIGURE 94–11 The increase in application force created by the large brake caliper piston is offset by a decrease in piston travel.

be rewritten to explain how changes in piston size affect brake application force.

$$P \times A = F$$

It is piston surface *area,* not diameter, that affects force.

In the simple brake system, the pedal and linkage apply a 100-lb force on a master cylinder piston with an area of 1 sq. in. ● **SEE FIGURE 94–10.** This results in a pressure of 100 PSI throughout the hydraulic system. At the front wheels, the 100 PSI is applied to a brake caliper piston that has an area of 4 sq. in. The equation for this example is as follows.

100 PSI × 4 sq. in. = 400 lb

In this case the difference in piston areas (1 sq. in. compared to 4 sq. in.) results in the 100-PSI brake pedal pushrod force being increased for 400 lb of application force at the wheel friction assembly. The hydraulic pressure is still 100 PSI at all points within the system and the increase in application pressure is solely the result of 100 PSI acting on a 4-sq.-in. piston. The 400 lb is a mechanical force, not hydraulic pressure.

The drum brakes at the rear wheels of the same brake system use wheel cylinders whose pistons have three-quarters (3/4 or 0.75) of an inch of surface area. If the hydraulic system pressure remains 100 PSI, the equation for this example is as follows.

100 PSI × 0.75 sq. in. = 75 lb

Just as larger pistons increase application force, this example shows that smaller pistons decrease it. The system hydraulic pressure remains 100 PSI at all points, but the smaller piston is unable to transmit all of the available pressure. As a result, the mechanical application force is reduced to only 75 lb.

PISTON SIZE VERSUS PISTON TRAVEL

In disc brakes, the mechanical force available to apply the brakes is four times greater because of the size difference between the master cylinder and caliper pistons. Some of the hydraulic energy is converted into *increased* mechanical force. The trade-off is that the larger caliper piston with the greater force will not move as far as the smaller master cylinder piston. The amount of hydraulic energy converted into mechanical motion is *decreased.* For example in a typical disc brake system, if the master cylinder piston stroke is 1 in., the caliper piston will move only 1/4 inch. ● **SEE FIGURE 94–11.**

HYDRAULIC PRINCIPLES AND BRAKE DESIGN

When a brake system is designed, the hydraulic relationships play a major part in determining the sizes of the many pistons within the system. The piston sizes selected must move enough fluid to operate the wheel cylinder and brake caliper pistons through a wide range of

REAL WORLD FIX

Bigger Is Not Better

A vehicle owner wanted better braking performance from his off-road race vehicle. Thinking that a larger master cylinder would help, a technician replaced the original 1-in.-bore-diameter master cylinder with a larger master cylinder with a 1 1/8-in.-bore-diameter master cylinder.

After bleeding the system, the technician was anxious to test-drive the "new" brake system. During the test-drive the technician noticed that the brake pedal "grabbed" much higher than with the original master cylinder. This delighted the technician. The owner of the vehicle was also delighted until he tried to stop from highway speed. *The driver had to use both feet to stop!*

The technician realized, after the complaint, that the larger master cylinder was able to move more brake fluid, but with *less* pressure to the wheel cylinders. The new master cylinder gave the impression of better brakes because the fluid was moved into the wheel cylinders (and calipers) quickly, and the pads and shoes contacted the rotor and drums sooner because of the greater volume of brake fluid moved by the larger pistons in the master cylinder.

To calculate the difference in pressure between the original (stock) master cylinder and the larger replacement, the technician used Pascal's law with the following results:

Original Master Cylinder (1 in. bore)	**Replacement Master Cylinder (1 1/8 in. bore)**
$\text{Pressure} = \frac{\text{Force}}{\text{Area}}$	$\text{Pressure} = \frac{\text{Force}}{\text{Area}}$
$\text{PSI} = \frac{450\text{ lb}}{\text{Area}}\text{ (typical)}$	$\text{PSI} = \frac{450\text{ lb}}{\text{Area}}\text{ (typical)}$
Area = $\pi r^2 = 3.14 \times .5^2$ (1/2 of 1 in.)	Area = πr^2 5 $3.14 \times .5625^2$ (1/2 of 1 1/8 in.)
Area = $3.14 \times .25$	Area = $3.14 \times .316$
Area = .785 sq. in.	Area = .992 sq. in.
$\text{Pressure} = \frac{450}{.785} = 573\text{ PSI}$	$\text{Pressure} = \frac{450}{.992} = 454\text{ PSI}$

The difference in pressure is 119 PSI less with the larger master cylinder (573 − 454 = 119).

The stopping power of the brakes was reduced because the larger diameter master cylinder piston produced lower pressure (the same force was spread over a larger area and this means that the pressure [PSI] is less).

All master cylinders are sized correctly from the factory for the correct braking effort, pressure, pedal travel, and stopping ability. *A technician should never change the sizing of any hydraulic brake component on any vehicle!*

travel, while at the same time they must create enough application force to lock the wheel brakes. The piston sizes chosen should also provide the driver with good brake pedal "feel" so the brakes are easy to apply in a controlled manner.

Most vehicles with disc brakes have large master cylinder pistons to move the required volume of fluid, and a power booster to increase the force that the driver applies to the master cylinder.

MASTER CYLINDERS

PURPOSE AND FUNCTION

The **master cylinder** is the heart of the entire braking system. No braking occurs until the driver depresses the brake pedal. The brake pedal linkage is used to apply the force of the driver's foot into a closed hydraulic system that begins with the master cylinder.

MASTER CYLINDER RESERVOIRS

Most vehicles built since the early 1980s are equipped with see-through master cylinder reservoirs, which permit owners and service technicians to check the brake fluid level without having to remove the top of the reservoir. Some countries have laws that require this type of reservoir. ● **SEE FIGURE 94–12.**

The reservoir capacity is great enough to allow for the brakes to become completely worn out and still have enough fluid reserve for safe operation. The typical capacity of the entire braking system is usually 2 to 3 pints (1 to 1.5 liters). Vehicles equipped with four-wheel disc brakes usually hold 4 pints (2 liters) or more.

MASTER CYLINDER RESERVOIR DIAPHRAGM

The entire brake system is filled with brake fluid up to the "full" level of the master cylinder reservoir.

CAUTION: The master cylinder should never be filled higher than the recommended full mark to allow for brake fluid expansion that occurs normally when the brake fluid gets hot due to the heat generated by the brakes.

The reservoir is vented to the atmosphere so the fluid can expand and contract without difficulty as would be the case if the reservoir were sealed.

Being open to the atmosphere allows the moisture in the air to come in contact with the brake fluid. This moisture in the air is absorbed into the brake fluid because brake fluid has an affinity (attraction) to moisture (water).

To help reduce the moisture from getting in contact with the brake fluid, master cylinders use a rubber diaphragm or floating disc to help seal outside air from direct contact with brake fluid. This seal

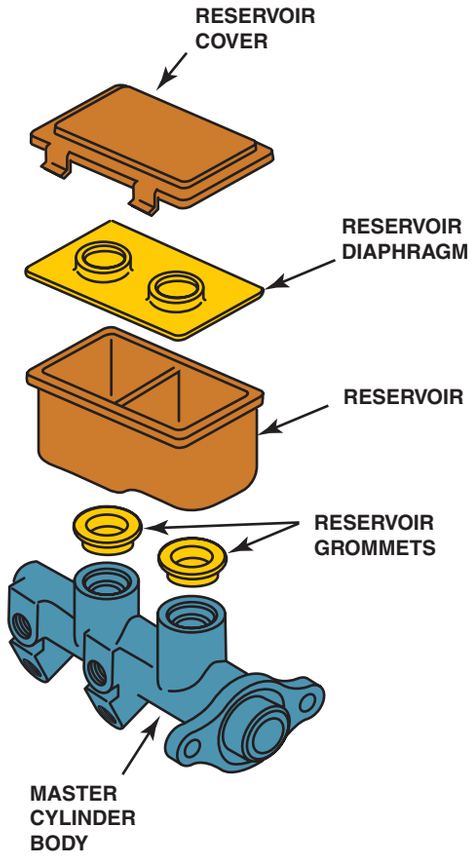

FIGURE 94–12 Typical master cylinder showing the reservoir and associated parts. The reservoir diaphragm lays directly on top of the brake fluid, which helps keep air from the surface of the brake fluid because brake fluid easily absorbs moisture from the air.

FIGURE 94–13 Master cylinder with brake fluid level at the "max" (maximum) line.

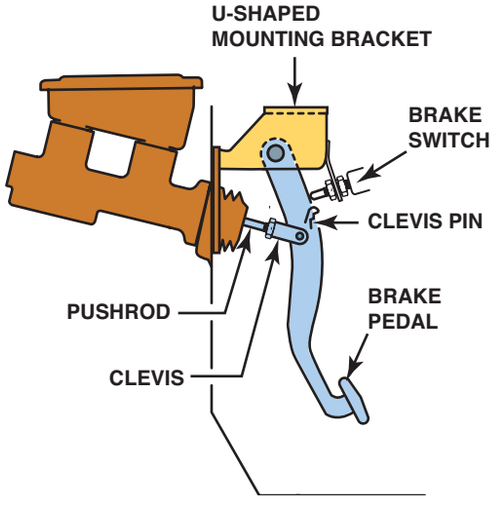

FIGURE 94–14 The typical brake pedal is supported by a mount and attached to the pushrod by a U-shaped bracket. The pin used to retain the clevis to the brake pedal is usually called a clevis pin.

TECH TIP

Don't Fill the Master Cylinder Without Seeing Me!

The boss explained to the beginning technician that there are two reasons why the customer should be told not to fill the master cylinder reservoir when the brake fluid is down to the "minimum" mark, as shown in ● **FIGURE 94–13.**

1. If the master cylinder reservoir is low, there may be a leak that should be repaired.
2. As the brakes wear, the disc brake piston moves outward to maintain the same distance between friction materials and the rotor. Therefore, as the disc brake pads wear, the brake fluid level goes down to compensate.

Therefore if the brake fluid is low, the vehicle should be serviced—either for new brakes or to repair a leak.

still allows the brake fluid to expand and contract as the fluid heats up and cools down during normal brake system operation. This rubber diaphragm is vented between the steel cap and diaphragm. As the brake fluid level drops due to normal disc brake pad wear, the rubber diaphragm also lowers to remain like a second skin on top of the brake fluid.

Whenever adding brake fluid, push the rubber diaphragm back up into the cover. Normal atmospheric pressure will allow the diaphragm to return to its normal position on top of the brake fluid. Whenever servicing a brake system, be sure to check that the vent hole is clear on the cover to allow air to get between the cover and the diaphragm.

MASTER CYLINDER OPERATION

The master cylinder is the heart of any hydraulic braking system. Brake pedal movement and force are transferred to the brake fluid and directed to wheel cylinders or calipers. ● **SEE FIGURE 94–14.** The master cylinder is also separated into two pressure-building chambers (or circuits) to provide braking force to one-half of the brake in the event of a leak or damage to one circuit. ● **SEE FIGURE 94–15.**

Both pressure-building sections of the master cylinder contain two holes from the reservoir. The Society of Automotive Engineers' (SAE) term for the forward (tapered) hole is the **vent port,** and the rearward straight drilled hole is called the **replenishing port.** ● **SEE FIGURE 94–16.**

Various vehicle and brake component manufacturers call these ports by various names. For example, the vent port is the high-pressure port. This tapered forward hole is also called the **compensating port.**

The replenishing port is the low-pressure rearward, larger diameter hole. The inlet port is also called the **bypass port, filler port,** or **breather port.**

The function of the master cylinder can be explained from the at-rest, applied, and released positions.

AT-REST POSITION. The primary (forward facing) sealing cups are between the compensating port hole and the inlet port hole. In this position, if the temperature of the brake fluid rises and the fluid expands, the brake fluid is free to expand up into the reservoir through the vent port (compensating port). If the fluid was trapped, the pressure of the brake fluid would increase with temperature, causing the brakes to **self-apply.** ● **SEE FIGURE 94–17.**

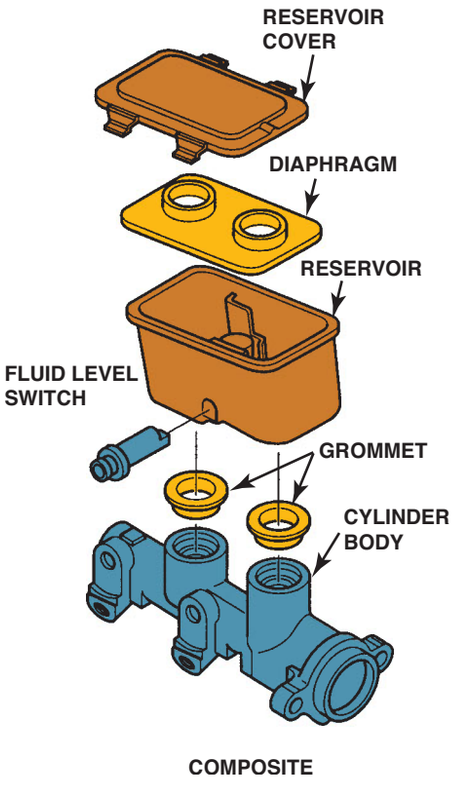

FIGURE 94–15 The composite master cylinder is made from two different materials—aluminum for the body and plastic materials for the reservoir and reservoir cover. This type of reservoir feeds both primary (closest to the driver) and secondary chambers, and therefore uses a fluid level switch that activates the red dash warning lamp if the brake fluid level drops.

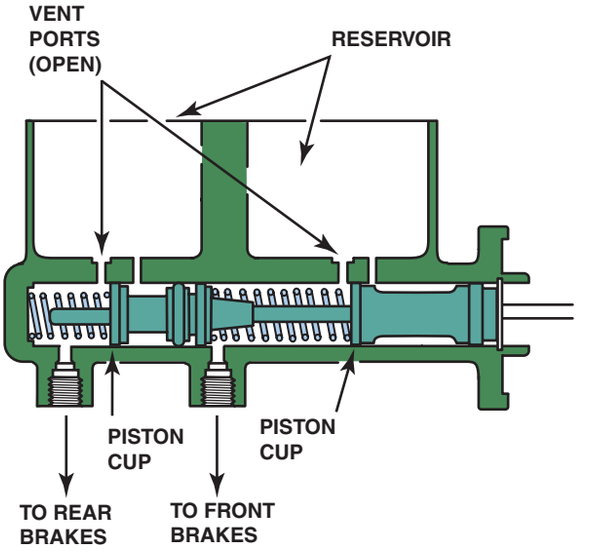
APPLIED POSITION. When the brake pedal is depressed, the pedal linkage forces the pushrod and primary piston (closest to the driver) down the bore of the master cylinder. ● **SEE FIGURE 94–18.** As the piston moves forward, the primary sealing cup covers and blocks off the vent port (compensating port). Hydraulic pressure builds in front of the primary seal as the pushrod moves forward. The back of the piston is kept filled through the replenishing port. ● **SEE FIGURE 94–19.** This stops any suction (vacuum) from forming behind the piston. The secondary piston is moved forward as pressure is exerted by the primary piston. If, for any reason, such as a leak, the primary piston cannot build pressure, a mechanical extension rod on the front of the primary piston will touch the secondary piston and move it forward, as the primary piston is pushed forward by the pushrod and brake



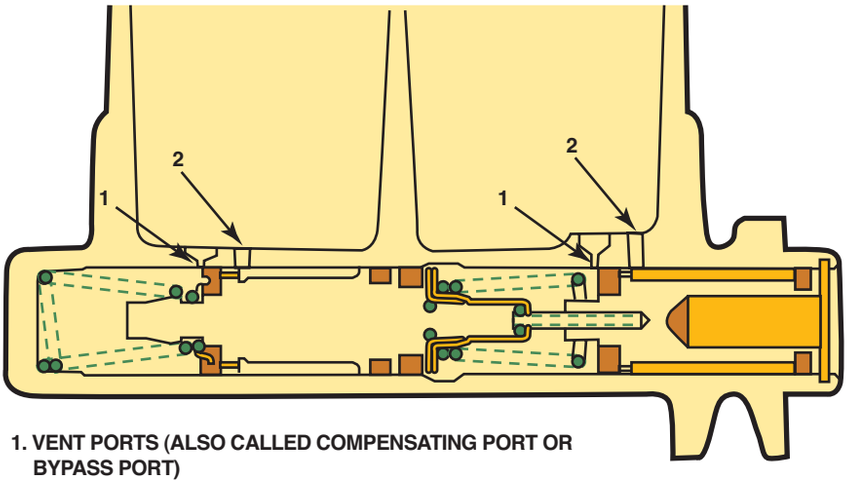


FIGURE 94–17 The vent ports must remain open to allow brake fluid to expand when heated by the friction material and transferred to the caliper and/or wheel cylinder. As the brake fluid increases in temperature, it expands causing the brakes to self-apply which is prevented by the open vent ports.

1. VENT PORTS (ALSO CALLED COMPENSATING PORT OR BYPASS PORT)
2. REPLENISHING PORTS (ALSO CALLED INLET PORT, BYPASS PORT, FILLER PORT, OR BREATHER PORT)

FIGURE 94–16 Note the various names for the vent port (front port) and the replenishing port (rear port). Names vary by vehicle and brake component manufacturer. The names vent port and replenishing port are the terms recommended by the Society of Automotive Engineers (SAE).

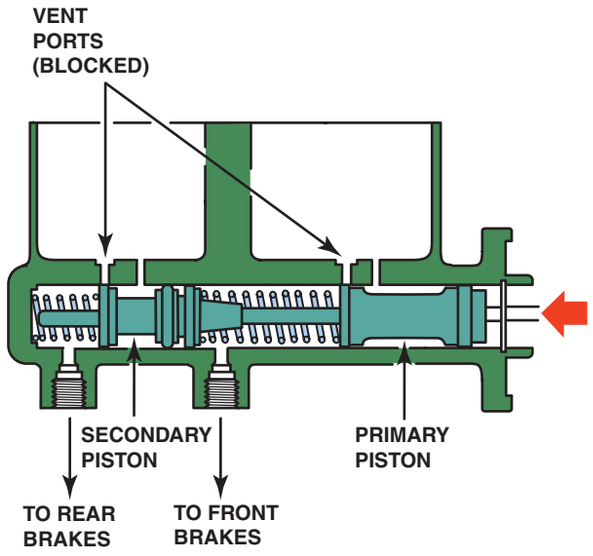

FIGURE 94–18 As the brake pedal is depressed, the pushrod moves the primary piston forward, closing off the vent port. As soon as the port is blocked, pressure builds in front of the primary sealing cup, which pushes on the secondary piston. The secondary piston also moves forward, blocking the secondary vent port and building pressure in front of the primary sealing cup.

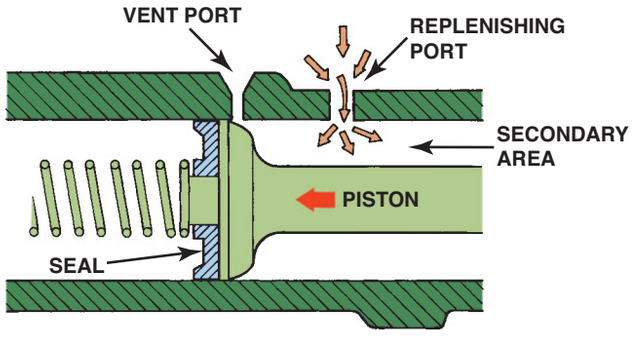

FIGURE 94–19 The purpose of the replenishing port is to keep the volume behind the primary piston filled with brake fluid from the reservoir as the piston moves forward during a brake application.

TECH TIP

Too Much Is Bad

Some vehicle owners or inexperienced service people may fill the master cylinder to the top. Master cylinders should only be filled to the "maximum" level line or about 1/4 in. (6 mm) from the top to allow room for expansion when the brake fluid gets hot during normal operation. If the master cylinder is filled to the top, the expanding brake fluid has no place to expand and the pressure increases. This increased pressure can cause the brakes to "self-apply," shortening brake friction material life and increasing fuel consumption. Overheated brakes can result and the brake fluid may boil, causing a total loss of braking.

pedal. As a result of these actions, brake fluid pressure is applied to both outlets of the master cylinder.

RELEASED POSITION. Releasing the brake pedal removes the pressure on the pushrod and master cylinder pistons. A spring on the brake pedal linkage returns the brake pedal to its normal at-rest (up)

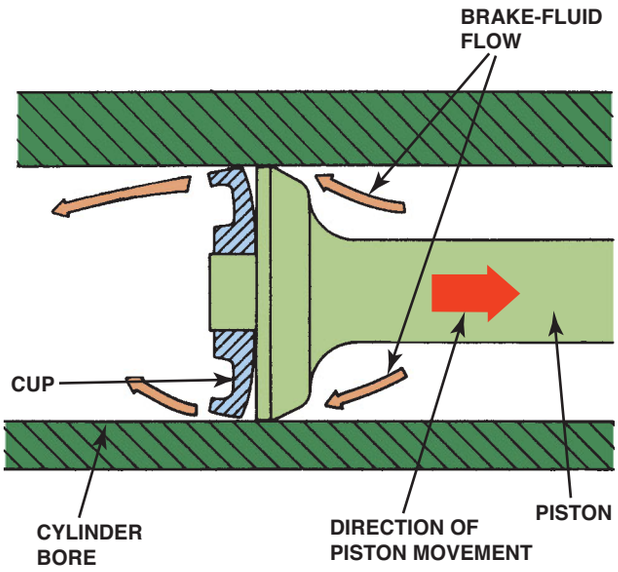

FIGURE 94–20 When the brake pedal is released, the master cylinder piston moves rearward. Some of the brake fluid is pushed back up through the replenishing port, but most of the fluid flows past the sealing cup. Therefore, when the driver pumps the brake pedal, the additional fluid in front of the pressure-building sealing cup is available quickly.

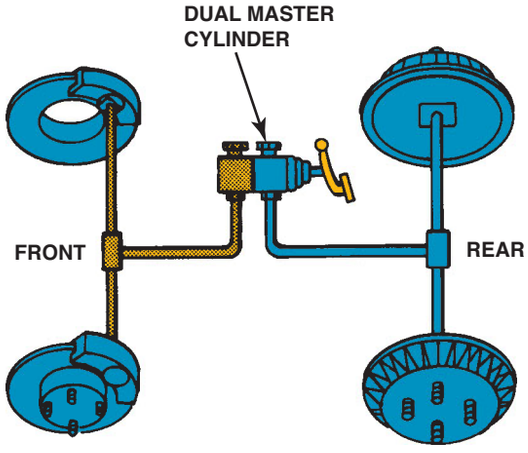

FIGURE 94–21 Rear-wheel-drive vehicles use a dual split master cylinder.

position. The spring in front of the master cylinder piston expands, pushing the pistons rearward. At the same time, pressure is released from the entire braking system and the released brake fluid pressure is exerted on the master cylinder pistons, forcing them rearward. As the piston is pushed back, the lips of the seal fold forward allowing fluid to quickly move past the piston, as shown in ● **FIGURE 94–20.** Some pistons have small holes that allow the fluid to move more quickly. Once the primary seal passes the vent port, the remaining hydraulic pressure forces any excess fluid into the reservoir.

MASTER CYLINDER DESIGNS

DUAL SPLIT MASTER CYLINDERS **Dual split master cylinders** use two separate pressure-building sections. One section operates the front brakes and the other section operates the rear brakes on vehicles equipped with a front/rear-split system. ● **SEE FIGURE 94–21.** The *nose end* of the master cylinder is the

TECH TIP

Always Check for Venting (Compensation)

Whenever diagnosing any braking problem, start the diagnosis at the master cylinder—the heart of any braking system. Remove the reservoir cover and observe the brake fluid for spurting while an assistant depresses the brake pedal.

Normal operation (movement of fluid observed in the reservoir)

There should be a squirt or movement of brake fluid out of the vent port of both the primary and secondary chambers. This indicates that the vent port is open and that the sealing cup is capable of moving fluid upward through the port before the cup seals off the port as it moves forward to pressurize the fluid.

No movement of fluid observed in the reservoir in the primary piston

This indicates that brake fluid is not being moved as the brake pedal is depressed. This can be caused by the following:

a. Incorrect brake pedal height—brake pedal or pushrod adjustment could be allowing the primary piston to be too far forward, causing the seal cup to be forward of the vent port. Adjust the brake pedal height to a higher level and check for a too-long pushrod length.
b. A defective or swollen rubber sealing cup on the primary piston could cause the cup itself to block the vent port.

NOTE: If the vent port is blocked for any reason, the brakes of the vehicle may *self-apply* when the brake fluid heats up during normal braking. Since the vent port is blocked, the expanded hotter brake fluid has no place to expand and instead increases the pressure in the brake lines. The increase in pressure causes the brakes to apply. Loosening the bleeder valves and releasing the built-up pressure is a check that the brakes are self-applying. Then check the master cylinder to see if it is "venting."

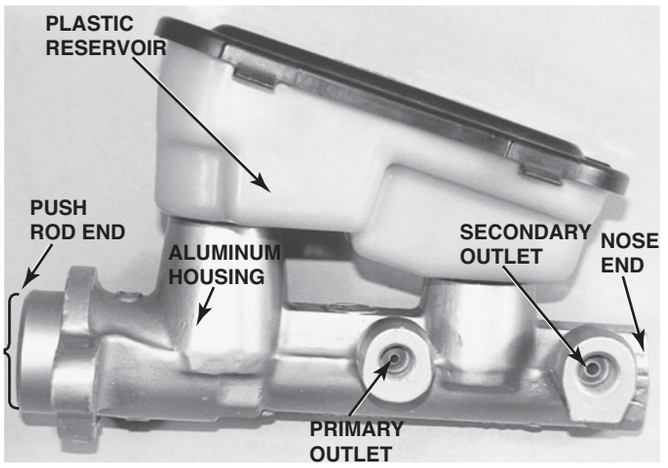

FIGURE 94–22 The primary outlet is the outlet closest to the pushrod end of the master cylinder and the secondary outlet is closest to the nose end of the master cylinder.

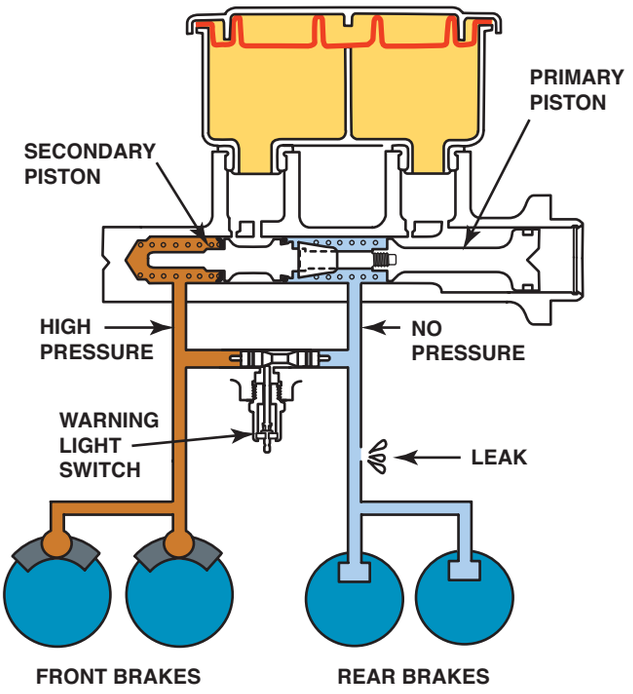

FIGURE 94–23 In the event of a primary system failure, no hydraulic pressure is available to push the second piston forward. As a result, the primary piston extension rod contacts the secondary piston and pushes on the secondary piston mechanically rather than hydraulically. The loss of pressure in the primary system is usually noticed by the driver by a lower-than-normal brake pedal and the lighting of the red brake warning lamp.

closed end toward the front of the vehicle. The open end is often called the *pushrod end* of the master cylinder. ● **SEE FIGURE 94–22.** Some manufacturers operate the front brakes (which do the most braking) from the "nose end" section (secondary piston end) of the master cylinder. The secondary piston has only one pressure-building seal. The primary piston (pushrod end) requires two seals to build pressure. Therefore, the nose end of the master cylinder is considered the more reliable of the two master cylinder pressure-building sections.

NOTE: On vehicles equipped with front and rear split master cylinders, the front brakes may or may *not* be operated from the front chamber. General Motors typically uses the front (nose end) chamber for the front brakes and the rear (pushrod end) for the rear brakes. Many other makes and models of vehicles use the rear chamber for the front brakes. If in doubt, consult the factory service information for the exact vehicle being serviced.

If the rear section of the hydraulic system fails, the primary piston will not build pressure to operate the secondary piston. To permit the operation of the secondary piston (nose end piston) in the event of a hydraulic failure of the rear section, the primary piston extension rod will mechanically contact and push on the secondary piston. ● **SEE FIGURE 94–23.** If there is a failure of the front section hydraulic system, the primary piston (pushrod end) operates normally and exerts pressure on the secondary piston. The secondary piston, however, will not be able to build pressure because of the leak in the system.

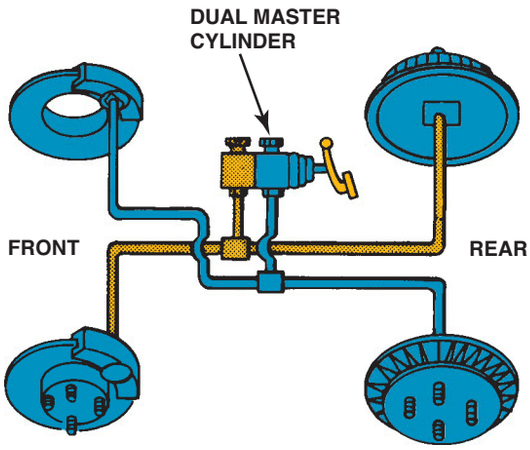

FIGURE 94–24 Front-wheel-drive vehicles use a diagonal split master cylinder. In this design one section of the master cylinder operates the right front and the left rear brake and the other section operates the left front and right rear. In the event of a failure in one section, at least one front brake will still function.

DIAGONAL SPLIT MASTER CYLINDERS

With front-wheel-drive vehicles, the weight of the entire powertrain is on the front wheels and 80% to 90% of the braking force is achieved by the front brakes. This means that only 10% to 20% of the braking force is being handled by the rear brakes. If the front brakes fail, the rear brakes alone would not provide adequate braking force. The solution is the use of a **diagonal split master cylinder.** ● **SEE FIGURE 94–24.**

In a diagonal split braking system, the left front brake and the right rear brake are on one circuit, and the right front with the left rear is another circuit of the master cylinder. If one circuit fails, the remaining circuit can still stop the vehicle in a reasonable fashion because each circuit has one front brake. To prevent this one front brake from causing the vehicle to pull toward one side during braking, the front suspension is designed with negative scrub radius geometry. This effectively eliminates any handling problem in the event of a brake circuit failure.

QUICK TAKE-UP MASTER CYLINDERS

Many newer vehicles use low-drag disc brake calipers to increase fuel economy. However, due to the larger distance between the rotor and the friction pads, excessive brake pedal travel would be required before the pads touched the rotor. The solution to this problem is a master cylinder design that can take up this extra clearance.

The design of a **quick take-up master cylinder** includes a larger diameter primary piston (low-pressure chamber) and a quick take-up valve. This type of master cylinder is also called **dual-diameter bore, step-bore,** or **fast-fill master cylinders.**

A spring-loaded check ball valve holds pressure on the brake fluid in the large diameter rear chamber of the primary piston. When the brakes are first applied, the movement of the rear larger piston forces this larger volume of brake fluid forward past the primary piston seal and into the primary high-pressure chamber. This extra volume of brake fluid "takes up" the extra clearance of the front disc brake calipers without increasing the brake pedal travel distance. ● **SEE FIGURE 94–25.**

At 70 to 100 PSI, the check ball valve in the quick take-up valve allows fluid to return to the brake fluid reservoir. Because the quick take-up "works" until 100 PSI is reached, a metering valve is not required to hold back the fluid pressure to the front brakes.

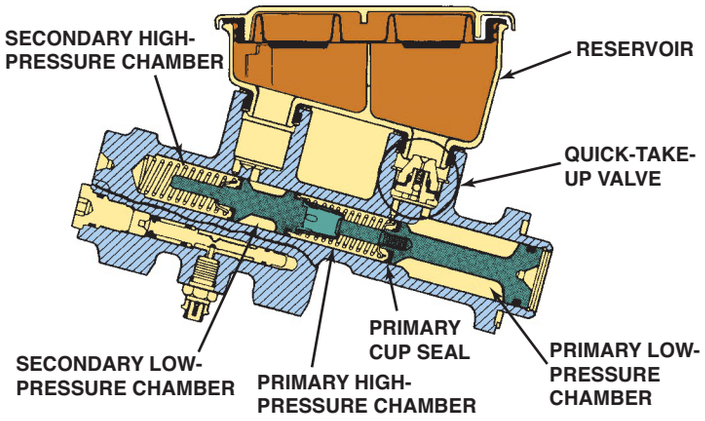

FIGURE 94–25 Quick take-up master cylinder can be identified by the oversize primary low-pressure chamber.

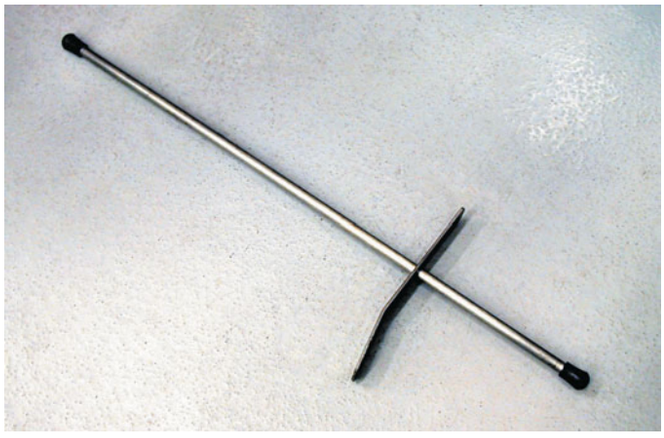

FIGURE 94–26 A brake pedal depressor like this can be used during a wheel alignment to block the flow of brake fluid from the master cylinder during service work on the hydraulic system.

TECH TIP

The Brake Pedal Depressor Trick

The master cylinder can be used to *block* the flow of brake fluid. Whenever any hydraulic brake component is removed, brake fluid tends to leak out because the master cylinder is usually higher than most other hydraulic components such as wheel cylinders and calipers.

To prevent brake fluid loss that can easily empty the master cylinder reservoir, simply *depress* the brake pedal slightly or prop a stick or other pedal depressor to keep the brake pedal down. When the brake pedal is depressed, the piston sealing cups move forward, blocking off the reservoir from the rest of the braking system. The master cylinder stays full and the brake fluid stops dripping out of brake lines that have been disconnected. ● **SEE FIGURE 94–26.**

NOTE: Try this—put a straw into a glass of water. Use a finger to seal the top of the straw and then remove the straw from the glass of water. The water remains in the straw because air cannot get into the top of the straw. This is why the brake pedal depressor trick works to prevent the loss of brake fluid from the system even if the brake line is totally disconnected.

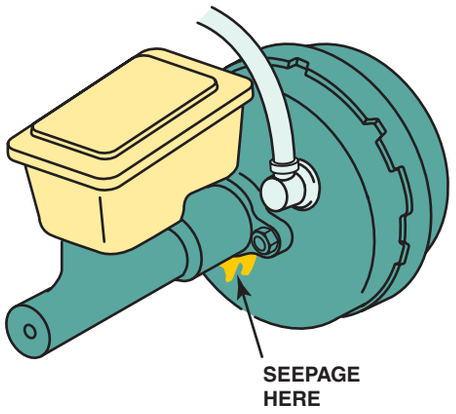

FIGURE 94–27 Some seepage is normal when a trace of fluid appears on the vacuum booster shell. Excessive leakage, however, indicates a leaking secondary (end) seal.

DIAGNOSING AND TROUBLESHOOTING MASTER CYLINDERS

A thorough visual inspection is important when inspecting any master cylinder. The visual inspection should include checking the following items:

1. Check the brake fluid for proper level and condition. (Brake fluid should not be rusty, thick, or contaminated.)
2. Check that the vent holes in the reservoir cover are open and clean.
3. Check that the reservoir cover diaphragm is not torn or enlarged.

   NOTE: If the rubber cover diaphragm is enlarged, this is an indication that a mineral oil, such as automatic transmission fluid or engine oil, has been used in or near the brake system, because rubber that is brake fluid resistant expands when exposed to mineral oil.

4. Check for any external leaks at the brake lines or at the pushrod area. ● **SEE FIGURE 94–27.**

After a thorough visual inspection, check for proper operation of **pedal height, pedal free play,** and **pedal reserve distance.** ● **SEE FIGURES 94–28 AND 94–29.**

Proper brake pedal height is important for the proper operation of the stop (brake) light switch. If the pedal is not correct, the pushrod may be in too far forward, preventing the master cylinder cups from uncovering the vent port. If the pedal is too high, the free play will be excessive. Pedal reserve height is easily checked by depressing the brake pedal with the right foot and attempting to slide your left foot under the brake pedal. ● **SEE FIGURE 94–30.** Free play is the distance the brake pedal travels before the primary piston in the master cylinder moves. *Most vehicles require brake pedal free play between 1/8 to 1 1/2 in. (3 to 38 mm).* Too little or too much free play can cause braking problems that can be mistakenly contributed to a defective master cylinder, such as the following:

- **Spongy brake pedal.** A spongy pedal with a larger than normal travel indicates air in the lines. Check for leaks and bleed the air from the system.

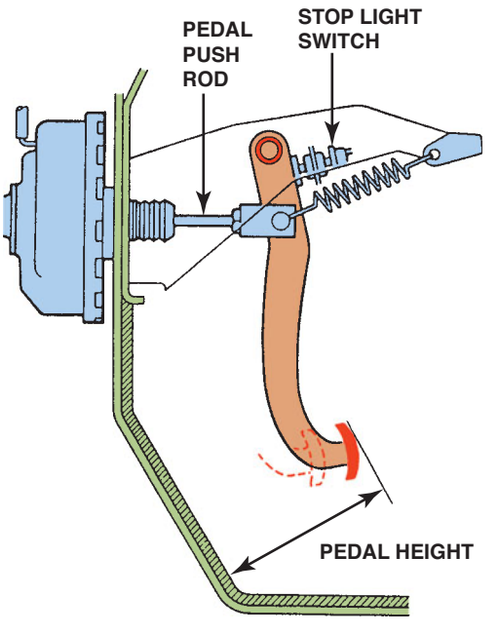

FIGURE 94–28 Pedal height is usually measured from the floor to the top of the brake pedal. Some vehicle manufacturers recommend removing the carpet and measuring from the asphalt matting on the floor for an accurate measurement. Always follow the manufacturer's recommended procedures and measurements. (*Courtesy of Toyota Motor Sales, U.S.A., Inc.*)

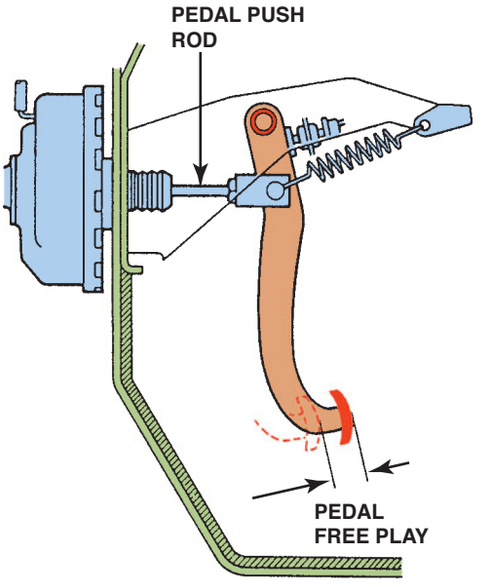

FIGURE 94–29 Brake pedal free play is the distance between the brake pedal fully released and the position of the brake pedal when braking resistance is felt. (*Courtesy of Toyota Motor Sales, U.S.A., Inc.*)

- **Lower-than-normal brake pedal.** A brake pedal that travels downward more than normal and then gets firm is an indication that one circuit of the dual-circuit hydraulic system is probably not working. Check for leaks in the system and repair as necessary. Another possible reason is an out-of-adjustment drum brake allowing too much pedal travel before the shoes touch the brake drum.

  NOTE: A lower-than-normal brake pedal may also be an indication of air in the hydraulic system.

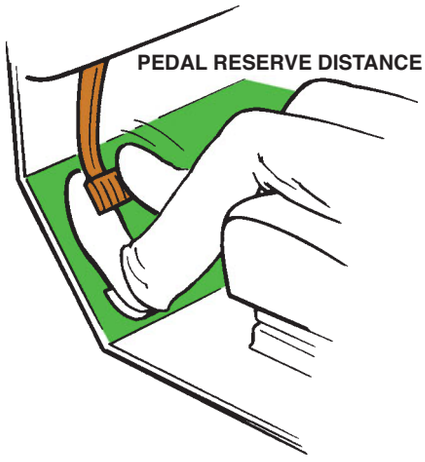

FIGURE 94–30 Brake pedal reserve is usually specified as the measurement from the floor to the top of the brake pedal with the brakes applied. A quick-and-easy test of pedal reserve is to try to place your left toe underneath the brake pedal while the brake pedal is depressed with your right foot. If your toe will *not* fit, then pedal reserve *may* not be sufficient.

TECH TIP

Check for Bypassing

If a master cylinder is leaking internally, brake fluid can be pumped from the rear chamber into the front chamber of the master cylinder. This internal leakage is called *bypassing.* When the fluid bypasses, the front chamber can overflow while emptying the rear chamber. Therefore, whenever checking the level of brake fluid, do not think that a low rear reservoir is always due to an external leak. Also, a master cylinder that is bypassing (leaking internally) will usually cause a lower-than-normal brake pedal.

- **Sinking brake pedal.** If the brake pedal sinks all the way to the floor especially when the vehicle is not moving, suspect a defective master cylinder that is leaking internally. This internal leakage is often called **bypassing** because the brake fluid is leaking past the sealing cup.

MASTER CYLINDER SERVICE

Check the vehicle manufacturer's recommendation before attempting to overhaul or service a master cylinder. Many manufacturers recommend replacing the master cylinder as an assembly. If disassembling a master cylinder, perform the following steps:

STEP 1 Remove the master cylinder from the vehicle, being careful to avoid dripping or spilling brake fluid onto painted surfaces of the vehicle. Dispose of all old brake fluid and clean the outside of the master cylinder.

STEP 2 Remove the reservoir, if possible, as shown in ● **FIGURE 94–31.**

STEP 3 Remove the retaining bolt that holds the secondary piston assembly in the bore.

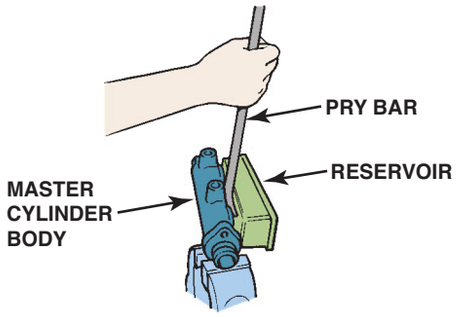

FIGURE 94–31 Using a prybar to carefully remove the reservoir from the master cylinder.

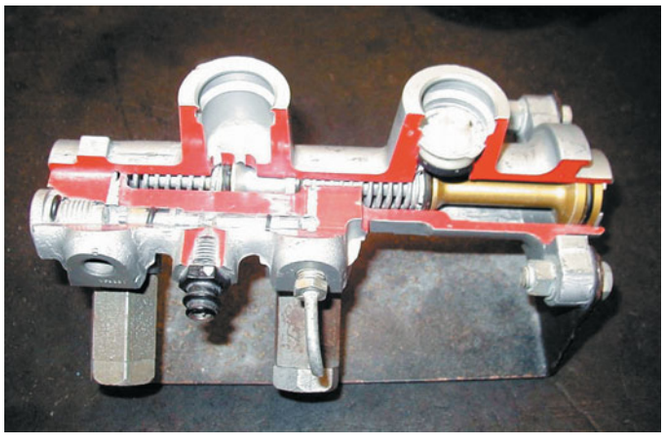

FIGURE 94–32 Whenever disassembling a master cylinder, note the exact order of parts as they are removed. Master cylinder overhaul kits (when available) often include entire piston assemblies rather than the individual seals.

STEP 4 Depress the primary piston with a *blunt* tool such as a Phillips screwdriver, a rounded wooden dowel, or an engine pushrod. Use of a straight-blade screwdriver or other non-rounded tool can damage and distort the aluminum piston.

CAUTION: If holding the master cylinder in a vise, use the flange area. Never clamp the body of the master cylinder.

STEP 5 Remove the snap ring and slowly release the pressure on the depressing tool. Spring pressure should push the primary piston out of the cylinder bore. ● **SEE FIGURE 94–32.**

STEP 6 Remove the master cylinder from the vise and tap the open end of the bore against the top of a workbench to force the secondary piston out of the bore. If necessary, use compressed air in the outlet to force the piston out.

WARNING

Use extreme care when using compressed air. The piston can be shot out of the master cylinder with a great force, which could cause personal injury.

INSPECTION AND REASSEMBLY OF THE MASTER CYLINDER Inspect the master cylinder bore for pitting, corrosion, or wear. Most cast-iron master cylinders cannot be honed because of the special bearingized surface finish that is applied to

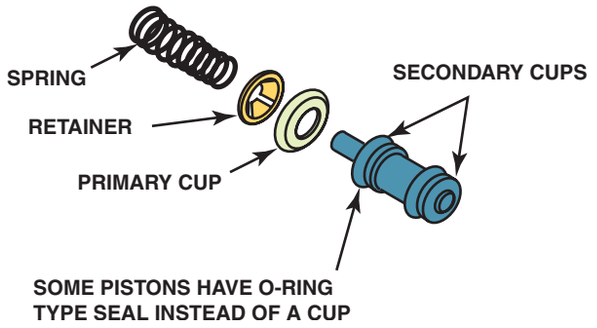

FIGURE 94–33 Piston assembly.

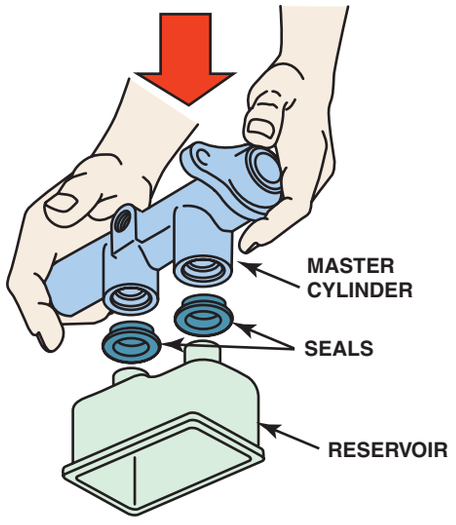

FIGURE 94–34 To reinstall the reservoir onto a master cylinder, place the reservoir on a clean flat surface and push the housing down onto the reservoir after coating the rubber seals with brake fluid.

the bore during manufacturing. Slight corrosion or surface flaws can usually be removed with a hone or crocus cloth. Otherwise, the master cylinder should be replaced as an assembly. Always follow the recommended procedures for the vehicle being serviced.

Aluminum master cylinders cannot be honed. Aluminum master cylinders have an anodized surface coating applied that is hard and wear resistant. Honing would remove this protective coating. Thoroughly clean the master cylinder and any other parts to be reused (except for rubber components) in clean denatured alcohol. If the bore is okay, replacement **piston assemblies** can be installed into the master cylinder after dipping them into clean brake fluid.

NOTE: While most master cylinder overhaul kits include the entire piston assemblies, some kits just contain the sealing cups and/or O-rings. Always follow the installation instructions that accompany the kit and always use the installation tool that is included to prevent damage to the replacement seals.

STEP 1 Install the secondary (smaller) piston assembly into the bore, spring end first. ● **SEE FIGURE 94–33.**

STEP 2 Install the primary piston assembly, spring end first.

STEP 3 Depress the primary piston and install the snap ring.

STEP 4 Install the retaining bolt.

STEP 5 Reinstall the plastic reservoir, if equipped, as shown in ● **FIGURE 94–34.**

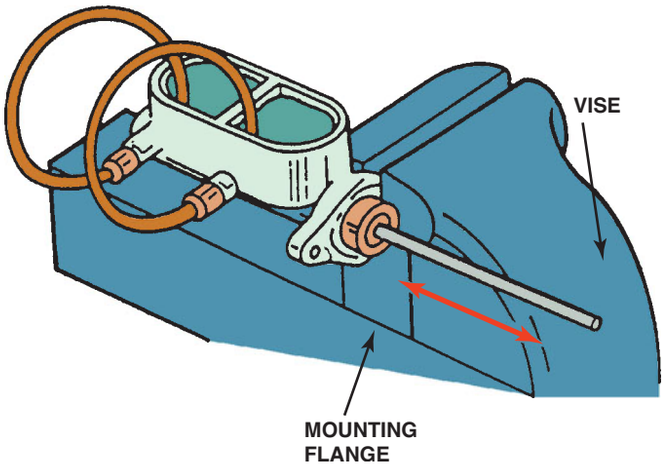

FIGURE 94–35 Bleeding a master cylinder before installing it on the vehicle. The master cylinder is clamped into a bench vise while using a rounded end of a dowel rod to push on the pushrod end with bleeder tubes down into the brake fluid. Master cylinders should be clamped on the mounting flange as shown to prevent distorting the master cylinder bore.

FIGURE 94–36 Installing a master cylinder. Always tighten the retaining fastener and brake lines to factory specifications.

STEP 6 Bench bleed the master cylinder. This step is very important. Failure to get all of the air out of the master cylinder can cause a lower than normal brake pedal and a lack of proper braking. ● **SEE FIGURE 94–35.**

INSTALLING THE MASTER CYLINDER

After the master cylinder has been bench bled, it can be installed in the vehicle.

NOTE: Brake fluid can drip from the outlet of the master cylinder and could drip onto the vehicle. Brake fluid is very corrosive and can remove paint. Use fender covers and avoid letting brake fluid touch any component of the vehicle.

Tighten the fasteners to factory specifications. ● **SEE FIGURE 94–36.** Bleed the system as needed.

INTRODUCTION

The hydraulic system is the heart of the braking system. Using hydraulics is a very efficient way to transfer the force that the driver exerts on the brake pedal to apply the friction materials at the individual wheel brakes. However valves and switches need to be added to the system to meet all possible braking conditions.

RESIDUAL CHECK VALVE

PURPOSE AND FUNCTION A **residual check valve** has been used on some drum brake systems to keep a slight amount of pressure, about 5 to 12 PSI, on the entire hydraulic system for drum brakes. ● **SEE FIGURE 95–1.**

This residual check valve is located in the master cylinder at the outlet for the drum brakes. The check ball and spring in the residual check valve permit all the brake fluid to return to the master cylinder until the designated pressure is reached.

With a low pressure kept on the hydraulic system, any small hole will cause fluid to leak out rather than permit air to enter the system. This slight pressure also keeps the wheel cylinder sealing cups tight against the inside wall of the wheel cylinder. ● **SEE FIGURE 95–2.**

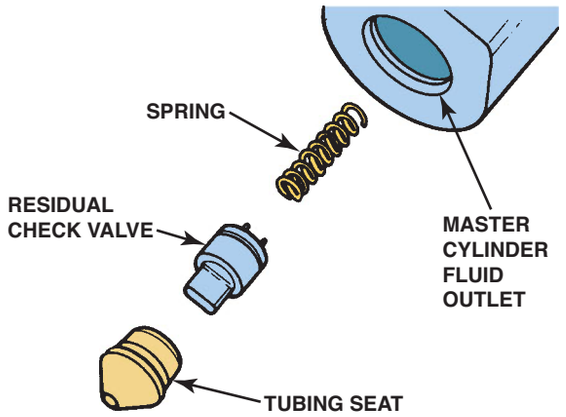

FIGURE 95–1 Most residual check valves are located under the tubing seats in the master cylinder outlet ports.

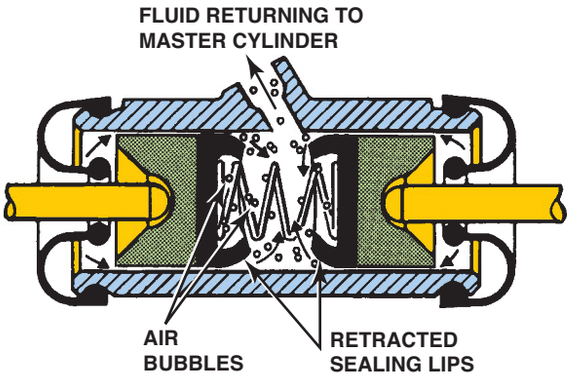

FIGURE 95–2 The momentary drop in pressure created when the brakes are released can draw air into the hydraulic system.

Residual check valves are often *not* used on late-model vehicles equipped with front disc/rear drum brakes. The residual check valve has been eliminated by equipping the wheel cylinder internal spring with a sealing cup **expander** to prevent sealing cup lip collapse. ● **SEE FIGURE 95–3.**

PRESSURE-DIFFERENTIAL SWITCH (BRAKE WARNING SWITCH)

PURPOSE AND FUNCTION A **pressure-differential switch** is used on all vehicles built after 1967 with dual master cylinders to warn the driver of a loss of pressure in one of the two separate systems by lighting the dashboard red brake warning indicator lamp. ● **SEE FIGURES 95–4 AND 95–5.**

The brake lines from both the front and the rear sections of the master cylinder are sent to this switch, which lights the brake warning indicator lamp in the event of a "difference in pressure" between the two sections. ● **SEE FIGURE 95–6.**

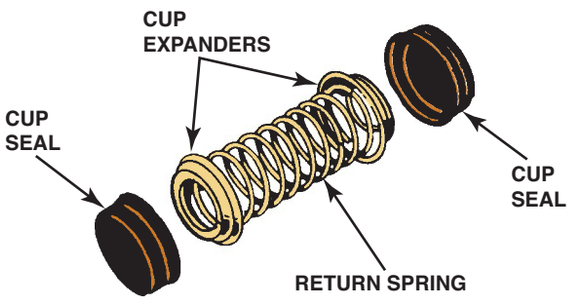

FIGURE 95–3 The use of cup expanders is the main reason why residual check valves are not used in most braking systems today.

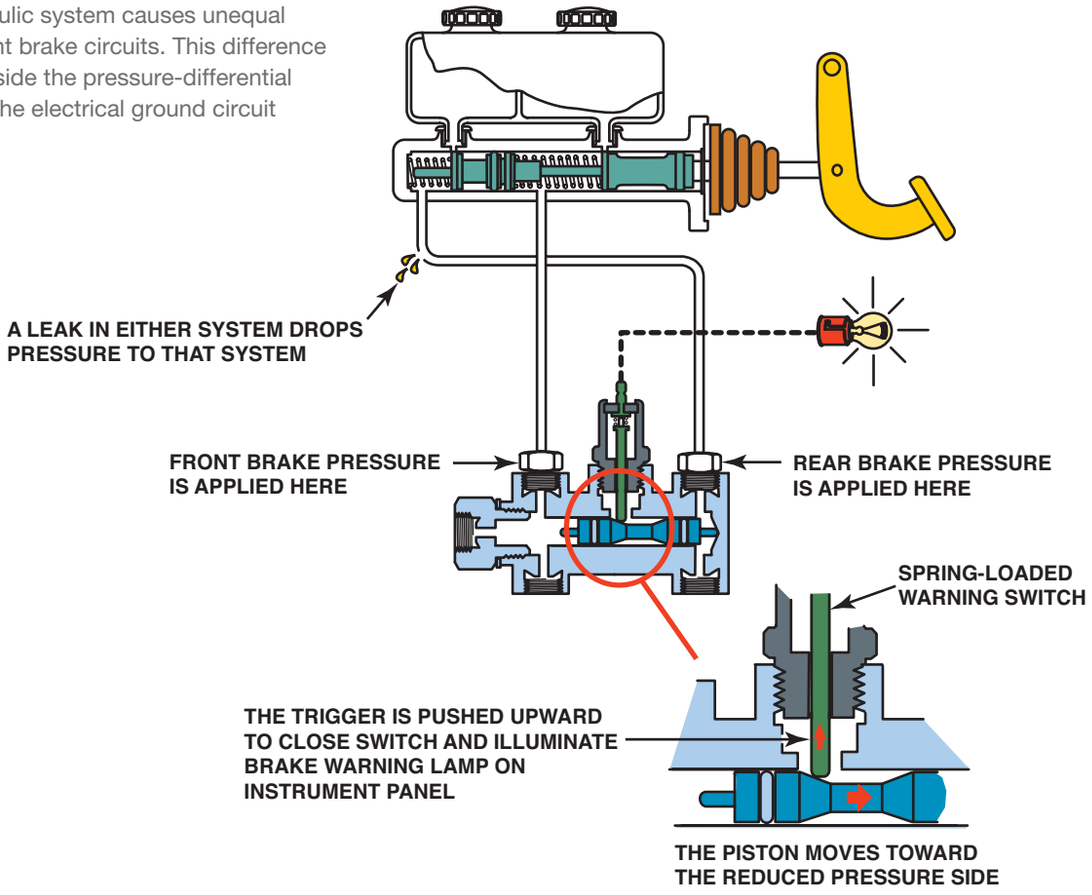
FIGURE 95–4 A red brake warning lamp.

FIGURE 95–5 A leak in the hydraulic system causes unequal pressures between the two different brake circuits. This difference in pressures causes the plunger inside the pressure-differential switch to move, which completes the electrical ground circuit for the red brake warning lamp.



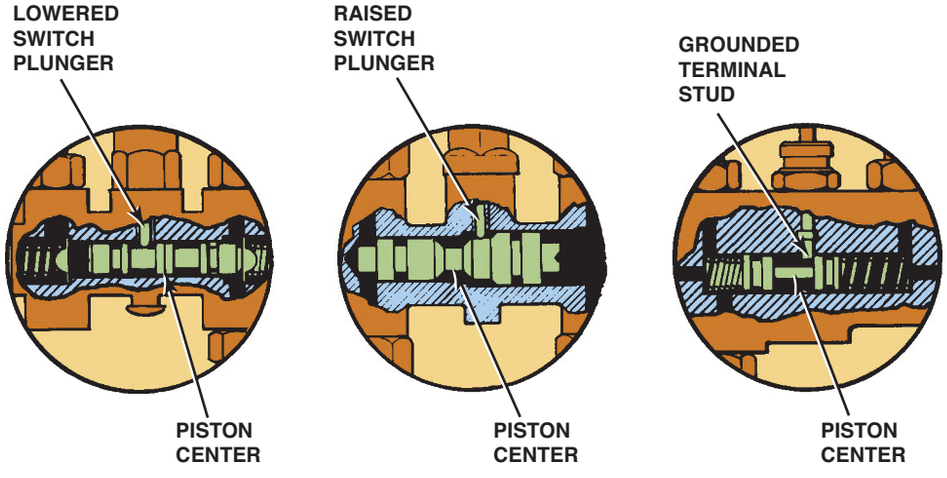


FIGURE 95–6 The pressure-differential switch piston is used to provide the electrical ground for the red brake warning light circuit.

A failure in one part of the brake system does not result in a failure of the entire hydraulic system. After the hydraulic system has been repaired and bled, moderate pressure on the brake pedal will center the piston in the switch and turn off the warning lamp.

If the lamp remains on, it may be necessary to do the following.

1. Apply light pressure to the brake pedal.
2. Momentarily open the bleeder valve on the side that did not have the failure until the warning light goes out.

This procedure should center the pressure-differential switch valve in those vehicles that are not equipped with self-centering springs.

BRAKE FLUID LEVEL SENSOR SWITCH

PURPOSE AND FUNCTION Many master cylinders, especially systems that are a diagonal split, usually use a **brake fluid level sensor** or switch in the master cylinder reservoir. This sensor will light the red brake warning lamp on the dash if low brake fluid level is detected. A float-type sensor or a magnetic reed switch are commonly used and provide a complete electrical circuit when the brake

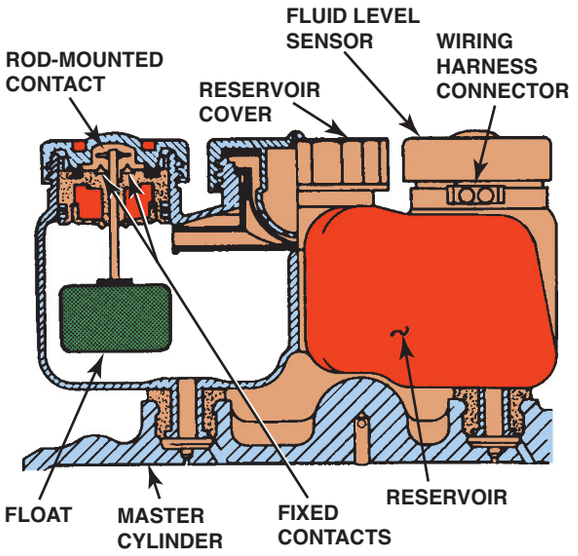

FIGURE 95–7 A movable contact brake fluid level switch. When the brake fluid level and float drop, the rod-mounted contact completes the electrical circuit which turns on the red brake warning lamp.

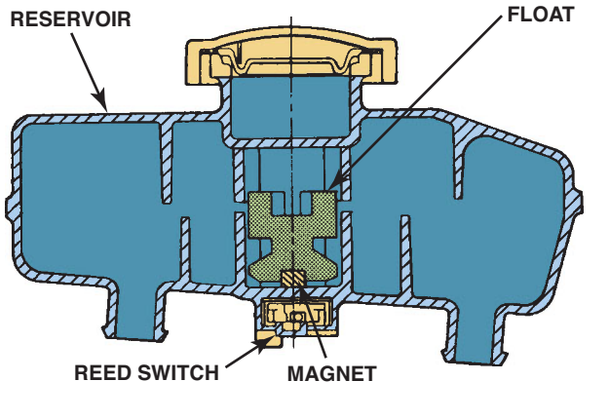

FIGURE 95–8 A magnetic brake fluid level switch.

fluid level is low. After refilling the master cylinder reservoir to the correct level, the red "brake" warning lamp should go out. ● **SEE FIGURES 95–7 AND 95–8.**

DIAGNOSING A RED "BRAKE" DASH WARNING LAMP

Activation of the red brake dash warning lamp can be for any one of several reasons:

1. **Parking Brake "On."** The same dash warning lamp is used to warn the driver that the parking brake is on.
2. **Low Brake Fluid.** This lights the red dash warning lamp on vehicles equipped with a master cylinder reservoir brake fluid level switch.
3. **Unequal Brake Pressure.** The pressure-differential switch is used on most vehicles with a front/rear brake split system to warn the driver whenever there is low brake pressure to either the front or rear brakes.

NOTE: Brake systems use *either* a pressure-differential switch *or* a low brake fluid switch to light the dash red "brake" lamp, but usually not both.

The most likely cause of the red "brake" warning lamp being on is low brake fluid caused by a leaking brake line, wheel cylinder, or caliper. Therefore, the first step in diagnosis is to determine the cause of the lamp being on, then to repair the problem.

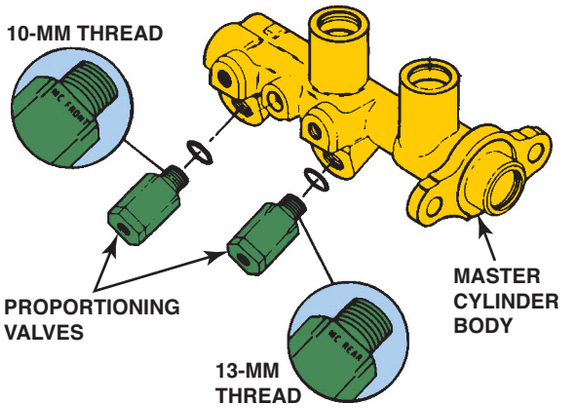

FIGURE 95–9 Many proportioning valves are mounted directly to the master cylinder in the outlet to the rear brakes.

STEP 1 **Check the Level of the Brake Fluid.** If low, carefully inspect the entire hydraulic brake system for leaks and repair as necessary.

STEP 2 **Disconnect the Wire from the Pressure-Differential Switch.** If the lamp is still "on," the problem is due to the parking brake lever switch being "on" or grounded, or the wire going to the switch is shorted to ground. If the red brake warning lamp is "off" after being disconnected from the pressure-differential switch, then the problem is due to a hydraulic failure (a low pressure in either the front or the rear system that creates a difference in pressure of at least 150 PSI).

NOTE: Some older Japanese vehicles energize the relay that turns off the red "brake" warning lamp from the output terminal of the alternator. If a quick inspection of the brake system seems to indicate that everything is okay, check for correct charging voltage before continuing a more detailed brake system inspection.

PROPORTIONING VALVE

PURPOSE AND FUNCTION

A **proportioning valve** improves brake balance during hard stops by limiting hydraulic pressure to the rear brakes. ● **SEE FIGURE 95–9.**

A proportioning valve is necessary because inertia creates weight shift toward the front of the vehicle during braking. The weight shift unloads the rear axle, which reduces traction between the tires and the road, and limits the amount of stopping power that can be delivered. Unless application pressure to the rear wheels is limited, the rear brakes will lock, making the vehicle unstable and likely to spin. The best overall braking performance is achieved when the front brakes lock just before the rear brakes.

Vehicles with front disc and rear drum brakes require a proportioning valve for two reasons.

1. Disc brakes require higher hydraulic pressure for a given stop than do drum brakes. In a disc/drum system, the front brakes always need more pressure than the rear brakes.
2. Once braking has begun, drum brakes require less pressure to *maintain* a fixed level of stopping power than they did to *establish* that level. In a disc/drum system, the rear brakes will always need less pressure than the front brakes.

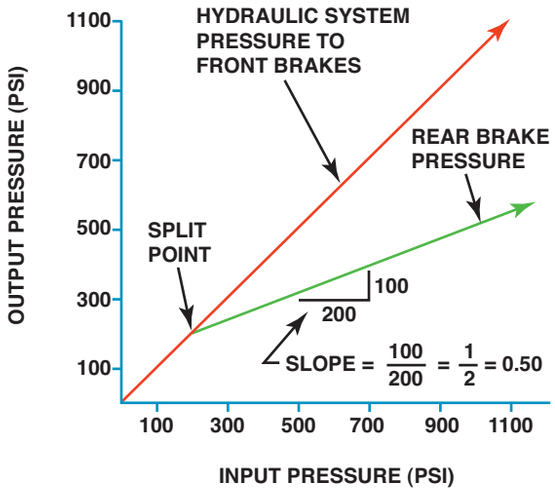

FIGURE 95–10 Typical proportioning valve pressure relationship. Note that, at low pressures, the pressure is the same to the rear brakes as is applied to the front brakes. After the split point, only a percentage (called the slope) of the master cylinder pressure is applied to the rear brakes.

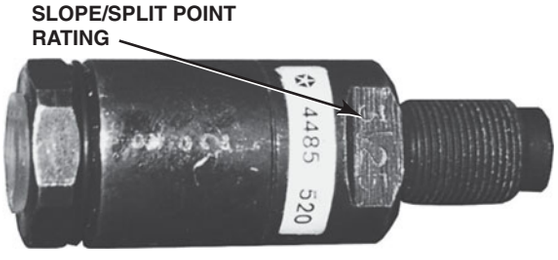

FIGURE 95–11 A Chrysler proportioning valve. Note that slope and split point are stamped on the housing.

A proportioning valve is used to compensate for these differences because it is easier to reduce pressure to the rear brakes than to increase pressure to the front brakes.

The proportioning valve does not work at all times. During light or moderate braking, there is insufficient weight transfer to make rear wheel locking a problem. Before proportioning action will begin, brake system hydraulic pressure must reach a minimum level called the **split point.** Below the split point full system pressure is supplied to the rear brakes. ● **SEE FIGURE 95–10.**

Above the split point, the proportioning valve allows only a portion of the pressure through to the rear brakes.

The proportioning valve gets its name from the fact that it regulates pressure to the rear brakes *in proportion* to the pressure applied to the front brakes. Once system hydraulic pressure exceeds the split point, the rear brakes receive a fixed percentage of any further increase in pressure. Brake engineers refer to the ratio of front to rear brake pressure proportioning as the **slope.** Full system pressure to the rear brakes equals a slope of 1, but if only half the pressure is allowed to reach the rear brakes, the proportioning valve is said to have a slope of 0.50. The proportioning valves on most vehicles have a slope between 0.25 and 0.50. ● **SEE FIGURES 95–11 AND 95–12.**

PROPORTIONING VALVE OPERATION

A simple proportioning valve consists of a spring-loaded piston that slides in a stepped bore. ● **SEE FIGURE 95–13.** The piston is exposed to pressure on both sides. The smaller end of the piston is acted on by pressure from the master cylinder, while the larger end reacts to pressure in the rear brake circuit. The actual proportioning valve is located in the center of the piston and is opened or closed depending on the position of the piston in the stepped bore.

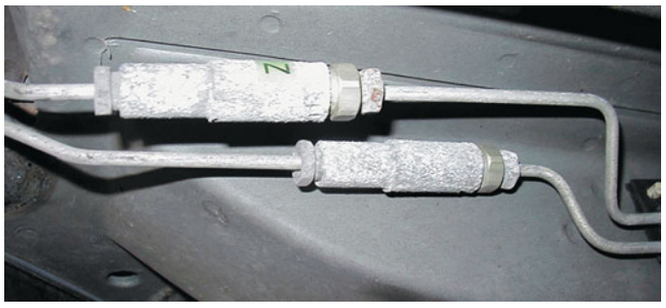

FIGURE 95–12 These two proportioning valves are found under the vehicle on this Dodge minivan.

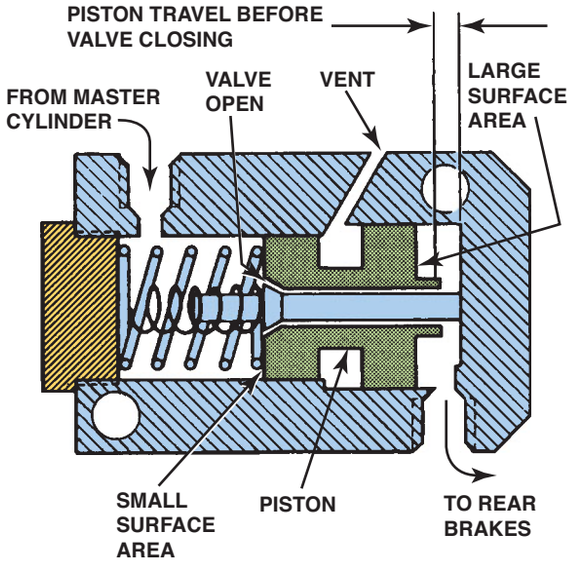

FIGURE 95–13 The proportioning valve piston can travel within the range shown without reducing pressure to the rear brakes.

When the brakes are first applied, hydraulic pressure passes through the proportioning valve to the rear brakes. Hydraulic pressure is the same on both sides of the piston, but because the side facing the rear brakes has more surface area than the side facing the master cylinder, greater force is developed and the piston moves to the left against the spring tension. At pressures below the split point, the proportioning valve is open, and pressure to both the front and rear brakes is the same.

As the vehicle is braked harder, increased system pressure forces the piston so far to the left that the proportioning valve is closed. ● **SEE FIGURE 95–14.** This seals off the brake line and prevents any additional pressure from reaching the rear brakes. The pressure at the moment the proportioning valve first closes is the split point of the valve. From this point on, the rear brakes receive only a portion of the pressure supplied to the front brakes.

As system pressure (the pressure to the front brakes) increases, enough force is developed on the master cylinder side of the piston to overcome the pressure trapped in the rear brake circuit. This forces the piston back to the right and opens the proportioning valve. Some of the higher pressure enters the rear brake circuit, but before pressure in the two circuits can equalize, the force developed on the larger piston area in the rear circuit moves the piston back to the left and closes the valve. The difference in surface area between the two ends of the piston determines the slope of the valve, and

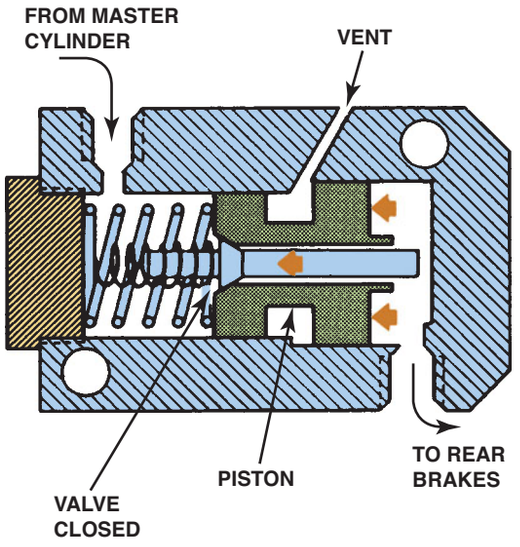

FIGURE 95–14 At the split point, the proportioning valve piston closes the fluid passage through the valve.

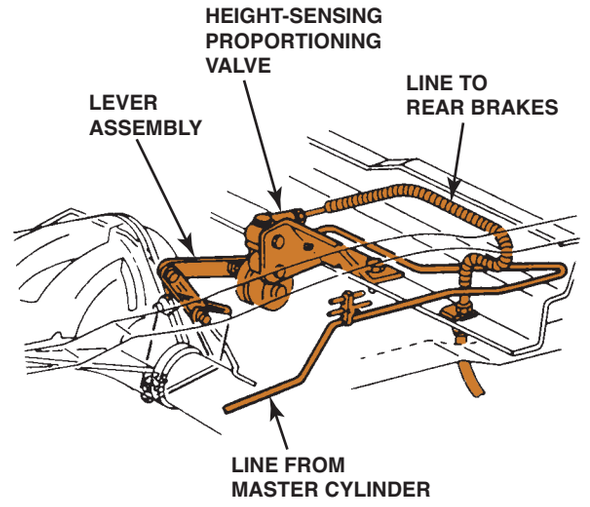

FIGURE 95–15 A height-sensing proportioning valve provides the vehicle with variable brake balance. The valve allows higher pressure to be applied to the rear brakes when the vehicle is heavily loaded and less pressure when the vehicle is lightly loaded.

TECH TIP

Always Inspect Both Front and Rear Brakes

If a vehicle tends to lock up the rear brakes during a stop, many technicians may try to repair the problem by replacing the proportioning valve or servicing the rear brakes. Proportioning valves are simple spring-loaded devices that are usually trouble free. If the rear brakes lock up during braking, carefully inspect the rear brakes looking for contaminated linings or other problems that can cause the rear brakes to grab. Do not stop there—always inspect the front brakes, too. If the front brakes are rusted or corroded, they cannot operate efficiently and greater force must be exerted by the driver to stop the vehicle. Even if the proportioning valve is functioning correctly, the higher brake pedal pressure by the driver could easily cause the rear brakes to lock up.

A locked wheel has less traction with the road than a rotating wheel. As a result, if the rear wheels become locked, the rear of the vehicle often "comes around" or "fishtails," causing the vehicle to skid. Careful inspection of the *entire* braking system is required to be assured of a safe vehicle.

thus the percentage of system pressure allowed to reach the rear brakes.

As long as system pressure continues to increase, the piston will repeatedly cycle back and forth, opening and closing the proportioning valve, and maintaining a fixed proportion of full system pressure to the rear brakes. When the brakes are released, the spring returns the piston all the way to the right, which opens the valve and allows fluid to pass in both directions.

HEIGHT-SENSING PROPORTIONING VALVES

Many vehicles use a proportioning valve that varies the amount of pressure that can be sent to the rear brakes depending on the height of the rear suspension. This type of valve is called a **height-sensing proportioning valve.** If the vehicle is lightly loaded, the rear suspension is high, especially during braking. In this case, the amount of pressure allowed to the rear brakes is reduced. This *helps* prevent rear-wheel lockup and possible skidding. Besides, a lightly loaded vehicle requires less braking force to stop than a heavily loaded vehicle.

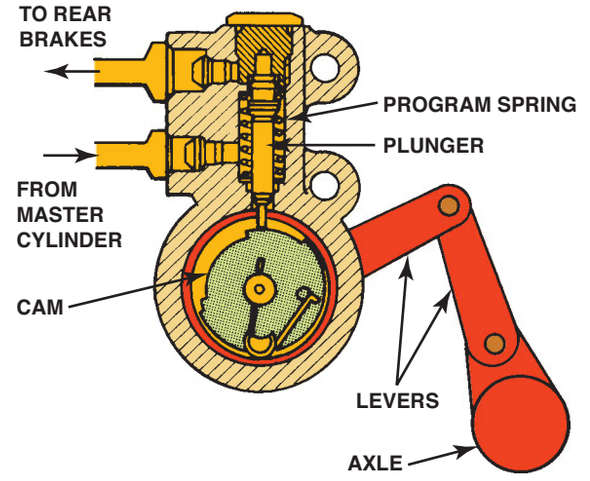

FIGURE 95–16 A stepped cam is used to alter the split point of this height-sensing proportioning valve.

When the vehicle is loaded, the rear suspension is forced downward. The lever on the proportioning valve moves and allows a greater pressure to be sent to the rear brakes. ● **SEE FIGURES 95–15 AND 95–16.** This greater pressure allows the rear brakes to achieve more braking force, helping to slow a heavier vehicle. When a vehicle is heavily loaded in the rear, the chances of rear-wheel lockup are reduced.

CAUTION: Some vehicle manufacturers warn that service technicians should never install replacement air lift shock absorbers or springs that may result in a vehicle height different than specified by the vehicle manufacturer. If the ride height is increased, the front to rear brake proportional relationship will be changed and could reduce stopping distances.

PROPORTIONING VALVE ADJUSTMENT. Height-sensing proportioning valves should be adjusted when replaced. The proper adjustment

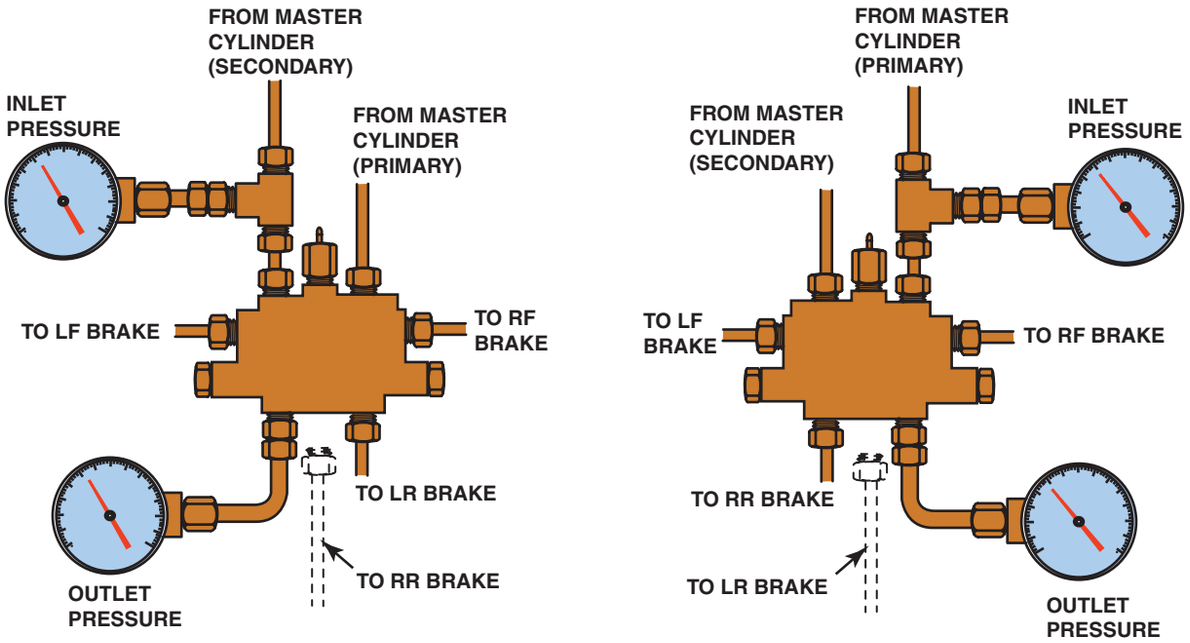

FIGURE 95–17 A proportioning valve pressure test can be performed using two pressure gauges—one to register the pressure from the master cylinder and the other gauge to read the pressure being applied to the rear brakes. This test has to be repeated in order to read the pressure to each rear wheel.

ensures that the proper pressure is applied to the rear brakes in relation to the loading of the vehicle.

Procedures vary from one vehicle to another. Always consult the factory service information for the exact procedure. Some trucks require the use of special plastic gauges available from the dealer.

PROPORTIONING VALVE DIAGNOSIS AND TESTING A defective proportioning valve usually allows rear brake pressure to increase too rapidly, causing the rear wheels to lock up during hard braking. When the rear brakes become locked, the traction with the road surface decreases and the vehicle often skids. Whenever rear brakes tend to lock during braking, the proportioning valve should be checked for proper operation. If the proportioning valve is height sensing, verify the proper vehicle ride (trim) height and adjustment of the operating lever. ● **SEE FIGURE 95–17.**

Pressure gauges can also be used to check for proper operation. Install one gauge into the brake line from the master cylinder and the second gauge to the rear brake outlet of the proportioning valve. While an assistant depresses the brake pedal, observe the two gauges. Both gauges should register an increasing pressure as the brake pedal is depressed until the split point. After the split point, the gauge connected to the proportioning valve (rear brakes) should increase at a slower rate than the reading on the gauge connected to the master cylinder.

If the pressures do not react as described, the proportioning valve should be *replaced.* The same procedure can be performed on a diagonal split-type system as used on most front-wheel-drive vehicles.

ELECTRONIC BRAKE PROPORTIONING

PURPOSE AND FUNCTION Many newer antilock braking systems eliminate the need for a conventional brake proportioning valve. A proportioning valve is usually necessary to reduce pressure to the rear brakes to keep them from locking up. This is because there is less weight over the rear wheels, and weight shifts forward when braking. Proportioning is needed most when a vehicle is lightly loaded or braking from a high speed. Most proportioning valves are calibrated to reduce pressure to the rear brakes by a fixed amount, which may increase the risk of rear-wheel lockup if the vehicle is loaded differently or is braking on a wet or slick surface. Dynamic rear proportioning is overcome by adjusting brake balance to match the need of the vehicle to changing road and load conditions.

PARTS AND OPERATION **Electronic brake proportioning (EBP)** in the antilock braking system is accomplished by monitoring front- and rear-wheel speeds, and reducing pressure to the rear brakes as needed using the ABS solenoids when there is a difference in wheel deceleration rates. The controller energizes the inlet valve solenoids for both rear brakes to hold pressure in the lines, and then energizes both rear outlet valve solenoids to release pressure as needed.

The dynamic rear proportioning function is enabled at all times unless there is a failure of the antilock brake controller or two wheel speed sensors on the same axle both fail at the same time. But as long as there is at least one functional speed sensor on the front and rear axles, the antilock brake controller can compare the relative speeds of the front and rear wheels.

METERING VALVE (HOLD-OFF) OPERATION

PURPOSE AND FUNCTION A **metering valve** is used on all front-disc, rear-drum-brake-equipped vehicles. The metering valve prevents the full operation of (holds off) the disc brakes until between 75 to 125 PSI is sent to the rear drum brakes to overcome rear-brake return spring pressure. This allows the front and rear brakes to apply at the same time for even stopping. Most metering valves also allow for the pressure to the front brakes to be gradually blended up to the

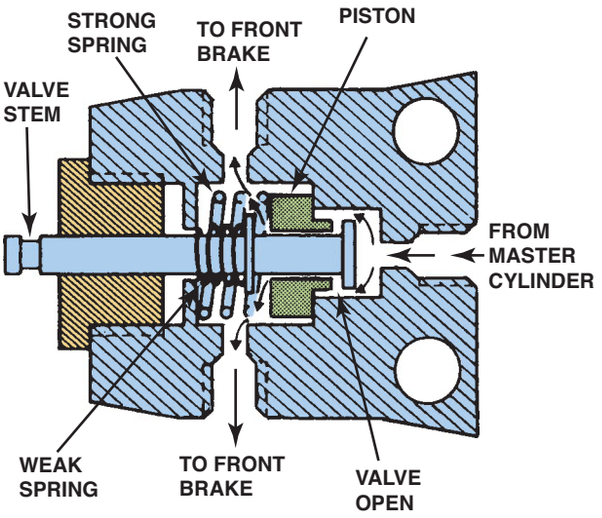

FIGURE 95–18 A metering valve when the brakes are not applied. Notice the brake fluid can flow through the metering valve to compensate for brake fluid expansion and contraction that occurs with changes in temperature.

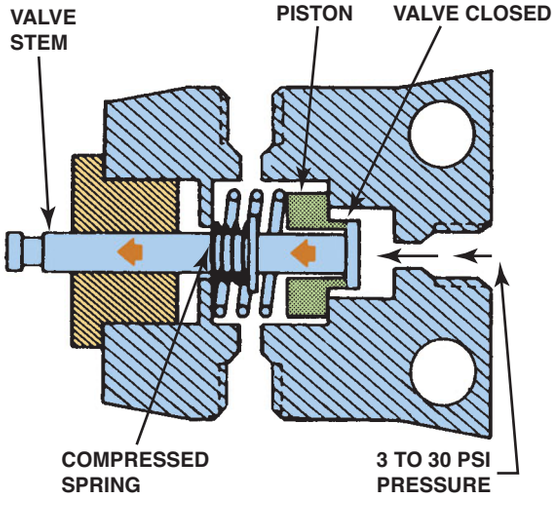

FIGURE 95–19 A metering valve under light brake pedal application.

metering valve pressure to prevent front brake locking under light pedal pressures on icy surfaces.

PARTS AND OPERATION

A metering valve consists of a piston controlled by a strong spring and a valve stem controlled by a weak spring. ● **SEE FIGURE 95–18.** When the brakes are not applied, the strong spring seats the piston and prevents fluid flow around it. At the same time, the weak spring holds the valve stem to the right and opens a passage through the center of the piston. Brake fluid is free to flow through this passage to compensate for changes in system fluid volume.

When the brakes are applied and pressure in the front brake line reaches 3 to 30 PSI (20 to 200 kPa), the tension of the weak spring is overcome and the metering valve stem moves to the left, which closes the passage through the piston and prevents fluid flow to the front brakes. ● **SEE FIGURE 95–19.**

The small amount of pressure applied to the calipers before the metering valve closes is enough to take up any clearance, but not enough to generate braking force.

While the fluid flow to the front calipers is shut off, the rear brake shoes move into contact with the drums, braking begins, and hydraulic pressure throughout the brake system increases. When

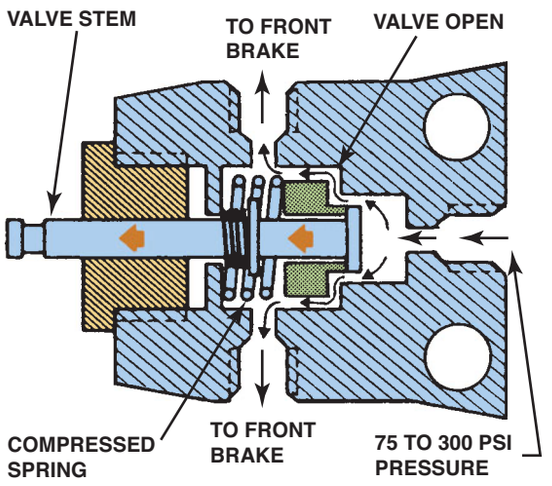

FIGURE 95–20 A metering valve during a normal brake application.

the pressure at the metering valve reaches 75 to 300 PSI, the tension of the strong spring is overcome and the valve stem and piston move farther to the left. ● **SEE FIGURE 95–20.** This opens a passage around the outside of the piston and allows fluid to flow through the valve to the front brake calipers.

When the brakes are released, the strong spring seats the piston and prevents fluid flow around it. At the same time, the weak spring opens the fluid passage through the center of the piston. Excess fluid returns to the master cylinder through this passage and the valve is ready for another brake application.

SYSTEMS WITHOUT METERING VALVES

Braking systems that are diagonal split, such as those found on most front-wheel-drive vehicles, do *not* use a metering valve. A metering valve is only used on front/rear split braking systems such as those found on most rear-wheel-drive vehicles.

There are three reasons why front-wheel-drive vehicles do not use metering valves.

1. Front-wheel-drive vehicles usually have a diagonally split dual braking system that would require a separate metering valve for each hydraulic circuit. This would make the brake system more costly and complicated.
2. Front-wheel-drive vehicles have a forward weight bias that requires the front brakes to supply up to 80% of the total braking power. Since the front brakes do most of the work, it is desirable to apply them as soon as possible when the brake pedal is depressed. A metering valve would create a slight delay.
3. Until all the clearance in the brake system is taken up, there will not be enough pressure in the brake hydraulic system for the front disc brakes to overcome the engine torque applied to the driven front wheels.

Engine torque and a heavy front weight bias help prevent front-wheel lockup from being a problem during light braking or when the brakes are first applied.

Most rear-wheel-drive vehicles without metering valves are equipped with four-wheel disc brakes. Because the clearance between the pads and rotors is approximately the same at all four wheels, there is no need to delay front brake actuation. Some of these vehicles also have antilock brake systems that prevent the wheels from locking at any time.

METERING VALVE DIAGNOSIS AND TESTING

A defective metering valve can leak brake fluid and/or cause the front brakes

TECH TIP

Push-In or Pull-Out Metering Valve?

Whenever bleeding the air out of the hydraulic brake system, the metering valve should be bypassed. The metering valve stops the passage of brake fluid to the front wheels until pressure exceeds about 125 PSI (860 kPa). It is important not to push the brake pedal down with a great force so as to keep from dispersing any trapped air into small and hard-to-bleed bubbles. To bypass the metering valve, the service technician has to push or pull a small button located on the metering valve. An easy way to remember whether to push in or to pull out is to inspect the button itself. *If the button is rubber coated, then you push in. If the button is steel, then pull out.*

Special tools allow the metering valve to be held in the bypass position. Failure to remove the tool after bleeding the brakes can result in premature application of the front brakes before the rear drum brakes have enough pressure to operate.

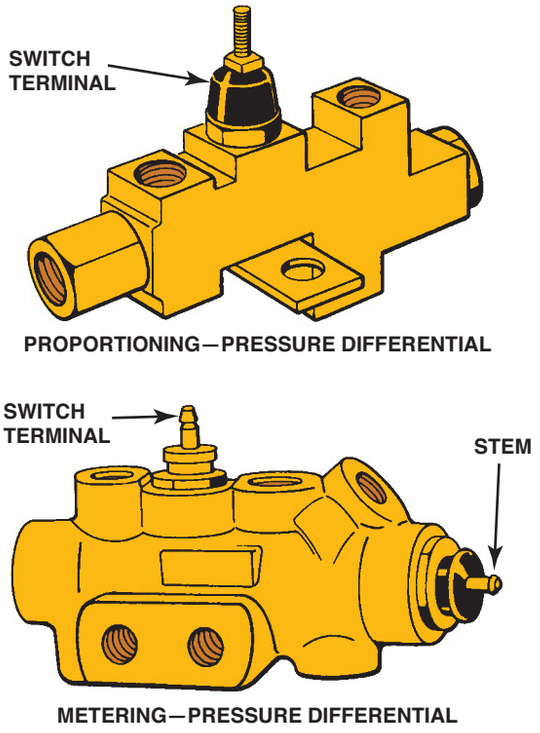

FIGURE 95–21 Typical two-function combination valves.

to apply before the rear brakes. This is most commonly noticed on slippery surfaces such as on snow or ice or on rain-slick roads. If the front brakes lock up during these conditions, the front wheels cannot be steered. Inspect the metering valve for these two conditions:

1. Look around the bottom of the metering valve for brake fluid leakage. (Ignore slight dampness.) Replace the metering valve assembly if it is leaking.
2. As the pressure builds to the front brakes, the metering valve stem should move. If it does not, replace the valve.

More accurate testing of the metering valve can be accomplished using pressure gauges. Install two gauges, one in the pressure line coming from the master cylinder and the other in the outlet line leading to the front brakes. When depressing the brake pedal, both gauges should read the same until about 3 to 30 PSI (20 to 200 kPa) when the metering valve shuts, thereby delaying the operation of the front brakes. The master cylinder outlet gauge should show an increase in pressure as the brake pedal is depressed further.

Once 75 to 300 PSI is reached, the gauge showing pressure to the front brakes should match the pressure from the master cylinder. If the pressures do not match these ranges, the metering valve assembly should be replaced.

TECH TIP

No Valves Can Cause a Pull

When diagnosing a pull to one side during braking, some technicians tend to blame the metering valve, proportional valve, the pressure-differential switch, or the master cylinder itself.

Just remember that if a vehicle pulls during braking that the problem *has* to be due to an individual wheel brake or brake line. The master cylinder and all the valves control front or rear brakes together or diagonal brakes and cannot cause a pull if not functioning correctly.

COMBINATION VALVE

Most vehicle manufacturers combine the function of a proportioning valve with one or more other valves into one unit called a **combination valve.** ● **SEE FIGURES 95–21 AND 95–22.**

On a typical rear-wheel-drive vehicle, a typical combination valve consists of the following components all in one replaceable unit:

- Metering valve
- Proportioning valve
- Pressure-differential switch

Some combination valves have only two functions and contain the pressure-differential and the metering valve, while others combine the pressure-differential with the proportioning valve.

BRAKE LIGHT SWITCH

The job of the **brake light switch** is to turn on the brake lights at the back of the vehicle when the brakes are applied. A properly adjusted light switch will activate the brake lights as soon as the brake pedal is applied and before braking action actually begins at the wheels. Depending on the make, model, and year of vehicle, a brake light switch can be called:

- Stop light switch
- Brake pedal position (BPP) switch
- Brake on/off (BOO) switch (Fords)

Mechanical switches that operate directly off the brake pedal arm are most often used. ● **SEE FIGURE 95–23.**

Brake light switches are normally open. When the brakes are applied, the switch closes, which completes the brake light circuit.

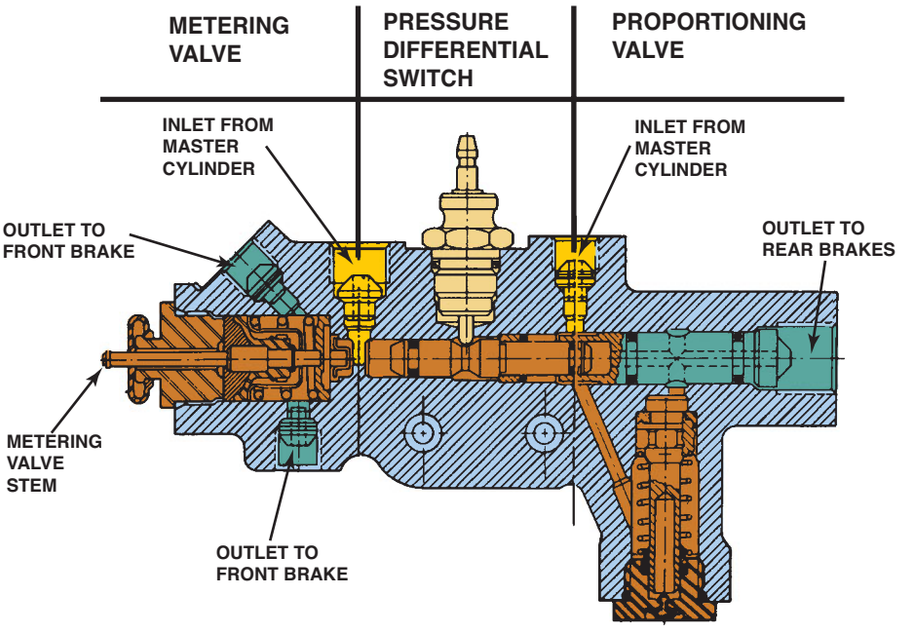

FIGURE 95–22 Combination valve containing metering, pressure-differential (warning switch), and proportioning valves all in one unit. This style is often called a "pistol grip" design because the proportioning valve section resembles the grip section of a handgun.

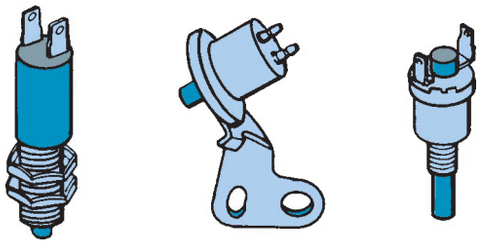

FIGURE 95–23 Typical brake light switches.

Most newer vehicles use the brake switch as an input to the body computer for many functions including:

- Brake lights
- Antilock brake system (ABS) input signal
- Traction control is disabled when the brake pedal is depressed
- Electronic stability control (ESC) system input signal

BRAKE FLUID

PURPOSE AND FUNCTION

Brake fluid is designed to function in the hydraulic brake system under all operating conditions. Brake fluid boiling point is one of the most critical aspects and ratings for brake fluid. As brake fluid ages, it absorbs moisture, which lowers its boiling point and causes increased corrosion of the brake system components.

All automotive experts agree that brake fluid should be changed regularly as part of normal routine service. Even through the driver may not notice an immediate improvement, the reduced corrosion will eventually result in less money being spent for brake system component replacement in the future. Getting the old low-boiling-point brake fluid out of the system could prevent a total loss of brakes due to brake fluid boiling.

All brake fluids must be able to pass tests for the following:

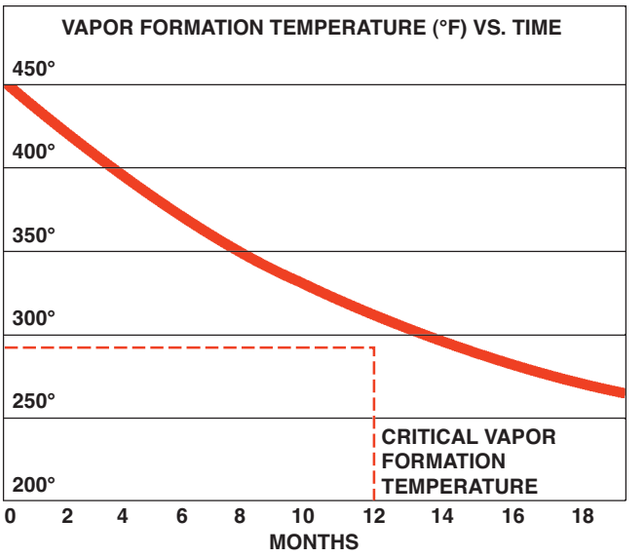
1. Fluidity at low temperatures
2. Controlled percentage loss due to evaporation at high temperatures (tested at 212°F [100°C])
3. Compatibility with other brake fluids
4. Resistance to oxidation
5. Specific effects on rubber, including:
   a. No disintegration
   b. No increase in hardness of the rubber tested
   c. Limited amount of decrease in hardness of the rubber

PHYSICAL PROPERTIES

Brake fluid is made from a combination of various types of glycol, a non-petroleum-based fluid. Brake fluid is a polyalkylene–glycol–ether mixture called **polyglycol** for short. All *polyglycol brake fluid is clear to amber in color.* Brake fluid has to have the following characteristics:

- A high boiling point
- A low freezing point
- Ability to not damage rubber parts in the brake system

BRAKE FLUID SPECIFICATIONS



All automotive brake fluid must meet Federal Motor Vehicle Safety Standard (FMVSS) 116. The Society of Automotive Engineers (SAE) and the Department of Transportation (DOT) have established brake fluid specification standards as shown in the following chart.

	DOT 3	DOT 4	DOT 5.1	DOT 5
Dry boiling point				
°F	401	446	500	500
°C	205	230	260	260
Wet boiling point				
°F	284	311	356	356
°C	140	155	180	180

The wet boiling point is often referred to as “equilibrium reflux boiling point” (ERBP). ERBP refers to the method in the specification (SAE J1703) by which the fluid is exposed to moisture and tested.

FIGURE 96–1 Brake fluid can absorb moisture from the air even through plastic, so many experts recommend that brake fluid be purchased in metal containers, if possible.

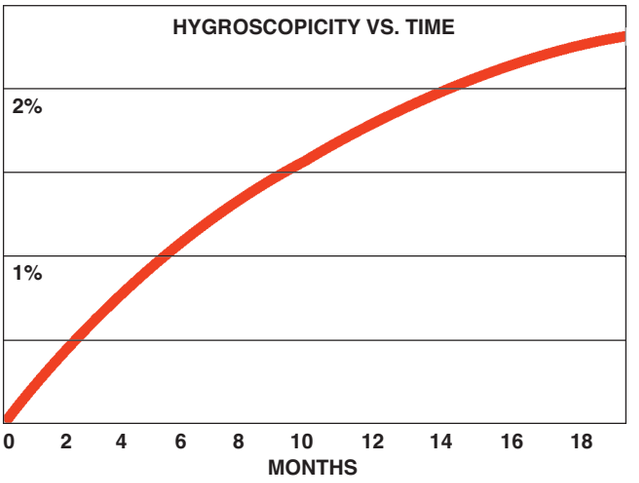


FIGURE 96–2 Brake fluid absorbs moisture from the air at the rate of about 2% per year. As the brake fluid absorbs water, its boiling temperature decreases.

FREQUENTLY ASKED QUESTION

What Is Blue Brake Fluid?

Some brake fluid vendors market a high-performance DOT 4 brake fluid that is dyed blue and is called super blue while others market a super DOT 4 that is yellow. These brake fluids are designed to be sold in Europe. The advertising states that the bright color of the brake fluid makes it easy to see when all of the old fluid has been purged from the system during a brake fluid replacement procedure.

DOT 3. **DOT 3** brake fluid is the type most often used. However, DOT 3 brake fluid has some important characteristics including:

1. DOT 3 absorbs moisture. According to the Society of Automotive Engineers (SAE), DOT 3 can absorb 2% of its volume in water per year. Moisture is absorbed by the brake fluid through microscopic seams in the brake system and around seals. Over time, the water will corrode the system and thicken the brake fluid. The moisture can also cause a spongy brake pedal, due to reduced vapor-lock temperature. ● **SEE FIGURES 96–1 AND 96–2.**
2. DOT 3 must be used from a sealed (capped) container. If allowed to remain open for any length of time, DOT 3 will absorb moisture from the surrounding air, which is called **hygroscopic.**
3. Always check the brake fluid recommendations on the top of the master cylinders of imported vehicles before adding DOT 3.

CAUTION: DOT 3 brake fluid is a very strong solvent and can remove paint! Care is required when working with DOT 3 brake fluid to avoid contact with the vehicle's painted surfaces. It also takes the color out of leather shoes.

DOT 4. **DOT 4** brake fluid is formulated for use by all vehicles, that are designed to use DOT 3 brake fluid. DOT 4 is polyglycol based but has borate esters added to provide an extra buffer for the fluid against acids that can form in the moisture that has been absorbed in the fluid when it is heated. DOT 4 is approximately double the cost of DOT 3. DOT 4 can often be used where DOT 3 is used and even though the two types of brake fluid are compatible and miscible (able to be mixed), some vehicle manufacturers recommend that DOT 3 and DOT 4 not be mixed. If DOT 4 is to be used, the system should be purged of all of the old DOT 3 and replaced with DOT 4.

NOTE: Because brake fluid absorbs moisture over time, many vehicle manufacturers recommend changing the brake fluid as part of the standard services to be performed routinely. The typical recommended brake fluid change interval is every two years or every 30,000 miles (48,000 km), whichever comes first. This is particularly important for vehicles equipped with an antilock braking system (ABS) because of the problem of expensive brake component wear or corrosion caused by contaminated brake fluid.

DOT 5.1. **DOT 5.1** brake fluid is a non-silicone-based polyglycol fluid and is clear to amber in color. This severe duty fluid has a boiling point of over 500°F equal to the boiling point of silicone-based DOT 5 fluid. Unlike DOT 5, DOT 5.1 can be mixed with either DOT 3 or DOT 4 according to brake fluid manufacturers' recommendations.

CAUTION: Some vehicle manufacturers such as Chrysler do not recommend the use of or the mixing of other types of polyglycol brake fluid and specify the use of DOT 3 brake fluid only. Always follow the vehicle manufacturer's recommendation.

FIGURE 96–3 DOT 5 brake fluid is used mostly in motorcycles because if spilled, it will not hurt painted surfaces.

DOT 5. **DOT 5** brake fluid is commonly called **silicone brake fluid** and is made from polydimethylsiloxanes. DOT 5 brake fluid is purple (violet) in color to distinguish it from DOT 3 or DOT 4 brake fluid. It does not absorb any water, and is therefore called **nonhygroscopic.** Even though DOT 5 does not normally absorb water, it is still tested using standardized SAE procedures in a humidity chamber. After a fixed amount of time, the brake fluid is measured for boiling point. Since it has had a chance to absorb moisture, the boiling point after this sequence is called the minimum wet boiling point.

Silicones have about three times the amount of dissolved air as glycol fluids (about 15% of dissolved air versus only about 5% for standard glycol brake fluid). It is this characteristic of silicone brake fluid that causes the most concern about its use.

1. Silicone brake fluid has an affinity for air; therefore, it is more difficult to bleed the hydraulic system of trapped air.
2. The trapped air expands with increasing temperature. This causes the brake pedal to feel "mushy" because the pressure exerted on the hydraulic system simply compresses the air in the system and does not transfer the force to the wheel cylinders and calipers as it should.

   NOTE: The characteristic of DOT 5 silicone brake fluid to absorb air is one of the major reasons why it is not recommended for use with an antilock braking system (ABS). In an ABS, valves and pumps are used which can aerate the brake fluid. Brake fluid filled with air bubbles cannot properly lubricate the ABS components and will cause a low, soft brake pedal.
3. The air trapped in the silicone brake fluid can also "off-gas" at high altitudes, causing a mushy brake pedal and reduced braking performance. DOT 5 brake fluid has been known to create a braking problem during high-altitude (over 5,000 ft [1,500 m]) and high-temperature driving. The high altitude tends to vaporize (off-gassing) some parts of the liquid, creating bubbles in the brake system, similar to having air in the brake system.
4. DOT 5 brake fluid should not be mixed with any other type of brake fluid. Therefore, the entire braking system must be completely flushed and refilled with DOT 5.
5. DOT 5 does not affect rubber parts and will not cause corrosion.
6. DOT 5 is expensive. It is approximately four times the cost of DOT 3 brake fluid. ● **SEE FIGURE 96–3.**

FIGURE 96–4 Both rubber sealing cups were exactly the same size. The cup on the left was exposed to mineral oil. Notice how the seal greatly expanded.

? **FREQUENTLY ASKED QUESTION**

What Is Hydraulic Brake System Mineral Oil?

Some French-built Citroen and British-designed Rolls-Royce vehicles use **hydraulic system mineral oil (HSMO)** as part of their hydraulic control systems. The systems in these vehicles use a hydraulic pump to pressurize hydraulic oil for use in the suspension leveling and braking systems.

CAUTION: Mineral hydraulic oil should never be used in a braking system that requires DOT 3 or DOT 4 polyglycol-based brake fluid. If any mineral oil, such as engine oil, transmission oil, or automatic transmission fluid (ATF), gets into a braking system that requires glycol brake fluid, every rubber part in the entire braking system must be replaced. Mineral oil causes the rubber compounds that are used in glycol brake fluid systems to swell (● SEE FIGURE 96–4).

To help prevent hydraulic system mineral oil from being mixed with glycol brake fluid, *hydraulic mineral oils are green.*

BRAKE FLUID INSPECTION AND TESTING

The brake fluid should be inspected regularly, including the following items:

1. **Proper Level.** The brake fluid level should be above the minimum level (labeled MIN) and below the maximum (labeled MAX) on the side of the master cylinder reservoir. Do not add brake fluid unless the entire brake system is carefully inspected for worn brake pads and shoes and for signs of any external leakage.
2. **Color/Condition.** New brake fluid is clear or amber in color. If the brake fluid is black or discolored like black coffee or coffee with cream, the fluid should be changed. ● **SEE FIGURE 96–5.**
3. **Tested Using a Tester or Test Strips.** Often, brake fluid does not look as if it is bad but has absorbed moisture enough to reduce its effectiveness. Test strips can be used to measure copper ions that increase as the brake fluid becomes deteriorated. The copper comes from sealing washers and other brass or copper brake system components.

   ● **SEE FIGURE 96–6.**
4. **Boiling Point Tester.** An electronic tester can be used to measure the actual boiling temperature of the brake fluid. The tester probe is inserted into the brake fluid and then a button

FIGURE 96–5 If the brake fluid is black in color, it should be replaced.

REAL WORLD FIX

The Sinking Brake Pedal

This author has experienced what happens when brake fluid is not changed regularly. Just as many technicians will tell you, we do not always do what we know should be done to our own vehicles.

While driving a four-year-old vehicle on vacation in very hot weather in mountainous country, the brake pedal sank to the floor. When the vehicle was cold, the brakes were fine. But after several brake applications, the pedal became soft and spongy and sank slowly to the floor if pressure was maintained on the brake pedal. Because the brakes were okay when cold, I knew it had to be boiling brake fluid. Old brake fluid (four years old) often has a boiling point under 300°F (150°C). With the air temperature near 100°F (38°C), it does not take much more heat to start boiling the brake fluid. After bleeding over a quart (1 liter) of new brake fluid through the system, the brakes worked normally. I'll never again forget to replace the brake fluid as recommended by the vehicle manufacturer.

is pushed and the boiling temperature is displayed. ● **SEE FIGURE 96–7.**

5. **Brake Fluid Contamination Test.** If brake fluid is mixed with any mineral oil, such as engine oil, power steering fluid, or automatic transmission fluid, rubber components will swell and cause brake system failure. To check for possible contamination, remove the reservoir cover from the master cylinder. If the rubber diaphragm is swelled or distorted, brake fluid contamination is likely. To check the brake fluid, use a Styrofoam cup filled with water.
   - Place a teaspoon (1 ml) of brake fluid from the master cylinder into the water.
   - Pure brake fluid will completely dissolve in the water. Petroleum or mineral oil fluids will float on the surface of

REAL WORLD FIX

The Pike's Peak Brake Inspection

All vehicles must stop about halfway down Pike's Peak Mountain in Colorado (14,110 ft [4,300 m]) for a "brake inspection." When this author stopped at the inspection station, a uniformed inspector simply looked at the right front wheel and waved us on. I pulled over and asked the inspector what he was checking. He said that when linings and drums/rotors get hot, the vehicle loses brake effectiveness. But if the brake fluid boils, the vehicle loses its brakes entirely. The inspector was listening for boiling brake fluid at the front wheel and feeling for heat about 1 ft (30 cm) from the wheel. The inspector used an infrared pyrometer to measure the front wheel brakes and if the brakes were too hot to continue, you would be instructed to pull over and wait for the brakes to cool. The inspector recommended placing the transmission into a lower gear, which uses the engine to slow the vehicle during the descent without having to rely entirely on the brakes.

the water and retain their color. Petroleum fluids will also dissolve the Styrofoam cup at the waterline.

- If the brake fluid is contaminated, the entire braking system must be drained and flushed and all rubber components replaced.

BRAKE FLUID SERVICE PROCEDURES AND PRECAUTIONS

1. Store brake fluid only in its original container.
   - To help prevent possible contamination with moisture, air, or other products, purchase brake fluid in small containers.
   - Keep all brake fluid containers tightly closed to prevent air (containing moisture) from being absorbed.
2. Before opening a brake fluid container, remove any dirt, moisture, or other contamination from the top and outside of the container.
3. When a brake fluid container is empty, it should be discarded—the container should never be used for anything except brake fluid.
4. Do not transfer brake fluid to any other container that may have contained oil, kerosene, gasoline, antifreeze, water, cleaners, or any other liquids or chemicals.
5. Do not reuse brake fluid that has been siphoned from another vehicle or drawn out during a brake bleeding operation. (Brake bleeding means to open special bleeder valves in the hydraulic system to rid the system of any trapped air.)
6. Use only fresh, new brake fluid for flushing the hydraulic brake system.

CAUTION: Alcohol or flushing fluids should not be used because they cannot be totally removed from a closed hydraulic brake system and will contaminate the system. Disassembled parts, however, can and should be cleaned with denatured alcohol or spray brake cleaner where the parts can be visually inspected to be free of cleaning solutions.

BRAKE FLUID HANDLING AND DISPOSAL

Polyglycol brake fluid presents little toxicity hazard, but for some individuals, brake fluid may produce moderate eye and skin irritation. For good safety practice, protective clothing and safety glasses or goggles should be worn.

Brake fluid becomes a hazardous waste if spilled onto open ground, where it can seep into groundwater. The disposal requirements for brake fluid spilled onto open ground vary with the exact amount spilled and other factors. Refer to local EPA guidelines and requirements for the exact rules and regulations in your area.

RUBBER TYPES

Vehicles use a wide variety of rubber in the braking system, suspension system, steering system, and engine. Rubber products are called **elastomers.** Some are oil- and grease-resistant elastomers and can be harmed by brake fluid, while others are brake-fluid resistant and can swell or expand if they come in contact with oil or grease. ● **SEE CHART 96–1** for types and compatible fluids.

● **SEE FIGURES 96–8 THROUGH 96–10** for examples of where rubber is used in the braking system.

Brake fluid (DOT 3 or DOT 4 glycol brake fluid) affects all elastomers and causes a slight swelling effect (about 5%). This swelling action is necessary for the seals to withstand high hydraulic pressures. Silicone (DOT 5) brake fluid does not cause rubber to swell; therefore, a rubber swell additive is used in silicone brake fluid. While these additives work well for EPDM rubber, it can cause SBR rubber to swell too much. Although most seals today use EPDM, many drum brakes still use SBR seals. This is a major reason that DOT 5 brake fluid is not recommended by many vehicle manufacturers.

BRAKE LINES

TERMINOLOGY

High-pressure double-walled steel brake lines or high-strength flexible lines are used to connect the master cylinder to each wheel. The steel **brake lines** are also called **brake pipes** or **brake tubing.** Brake lines carry brake fluid from the master cylinder to the ABS hydraulic control unit, wheel cylinders, and brake calipers. The brake lines contain and direct the pressure of the brake hydraulic system.

Most of the total length of the brake line consists of rigid tubing. For maximum strength and durability, all brake systems use double-walled brake tubing made from plated steel sheet. There are two types of double-walled tubing:

- Seamless
- Multiple ply

● **SEE FIGURE 96–11.**

All double-walled brake tubing is plated with tin, zinc, or other similar substances for protection against rust and corrosion. The Society of Automotive Engineers (SAE) has guidelines for brake tubing. SAE Standard J1047 specifies that a sample section of brake line must be able to withstand 8,000 PSI (55,000 kPa) plus other standards for resistance to fatigue, heat, rust, and corrosion.

CAUTION: Copper tubing should *never* be used for brake lines. Copper tends to burst at a lower pressure than steel.

CHART 96–1

Notice that if a rubber is OK to use for brake fluid it is not OK to use for oil or grease.

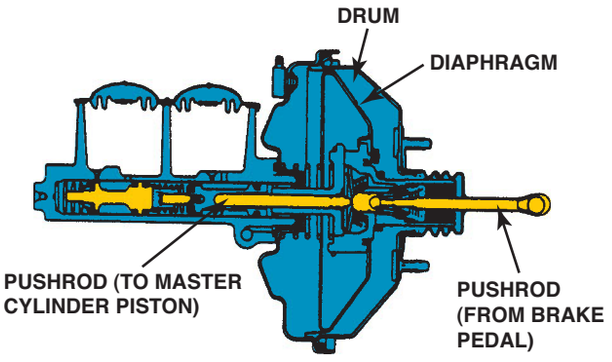

FIGURE 96–8 The master cylinder piston seals are usually constructed from EPDM rubber, and the diaphragm of the vacuum power brake booster is usually made from SBR.

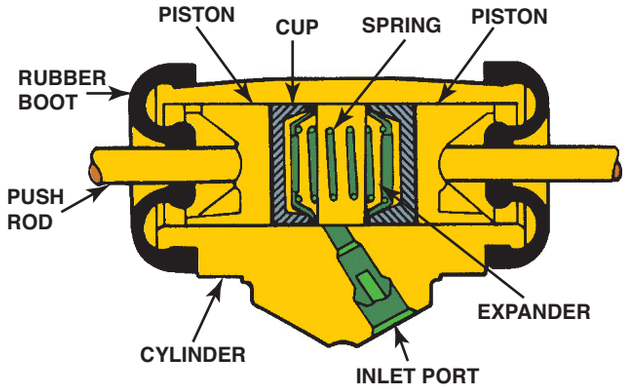

FIGURE 96–9 Cross-sectional view of a typical drum brake wheel cylinder. Most wheel cylinder boots and cups are either SBR or EPDM rubber.

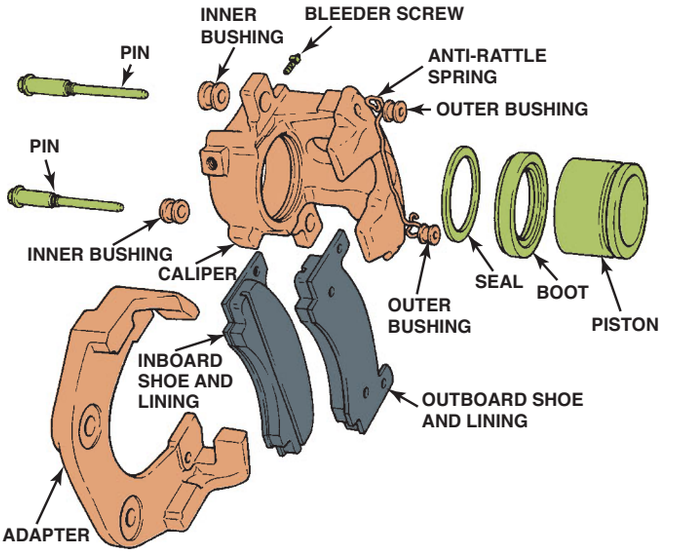

FIGURE 96–10 Exploded view of a typical disc brake caliper. Both the caliper seal and dust boot are constructed of EPDM rubber.

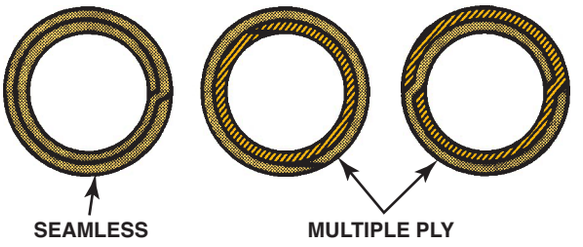

FIGURE 96–11 Steel brake tubing is double-walled for strength and plated for corrosion resistance.

All steel brake lines have one of two basic types of ends:

- **Double Flare.** This type of flare is a 45 degree flare that meets SAE standard J533 and is also called an *SAE flare* for that reason. ● **SEE FIGURE 96–12.**
- **ISO,** which means **International Standards Organization** (also called a *ball flare* or *bubble flare*). ● **SEE FIGURE 96–13.**

BRAKE LINE REPLACEMENT Always use a tubing cutter instead of a hacksaw when cutting brake line. A hacksaw will leave a rough and uneven end that will not flare properly. Always check the instructions that came with the flaring tool for the exact procedure to follow. ● **SEE FIGURE 96-14.**

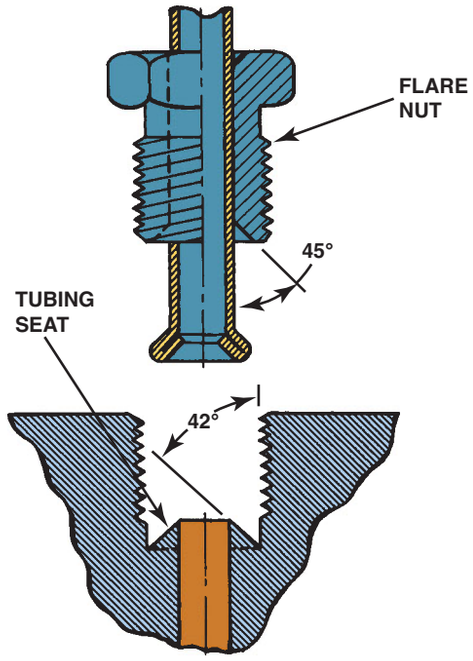

FIGURE 96–12 An SAE flare brake line fitting. Because of the slight difference in flare angle, double-flare fitting seals cause a wedging action.

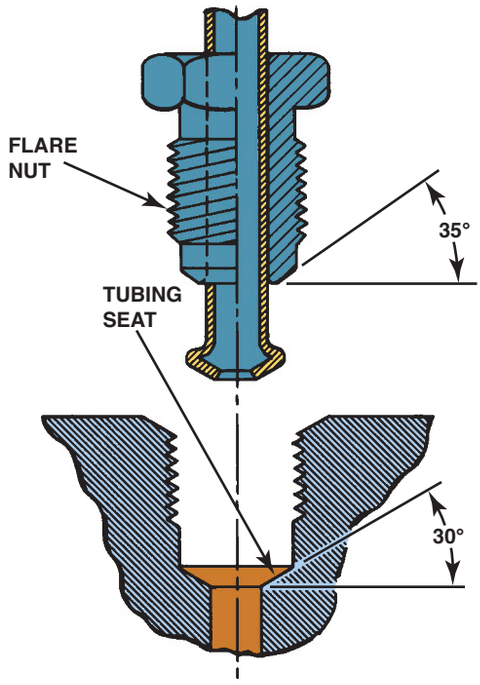

FIGURE 96–13 An ISO fitting, also called a bubble or ball-type flare.

FLARING BRAKE LINE When replacing steel brake line, new steel tubing should be used and a double flare or an ISO flare completed at each end using a special flaring tool. ● **SEE FIGURES 96–15 AND 96–16.**

Brake line can also be purchased in selected lengths already correctly flared. They are available in different diameters, the most commonly used being 3/16 in. (4.8 mm), 1/4 in. (6.4 mm), and 5/16 in. (7.9 mm) outside diameter (O.D.).

CAUTION: According to vehicle manufacturers' recommended procedures, compression fittings should never be used to join two pieces of steel brake line. Only use double-flare ends and connections, if necessary, when replacing damaged steel brake lines.

Always use two line wrenches when disconnecting or reattaching brake lines. ● **SEE FIGURE 96–17** on page 1058.

COILED BRAKE LINE Steel brake line is often coiled, ● **SEE FIGURE 96–18** on page 1058. The purpose of the coils is to allow movement between the brake components without stress that could lead to metal fatigue and brake line breakage. The typical master cylinder attaches to the bulkhead of the vehicle and the combination valve is often attached to the frame. Because the body and frame are usually insulated from each other using rubber isolators, some movement occurs while driving.

ARMORED BRAKE LINE In many areas of the brake system, the steel brake line is covered with a wire coil wrap, as shown in ● **FIGURE 96–19** on page 1058. This type of brake line is called **armored brake line.** This armor is designed to prevent damage from stones and other debris that could dent or damage the brake line. If a section of armored brake line is to be replaced, armored replacement line should be installed.

TECH TIP

Bend It Right the First Time

Replacing rusted or damaged brake line can be a difficult job. It is important that the replacement brake line be located in the same location as the original to prevent possible damage from road debris or heat from the exhaust. Often this means bending the brake line with many angles and turns. To make the job a lot easier, use a stiff length of wire and bend the wire into the exact shape necessary. Then use the wire as a pattern to bend the brake line. Always use a tubing bender to avoid kinking the brake line. A kink not only restricts the flow of brake fluid, but also weakens the line. To bend brake line without a tubing bender tool, use an old V-belt pulley. Clamp the pulley in a vise, lay the tubing in the groove, and smoothly bend the tubing. Different diameter pulleys will create various radius bends. ● **SEE FIGURE 96–20** on page 1059.

NOTE: Always use a tubing cutter instead of a hacksaw when cutting brake line. A hacksaw will leave a rough and uneven end that will not flare properly except when forming an ISO flare. A hacksaw is used to provide a rough surface to allow the flaring tool to grip the line during the procedure. Always check the instructions that came with the flaring tool for the exact procedure to follow.

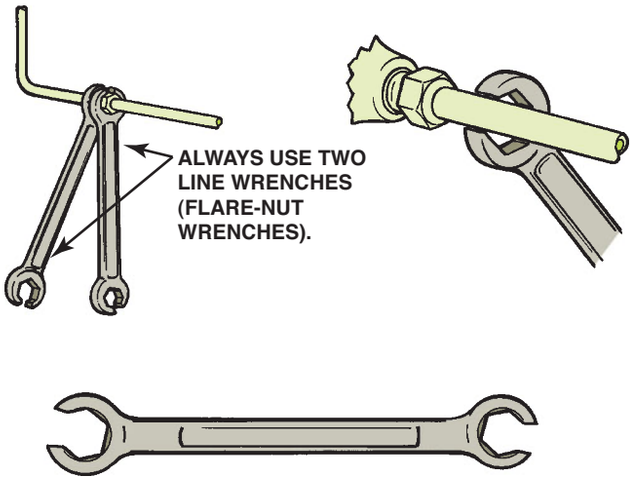

FIGURE 96–17 Whenever disconnecting or tightening a brake line, always use the correct size flare-nut wrench. A flare-nut wrench is also called a tube-nut wrench or a line wrench.

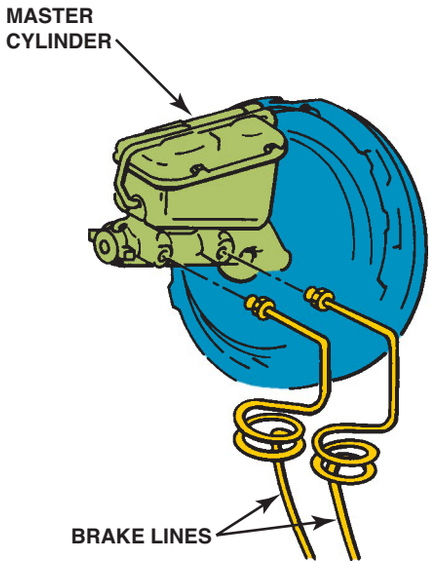

FIGURE 96–18 The coils in the brake line help prevent cracks caused by vibration.

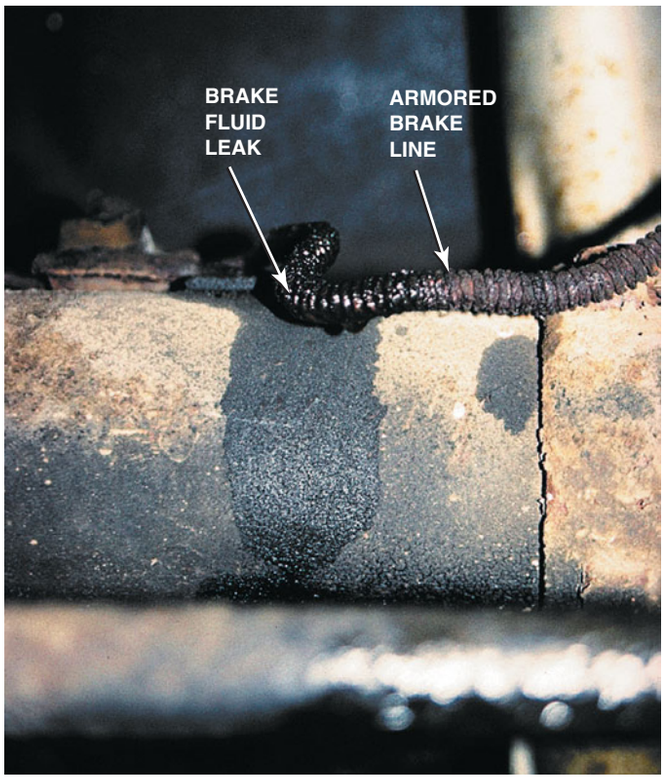

FIGURE 96–19 Armored brake line is usually used in the location where the line may be exposed to rock or road debris damage. Even armored brake line can leak and a visual inspection is an important part of any brake service.

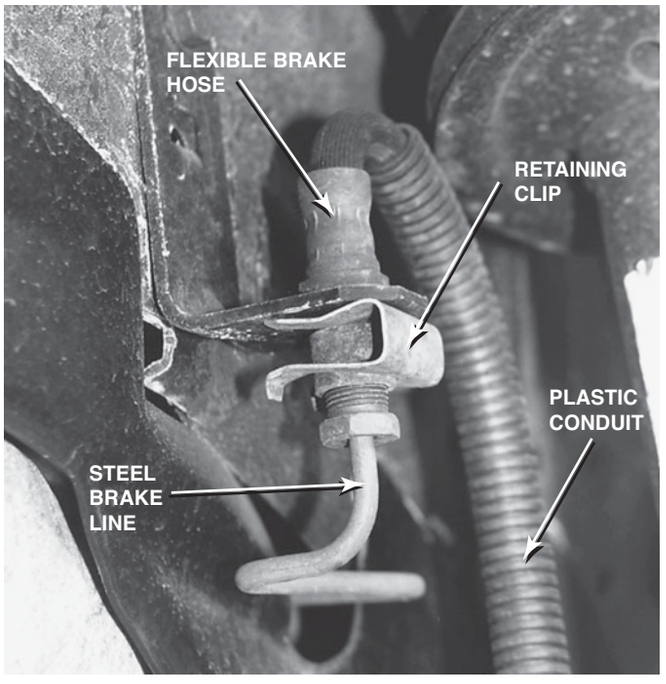
FLEXIBLE BRAKE HOSE

Flexible brake hoses are used on each front wheel to allow for steering and suspension movement and at the rear to allow for rear suspension travel. ● **SEE FIGURE 96–21.** These rubber high-strength hoses can crack, blister, or leak, and should be inspected at least every six months. ● **SEE FIGURE 96–22.**

Flexible brake hose is made from synthetic yarn (poly vinyl alcohol, abbreviated PVA) that is braided into position from multi-end yarn spindles. By braiding the yarn, all of the strands operate

FIGURE 96–20 A tube bender being used to bend a brake line.



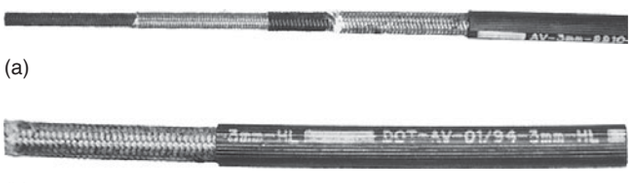


FIGURE 96–21 Flexible brake hoses are used between the frame or body of the vehicle and the wheel brakes. Because of suspension and/or steering movement, these flexible brake lines must be strong enough to handle high brake fluid pressures, yet remain flexible. Note that this flexible brake hose is further protected against road debris with a plastic conduit covering.

(b)

in tension and, therefore, have great strength to withstand braking system pressure over 1,000 PSI (6,900 kPa). ● **SEE FIGURE 96–23.**

A typical brake hose has an inner tube for conveying the brake fluid and a cushion liner that is between the braided layers to prevent the braids from chafing. All three layers use ethylene-propylene-diene-monomer (EPDM)-type thermosetting polymers, which help prevent the hose from absorbing moisture from the outside air. An outside jacket is made from rubber and protects the reinforcement fabric from moisture and abrasion. The outside covering is also ribbed as part of the manufacturing process to hide surface blemishes. These ribs also make it easy for the technician to see if the hose is twisted. It is not unusual for flexible brake lines to become turned around and twisted when the disc brake caliper is removed and then replaced during a brake pad change. ● **SEE FIGURE 96–24.**

A constricted brake hose can cause the brakes to remain applied, thereby causing excessive brake pad wear and unequal braking. A constricted flexible brake line can also cause the vehicle to pull to one side. ● **SEE FIGURE 96–25.**

FIGURE 96–25 Flexible brake hose should be carefully inspected for cuts or other damage, especially near sections where the brake hose is attached to the vehicle. Notice the crack and cut hose next to the mounting bracket.

CAUTION: Never allow a disc brake caliper to hang by the flexible brake hose. Damage to the line can result. Always use a wire to support the weight of the caliper.

Always replace flexible brake hoses in pairs. If one side is found to be defective the other side may be close to failing too. Both brake hoses have been subjected to the same weather and operating conditions so it is always wise to replace all of the flexible brake lines including the rear hose or hoses depending on vehicle design.

BRAKE BLEEDING

THE NEED FOR BRAKE BLEEDING

Brake bleeding is removing any trapped air from the hydraulic system. If air is the brake hydraulic system, the brake pedal will often feel "spongy". The brake pedal will also travel farther (lower than normal brake pedal) before the brakes start to apply. Air can get into the hydraulic system whenever any hydraulic brake line or unit is opened. Air can also be drawn into the hydraulic system through small holes or loose brake line connections during the release of the brake pedal. A common source of air in the brake system of this type can occur through very small holes in rubber flexible brake lines. Another source of air in the braking system is through the absorption of moisture by the brake fluid. When moisture is absorbed, the boiling point of the brake fluid is reduced. During severe braking, the heat generated can cause the brake fluid to boil and create air bubbles in the hydraulic brake system. Air eventually travels to the highest part of the brake system, if not restricted by pressure control valves.

If air is in the brake hydraulic system, the following conditions will likely occur:

1. A lower than normal brake pedal
2. A "spongy" or soft feeling brake pedal
3. A need to "pump up" the brake pedal before they stop the vehicle

BENCH BLEEDING THE MASTER CYLINDER

Whenever the master cylinder is replaced or the hydraulic system has been left opened for several hours, the air may have to be bled from the master cylinder. The master cylinder is located in the highest section of the hydraulic braking system. Some master cylinders are equipped with bleeder valves. If the master cylinder is not equipped with bleeder valves, it can be bled by loosening the brake line fittings at the master cylinder. Bleed the master cylinder "on the bench" before installing it on the vehicle. ● **SEE FIGURE 97–1.**

FIGURE 97–1 Bench bleeding a master cylinder. Always clamp a master cylinder in a vise by the mounting flange to prevent distortion of the cylinder bore. Bench bleeding tubes can also be used that route the fluid back into the reservoir.

ON-VEHICLE MASTER CYLINDER BLEEDING

If bleeding the master cylinder after working on the hydraulic system, follow these steps:

STEP 1 Fill the master cylinder with clean brake fluid from a sealed container up to the recommended "full" level.

STEP 2 Have an assistant slowly depress the brake pedal as you "crack open" the master cylinder bleed screw starting with the section closest to the brake pedal. It is very important that the primary section of the master cylinder be bled before attempting to bleed the air out of the secondary section of the master cylinder. Before the brake pedal reaches the floor, close the bleeder valve.

NOTE: A proper manual bleeding of the hydraulic system requires that accurate communications occur between the person depressing the brake pedal and the person opening and closing the bleeder valve(s). The bleeder valve (also called a *bleed valve*) should be open only when the brake pedal is being depressed. The valve *must* be closed when the brake pedal is released to prevent air from being drawn into the system.

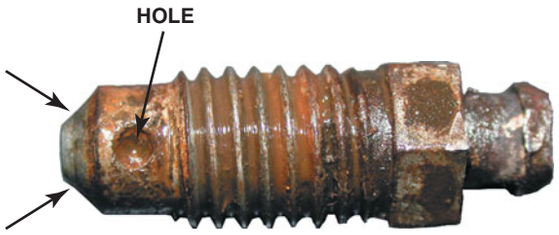

FIGURE 97–2 Typical bleeder valve from a disc brake caliper. The arrows point to the taper section that does the actual sealing. It is this taper that requires a shock to loosen. If the bleeder is simply turned with a wrench, the bleeder usually breaks off because the tapered part at the bottom remains adhered to the caliper or wheel cylinder. Once loosened, brake fluid flows around the taper and out through the hole in the side of the bleeder valve. The hole is clogged in this example and needs to be cleaned out.

TECH TIP

Check That All Bleeder Valves Are Pointing Up

Make certain all the brake components such as calipers and wheel cylinders are correctly installed with the bleeder valve located on the highest section of the part. Some wheel cylinders and calipers (such as many Ford calipers) can be installed upside down!

This usually occurs whenever both front calipers are off the vehicle and they accidentally get reversed left to right. If this occurs, the air will never be completely bled from the caliper.

STEP 3 Repeat the procedure several times until a solid flow of brake fluid is observed leaving the bleeder valve. If the master cylinder is not equipped with bleeder valves, the outlet tube nuts can be loosened instead.

BRAKE BLEEDER VALVE LOOSENING METHODS

Attempting to loosen a bleeder valve often results in breaking (shearing off) the bleeder valve. Several of these service procedures can be tried that help prevent the *possibility* of breaking a bleeder valve. Bleeder valves are tapered and become wedged in the caliper on the wheel cylinder housing. ● **SEE FIGURES 97–2 AND 97–3.** All of these methods use shock to "break the taper" and to loosen the stuck valve.

HIT AND TAP METHOD

STEP 1 Tap on the end of the bleeder valve with a steel hammer after applying a penetrating oil to help lubricate the threads of the bleeder valve. This shock often "breaks the taper" at the base of the bleeder valve. The shock also breaks loose any rust or corrosion on the threads.

STEP 2 Using a 6-point wrench or socket, *tap* the bleeder valve in the clockwise direction (tighten).

STEP 3 Using the same 6-point socket or wrench, *tap* the bleeder valve counter-clockwise to loosen and remove the bleeder valve.

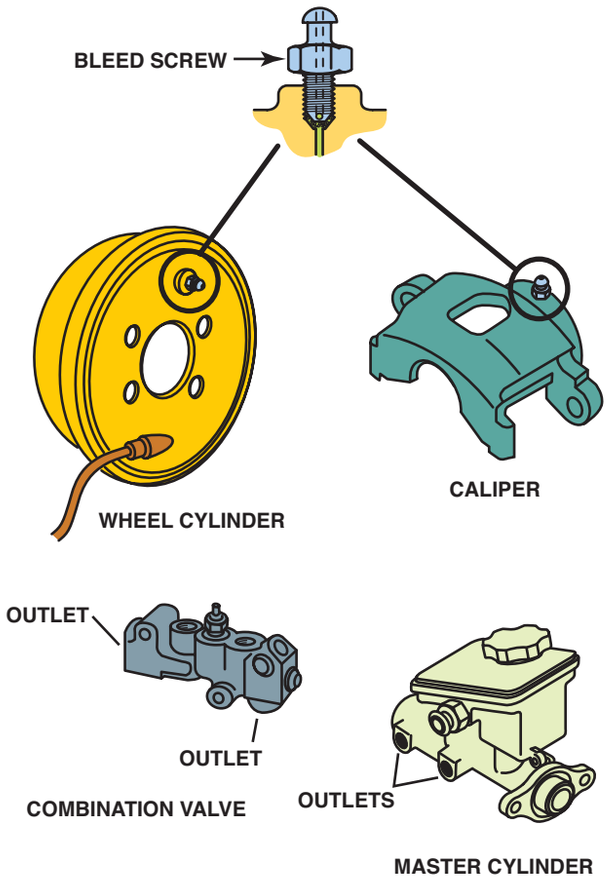

FIGURE 97–3 Typical bleeder locations. Note that the combination valve and master cylinder shown do not have bleeder valves; therefore, bleeding is accomplished by loosening the brake line at the outlet ports.

FIGURE 97–4 Using an air punch next to the bleeder valve to help "break the taper" on the bleeder valve.

NOTE: It is the *shock* of the tap on the wrench that breaks loose the bleeder valve. Simply pulling on the wrench often results in breaking off the bleeder.

STEP 4 If the valve is still stuck (frozen), repeat Step 1 through Step 3.

AIR PUNCH METHOD After using a penetrating oil, use an air punch near the bleeder valve while attempting to loosen the bleeder valve at the same time. ● **SEE FIGURE 97–4.**

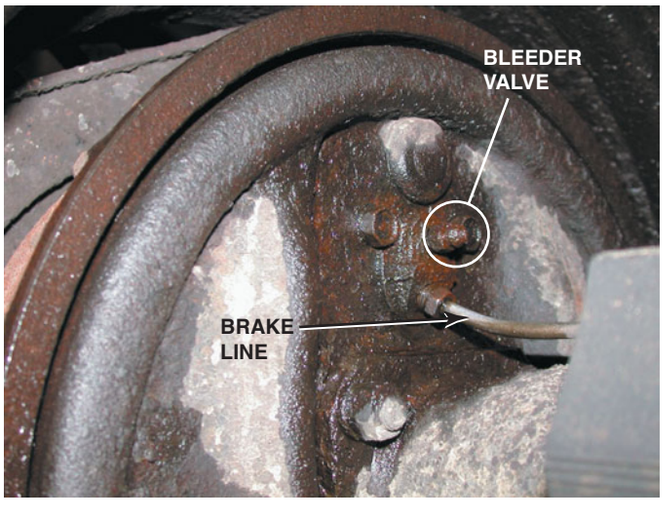

FIGURE 97–5 Most vehicle manufacturers recommend starting the brake bleeding process at the rear wheel farthest from the master cylinder.

The air punch creates a shock motion that often loosens the taper and threads of the bleeder valve from the caliper or wheel cylinder. It is also helpful to first attempt to turn the bleeder valve in the clockwise (tightening) direction, then turn the bleeder in the counter-clockwise direction to loosen and remove the bleeder valve.

HEAT AND TAP METHOD

Heat the area around the bleeder valve with a torch. The heat expands the size of the hole and usually allows the bleeder to be loosened and removed.

CAUTION: The heat from a torch will damage the rubber seals inside the caliper or wheel cylinder. Using heat to free a stuck bleeder valve will *require* that all internal rubber parts be replaced.

WAX METHOD

STEP 1 Heat the bleeder valve itself with a torch. The heat causes the valve itself to expand.

STEP 2 Remove the heat from the bleeder valve. As the valve is cooling, touch paraffin wax or candle wax to the hot valve. The wax will melt and run down around the threads of the bleeder valve.

STEP 3 Allow the bleeder valve to cool until it can be safely touched with your hand. This assures that the temperature is low enough for the wax to return to a solid and provide the lubricating properties necessary for the easy removal of the bleeder valve. Again, turn the bleeder valve clockwise before turning the valve counterclockwise to remove.

BLEEDING SEQUENCE

After bleeding the master cylinder, the combination valve should be bled if equipped. Check the level in the master cylinder frequently being careful not to allow the master cylinder to run dry and keep it filled with clean brake fluid throughout the brake bleeding procedure.

For most rear-wheel-drive vehicles equipped with a front/rear split system, start the bleeding with the wheel farthest from the master cylinder and work toward the closest. ● **SEE FIGURE 97–5.**

For most vehicles, this sequence is as follows:

1. Right rear
2. Left rear
3. Right front
4. Left front

NOTE: If the vehicle has two wheel cylinders on one brake, bleed the upper wheel cylinder first.

For vehicles equipped with a diagonal split section or equipped with ABS, follow the brake bleeding procedure recommended in the service information for the vehicle.

The two most commonly specified brake bleeding order for diagonal-split brake system vehicles include:

RR, LR, RF and then LF

RF, LF, RR and then LR

MANUAL BLEEDING

Manual bleeding is the most commonly used method and uses hydraulic pressure created by the master cylinder to pump fresh fluid through the brake system. This method is also called the **single stroke bleeding method.**

ITEMS NEEDED FOR MANUAL BLEEDING

The manual method of brake bleeding is the most common. Manual bleeding requires the following:

- An assistant to apply and release the brake pedal
- A bleeder screw wrench
- Approximately 2 feet of clear, plastic hose with an inside diameter small enough to fit snugly over the bleeder screws
- A clear jar partially filled with clean brake fluid

MANUAL BLEEDING PROCEDURE

To manually bleed the brake system, follow these steps:

STEP 1 Discharge the vacuum or hydraulic power booster (if equipped) by pumping the brake pedal with the ignition OFF until the pedal feels hard.

STEP 2 Fill the master cylinder reservoir with new brake fluid and make sure it remains at least half full throughout the bleeding procedure.

STEP 3 Attach the plastic hose over the bleeder screw of the first wheel cylinder or caliper in the bleeding sequence, and submerge the end of the tube in the jar of brake fluid. ● **SEE FIGURE 97–6.**

STEP 4 Have the assistant lightly depress the brake pedal, then open the bleeder valve about one half turn. It is extremely important when manually bleeding a brake system that the pedal be applied and released slowly and gently. Rapid pedal pumping can churn up the fluid and reduce the size of trapped air bubbles, making them more difficult to bleed from the system. Air bubbles leaving the bleeder screw will be visible in the hose to the jar.

STEP 5 Tighten the bleeder screw, then have your assistant slowly release the brake pedal.

FIGURE 97–6 Bleeding brakes using clear plastic tubing makes it easy to see air bubbles. Submerging the hose in a container of clean brake fluid helps ensure that all of the air will be purged by the system.

TECH TIP

Tiny Bubbles

Do not use excessive brake pedal force while bleeding and never bleed the brake with the engine running! The extra assist from the power brake unit greatly increases the force exerted on the brake fluid in the master cylinder. The trapped air bubbles may be dispersed into tiny bubbles that often cling to the inside surface of the brake lines. These tiny air bubbles may not be able to be bled from the hydraulic system until enough time has allowed the bubbles to re-form. If the dispersal of the air into tiny bubbles is suspected, try tapping the calipers or wheel cylinders with a plastic hammer. After this tapping, simply waiting for a period of time will cause the bubbles to re-form into larger and easier-to-bleed air pockets. Most brake experts recommend waiting *15 seconds or longer* between attempts to bleed each wheel. This waiting period is critical and allows time for the air bubbles to form.

NOTE: To help prevent depressing the brake pedal down too far, some experts recommend placing a 2 × 4 in. board under the brake pedal. This helps prevent the seals inside the master cylinder from traveling over unused sections inside the bore that may be corroded or rusty.

STEP 6 Wait at least 15 seconds to allow time for any small bubbles to form into larger bubbles. See the Tech Tip called, "Tiny Bubbles."

STEP 7 Repeat steps 4 and 5 until no more air bubbles emerge from the bleeder.

FIGURE 97–7 Using a compressed air-powered vacuum bleeder.

STEP 8 Transfer the plastic hose to the bleeder screw of the next wheel cylinder or caliper in the bleeding sequence, and repeat steps 4 through 7. Continue around the vehicle in the specified order until the brakes at all four wheels have been bled.

VACUUM BLEEDING

Vacuum bleeding uses a special suction pump that attaches to the bleeder screw. The pump creates a low-pressure area at the bleeder screw, which allows atmospheric pressure to force brake fluid through the system when the bleeder screw is opened.

ADVANTAGES OF VACUUM BLEEDING

Vacuum bleeding requires only one technician. It is easy and the required equipment can be purchased at low cost.

DISADVANTAGES OF VACUUM BLEEDING

The disadvantage of using a vacuum bleeding method is that a vacuum tool must be used and often air can be drawn into the line between the bleeder valve and the hose creating some bubbles that can be interpreted by the technician as air in the system.

VACUUM BLEEDING PROCEDURE

To vacuum bleed a brake system, use the following steps:

STEP 1 Fill the master cylinder reservoir with new brake fluid and make sure it remains at least half full throughout the bleeding procedure.

STEP 2 Attach the plastic tube from the vacuum bleeder to the bleeder screw of the first wheel cylinder or caliper in the bleeding sequence. ● **SEE FIGURES 97–7 AND 97–8.** If necessary, use one of the adapters provided with the vacuum in the catch bottle.

STEP 3 Operate the bleeder to create a partial vacuum in the catch bottle.

STEP 4 Loosen the bleeder screw approximately one-half turn. Brake fluid and air bubbles will flow into the bottle. When the fluid is free of bubbles, tighten the bleeder screw.

STEP 5 Repeat steps 3 and 4 until no more air bubbles emerge from the bleeder.

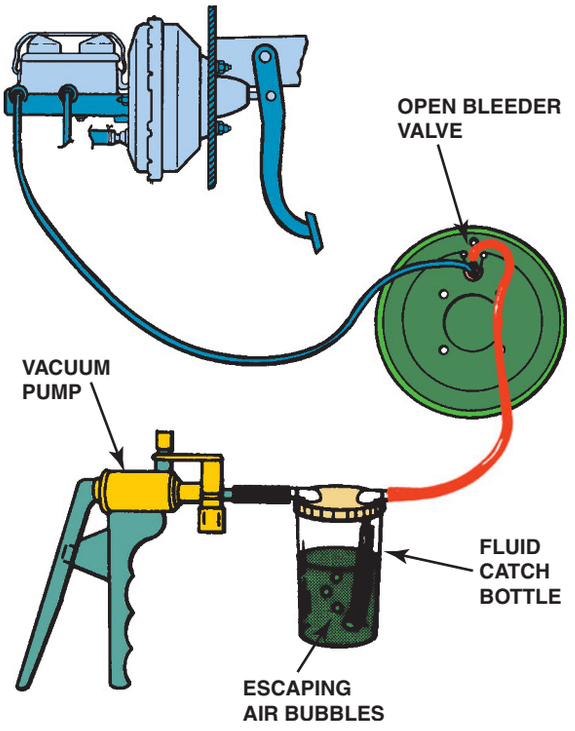

FIGURE 97–8 Vacuum bleeding uses atmospheric pressure to force brake fluid through the hydraulic system.

STEP 6 Transfer the vacuum bleeder to the bleeder screw of the next wheel cylinder or caliper in the bleeding sequence, and repeat steps 3 and 4. Continue around the vehicle in the specified order until the brakes at all four wheels have been bled.

GRAVITY BLEEDING

Gravity bleeding is a slow, but effective, method that will work on many vehicles to rid the hydraulic system of air. The procedure involves simply opening the bleeder valve and waiting until brake fluid flows from the open valve. Any air trapped in the part being bled will rise and escape from the port when the valve is opened. It may take several minutes before brake fluid escapes. Gravity bleeding works because any liquid tends to seek its own level. This means that the brake fluid in the master cylinder tends to flow downward toward the wheel cylinders or calipers. As long as the brake fluid level in the master cylinder is higher than the bleeder valve, the brake fluid will flow downward and out the open bleeder valve, as shown in ● **FIGURE 97–9.**

This flow of brake fluid can even get past the metering valve and proportioning valve. The proportioning valve is normally open to the rear brakes until the pressure reaches a predetermined level when it starts to limit increasing pressure to the rear brakes. The metering valve used to control or delay the operation of the front brakes is open to the front wheels until the pressure exceeds 10 to 15 PSI (70 to 100 kPa). Therefore, as long as no one is pushing on the brake pedal, the metering valve remains open to the front wheels and the brake fluid from the master cylinder can easily flow downward through the valve and out the open bleeder valve.

Since no pressure is exerted on the brake fluid, the large air bubbles remain large air bubbles and are not separated into smaller, harder-to-bleed air bubbles that can occur with manual bleeding.

FIGURE 97–9 Gravity bleeding is simply opening the bleeder valve and allowing gravity to force the brake fluid out of the bleeder valve. Because air is lighter than brake fluid all of the air escapes before the brake fluid runs out.

ADVANTAGES OF GRAVITY BLEEDING

All four wheel brakes can be bled at one time using the gravity method. In this process, the bleeder screws at all four wheels are opened at the same time, and the system is allowed to drain naturally until the fluid coming out of the bleeders is free of air. Gravity bleeding can be done by a single technician, who is freed to attend to other jobs while the brakes bleed.

DISADVANTAGES OF GRAVITY BLEEDING

Gravity bleeding is a slow process that can take an hour or more. In addition, this procedure cannot be used on brake systems with residual pressure check valves because the valves restrict the fluid flow. When other bleeding procedures fail, gravity bleeding can sometimes be effective on brake systems that trap small pockets of air.

GRAVITY BLEEDING PROCEDURE

Gravity bleeding requires:

- A bleeder wrench
- Four lengths of plastic hose that fit snugly over the bleeder screws
- Four jars to catch the dripping fluid—one for each wheel brake

Unless a plastic hose is used to "start a siphon" at each bleeder screw, it is possible that air may enter the system rather than be bled from it. This can occur because the total open area of the four bleeder screws is somewhat larger than that of the two compensating ports through which the fluid must enter the system. To gravity bleed the brake system, follow these steps:

STEP 1 Fill the master cylinder reservoir with new brake fluid. During the bleeding process, check the fluid level periodically to ensure that the reservoir remains at least half full.

STEP 2 Attach a length of plastic tubing to each bleeder screw, and place the ends of the tubes in jars to catch the drainage. Open each bleeder screw approximately one full turn and make sure that fluid begins to drain. Allow the system to drain until the fluid flowing from the bleeder screws is free of air bubbles. If no brake fluid comes out, remove the bleeder valve entirely—it may be clogged. Nothing but air and brake fluid will be *slowly* coming out of the wheel cylinder or caliper when the bleeder valve is removed. *Do not press on the brake pedal with the bleeder valve out while gravity bleeding.*

STEP 3 Close the bleeder screws and fill the brake fluid in the master cylinder reservoir to the maximum level mark.

TECH TIP

The Master Cylinder One-Drip-Per-Second Test

Excessive brake wear is often caused by misadjusted brake linkage or brake light switches keeping the brake pedal from fully releasing. If the brake pedal is not fully released, the primary piston sealing cup blocks the compensating port from the brake fluid reservoir. To test if this is the problem, loosen both lines from the master cylinder. Brake fluid should drip out of both lines about one drip per second. This is why this test is also called the "Master Cylinder Drip Test." If the master cylinder does not drip, the brake pedal may not be allowing the master cylinder to fully release. Have an assistant pull up on the brake pedal. If the dripping starts, the problem is due to a misadjusted brake light or speed (cruise) control switch or pedal stop. If the master cylinder still does not drip, loosen the master cylinder from the power booster. If the master cylinder now starts to drip, the pushrod adjustment is too long.

If the master cylinder still does not drip, the problem is in the master cylinder itself. Check for brake fluid contamination. If mineral oil, such as engine oil, power steering fluid, or automatic transmission fluid (ATF), has been used in the system, the rubber sealing cups swell and can block off the compensating port. If contamination is discovered, *every* brake component that contains rubber *must* be replaced.

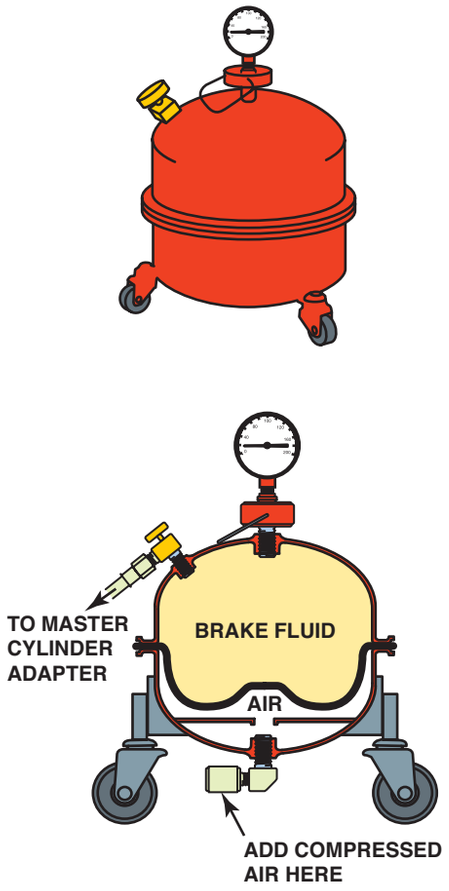

FIGURE 97–10 A typical pressure bleeder. The brake fluid inside is pressurized with air pressure in the air chamber. This air pressure is applied to the brake fluid in the upper section. A rubber diaphragm separates the air from the brake fluid.

PRESSURE BLEEDING

Pressure bleeding, sometimes called **power bleeding,** is a common method used to bleed the brake hydraulic system. In this process, a pressure bleeder attached to the master cylinder forces brake fluid through the system under pressure to purge any trapped air. Once the hydraulic system is pressurized, the technician simply opens the bleeder screws in the prescribed order and allows fluid to flow until it is free of air bubbles.

The tools required for pressure bleeding include a plastic hose and fluid catch jar as used in manual bleeding, as well as a pressure bleeder, a source of air pressure to charge the bleeder, and an adapter to attach the pressure bleeder to the master cylinder fluid reservoir. Cast-metal cylinders with integral reservoirs commonly use a flat, plate-type adapter that seals against the same surface as the reservoir cover. ● **SEE FIGURE 97–10.**

Some plastic master cylinder reservoirs also use plate-type adapters, but others require adapters that seal against the bottom of the reservoir. ● **SEE FIGURE 97–11.** Pressure bleeder manufacturers offer many adapters to fit specific applications.

METERING VALVE OVERRIDE TOOLS In addition to the tools previously described, a metering valve override tool is required when pressure bleeding the front brakes of certain vehicles. The override tool is used to deactivate the metering valve because the operating pressure of power bleeders is within the range where the metering valve blocks fluid flow to the front brakes. Metering valves that require an override tool have a stem or button on one

FIGURE 97–11 Brake fluid under pressure from the power bleeder is applied to the top of the master cylinder. It is very important that the proper adapter be used for the master cylinder. Failure to use the correct adapter or failure to release the pressure on the brake fluid before removing the adapter can cause fluid to escape under pressure.

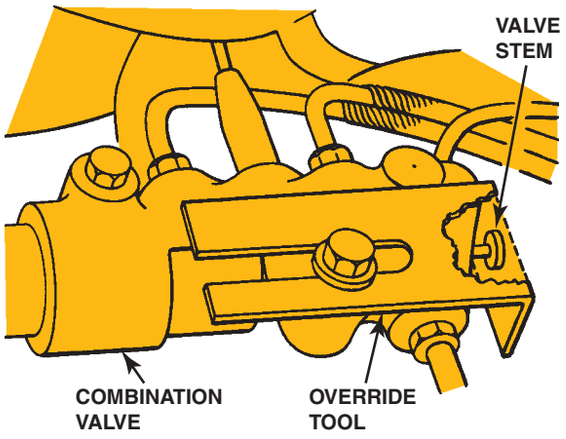

FIGURE 97–12 Metering valve override tool on a General Motors vehicle.

end that is either pushed in or pulled out to hold the valve open. The override tool performs this service.

To install the override tool used on General Motors vehicles, loosen the combination valve mounting bolt and slip the slot in the tool under the bolt head.

Push the end of the tool toward the valve body until it depresses the valve plunger, then tighten the mounting bolt to hold the tool in place.

Some full-size Ford vehicles have a metering valve with a stem that must be pushed in to bleed the front brakes, but Ford does not offer a special tool for this purpose. An assistant is needed to override the valve when the front brakes are being bled.

To install the override tool used on older Chrysler and Ford vehicles, slip one fork of the tool under the rubber boot, and the other fork under the valve stem head. ● **SEE FIGURE 97–12.**

The spring tension of the tool holds the valve open, but allows the valve stem to move slightly when the system is pressurized. If the valve is held rigidly open, internal damage will result.

PRESSURE BLEEDING PROCEDURE Just as in manual bleeding, it is important to follow the proper sequence when pressure bleeding a brake system. Some manufacturers recommend one sequence for manual bleeding and another for pressure bleeding. To pressure bleed a brake system, follow these steps:

STEP 1 If it has not already been done, consult the equipment manufacturer's instructions and fill the pressure bleeder with the proper type of brake fluid.

STEP 2 Make sure the bleeder is properly sealed and the fluid supply valve is closed, then use compressed air to pressurize the bleeder until approximately 30 PSI (207 kPa) is indicated on the bleeder gauge.

STEP 3 If the vehicle is equipped with a metering valve, override it with the appropriate tool. ● **SEE FIGURE 97–13.**

STEP 4 Clean the top of the master cylinder, then remove the master cylinder cover and clean around the gasket surface. Be careful not to allow any dirt to fall into the reservoir.

STEP 5 Fill the reservoir about half full with new brake fluid, then install the proper pressure bleeder adapter on the master cylinder.

STEP 6 Connect the pressure bleeder fluid supply hose to the adapter, making sure the hose fitting is securely engaged.

STEP 7 Open the fluid supply valve on the pressure bleeder to allow pressurized brake fluid to enter the system. Check carefully for fluid leaks that can damage the vehicle finish.

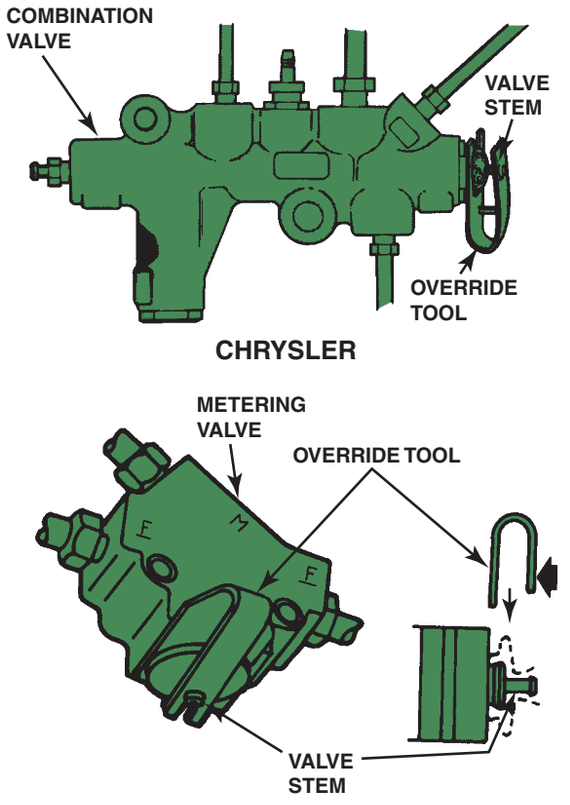

FIGURE 97–13 Pull-out-type metering valves being held out using a special override tool.

STEP 8 Slip the plastic hose over the bleeder screw of the first wheel cylinder or caliper to be bled, and submerge the end of the tube in the jar of brake fluid.

STEP 9 Open the bleeder screw approximately one-half turn, and let the fluid run until air bubbles no longer emerge from the tube. Close the bleeder screw.

STEP 10 Transfer the plastic hose to the bleeder screw of the next wheel cylinder or caliper in the bleeding sequence, and repeat steps 8 and 9. Continue around the vehicle in the specified order until the brakes at all four wheels have been bled.

STEP 11 Remove the metering valve override tool.

STEP 12 Close the fluid supply valve on the pressure bleeder.

STEP 13 Shut off or disconnect shop air supply before removing master cylinder adapter.

STEP 14 Wrap the end of the fluid supply hose in a shop towel, and disconnect it from the master cylinder adapter. Be careful to avoid spilling brake fluid.

STEP 15 Remove the master cylinder adapter, adjust the fluid level to the full point, and install the fluid reservoir cover.

HYDRAULIC ABS SERVICE

CHECK SERVICE INFORMATION Before doing any brake work on a vehicle equipped with antilock brakes, always consult the appropriate service information for the exact vehicle being serviced. For example, some manufacturers recommend discharging the hydraulic accumulator by depressing the brake pedal many times

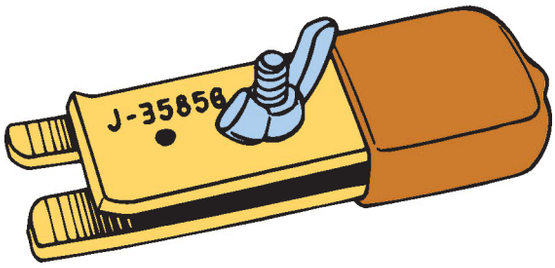

FIGURE 97–14 Special bleed valve tools are often required when bleeding some ABS units such as the Kelsey-Hayes 4WAL system.

before opening bleeder valves. Many service checks require that a pressure gauge be installed in the system.

BLEEDING THE ELECTRONIC-HYDRAULIC ASSEMBLY

Air can easily get trapped in the ABS electronic-hydraulic (E-H) assembly whenever the hydraulic system is opened. Even though the master cylinder and all four wheel cylinders/calipers have been bled, sometimes the brake pedal will still feel spongy. Some E-H units can be bled through the use of a scan tool where the valves are pulsed in sequence by the electronic brake controller (computer). Some units are equipped with bleeder valves while others must be bled by loosening the brake lines. Bleeding the E-H unit also purges out the older brake fluid, which can cause rust and corrosion damage. Only DOT 3 brake fluid is specified for use in an antilock braking system. Always check the label on the brake fluid reservoir and/or service manual or owner's manual.

CAUTION: Some ABS units require that the brake pedal be depressed as many as 40 times to discharge brake fluid fully from the accumulator. Failure to discharge the accumulator fully can show that the brake fluid level is too low. If additional brake fluid is added, the fluid could overflow the reservoir during an ABS stop when the accumulator discharges brake fluid back into the reservoir.

MANUALLY BLEEDING ABS WHEEL BRAKES

During routine brake service, attempt to keep the air from entering the hydraulic system by doing the following:

1. Do not allow the brake system to run dry. Use a brake pedal depressor or plug any open brake line to keep brake fluid from flowing out of the brake master cylinder reservoir.
2. Do not allow the master cylinder to run dry during the bleeding operation. Check the master cylinder reservoir often and keep it filled with fresh brake fluid from a sealed container.
3. Always bench bleed a replacement master cylinder to help prevent against introducing air into the hydraulic system.

After depressing the unit as per manufacturer's recommended procedures, the brakes can be bled using the same procedure as for a vehicle without ABS. Air trapped in the ABS hydraulic unit may require that a scan tool be used to cycle the valves. ● **SEE FIGURES 97–14 AND 97–15.**

The bleeding procedure for vehicles equipped with antilock brakes is often different than vehicles without ABS. Consult the service information for the specified bleeding procedure and sequence.

SCAN TOOL BLEEDING

To bleed the system using a scan tool use the following steps:

STEP 1 Check service information and determine the specified procedure to follow. This usually involves manually bleeding the wheel brakes before using a scan tool.

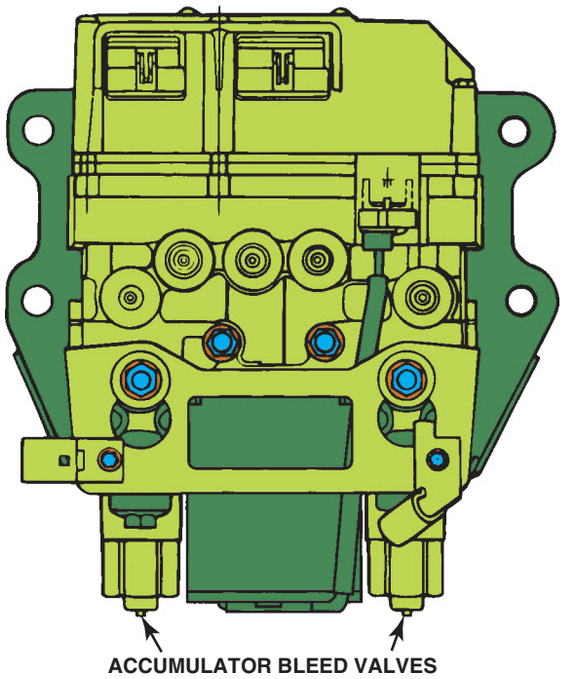

FIGURE 97–15 Two bleed valve tools are needed to bleed the Kelsey-Hayes 4WAL system, which attaches to the bleeder valves on the accumulator.

FIGURE 97–16 To perform an automated brake bleed procedure on an antilock braking system, first connect a factory or enhanced scan tool to the data link connector (DLC) located under the dash on this vehicle.

STEP 2 Use a factory scan tool or one that is capable of performing an automated bleed procedure.

STEP 3 Connect the scan tool to the data link connector (DLC). This connector can be located under the dash or in the center console or even covered by a panel. Check service information for the exact location of the DLC for the vehicle being serviced. ● **SEE FIGURE 97–16.**

STEP 4 Enter vehicle information as shown on the display of the scan tool and locate the antilock brake system (ABS) function area. ● **SEE FIGURE 97–17.**

FIGURE 97–17 Access the menu that includes antilock brake system (ABS) functions.

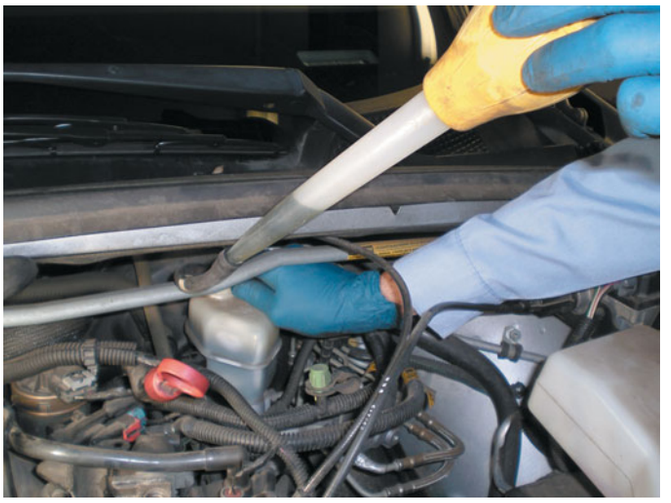

FIGURE 97–19 A turkey baster can be used to remove the old brake fluid from the master cylinder reservoir. A rubber hose was attached to the end of the turkey baster to get access to the brake fluid.

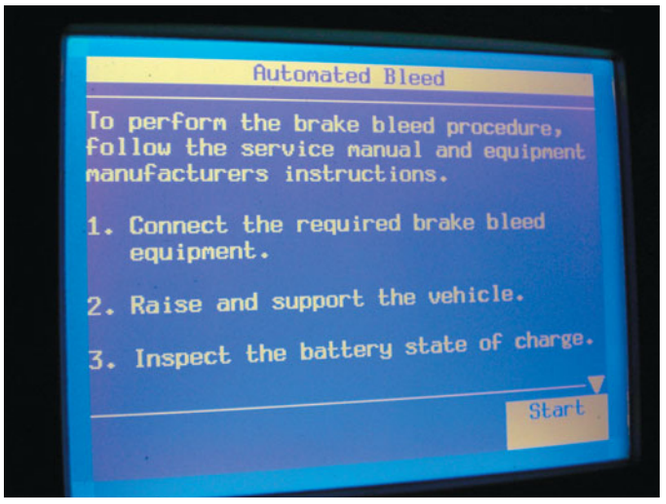

FIGURE 97–18 Scroll through the menus and select automated bleed procedure and follow the on-screen instructions.

STEP 5 Select ABS automated bleed from the ABS menu. The instructions on the scan tool could include several steps including manually bleeding the system, then allowing the scan tool to cycle the hydraulic ABS solenoid valves and then bleeding again. ● **SEE FIGURE 97–18**.

BRAKE FLUID REPLACEMENT/FLUSHING

Brake fluid flushing is a procedure where the old brake fluid is removed and new brake fluid is added to the hydraulic system.

FLUSHING PROCEDURE The brake fluid flushing procedure usually requires the following:

- An assistant to pump the brake pedal
- A bleeder screw wrench
- Approximately 2 feet of clear, plastic hose with an inside diameter small enough to fit snugly over the bleeder screw
- A jar partially filled with clean brake fluid

To flush a brake system, use the following steps:

STEP 1 Using a turkey baster or similar tool, remove the old brake fluid from the master cylinder reservoir. ● **SEE FIGURE 97–19**.

STEP 2 Fill the master cylinder reservoir with new brake fluid from a sealed container.

STEP 3 Slip the plastic hose over the bleeder screw of the wheel cylinder or caliper to be bled and submerge the end of the tube in the jar of brake fluid.

STEP 4 Open the bleeder screw approximately one-half turn.

STEP 5 With the bleeder screw *open,* have your assistant slowly depress the brake pedal.

STEP 6 While your assistant holds the brake pedal down, close the bleeder screw.

STEP 7 Continue to bleed at each wheel until the fluid that emerges from the bleeder screw is free of any discoloration and contamination.

STEP 8 Repeat steps 4 through 7 at each bleeder screw in the recommended order.

STEP 9 Check the brakes for proper operation and re-bleed the system if needed.

TECH TIP

ABS Bleeding Made Easy

To avoid having to bleed the hydraulic unit, use a brake pedal depressor during brake service to avoid losing brake fluid. This simple precaution keeps air from getting into the hard-to-bleed passages of the hydraulic unit.

ANTIFRICTION BEARINGS

PURPOSE AND FUNCTION Bearings allow the wheels of a vehicle to rotate and still support the weight of the entire vehicle. **Antifriction bearings** use rolling parts inside the bearing to reduce friction. Four styles of rolling contact bearings include ball, roller, needle, and tapered roller bearings, as shown in ● **FIGURE 98–1.** All four styles convert sliding friction into rolling motion. All of the weight of a vehicle or load on the bearing is transferred through the rolling part. In a ball bearing, the entire load is concentrated into small spots where the ball contacts the *inner and outer race (rings).* ● **SEE FIGURE 98–2.**

BALL BEARINGS **Ball bearings** use hardened steel balls between the inner and outer race to reduce friction. While ball bearings cannot support the same weight as roller bearings, there is less friction in ball bearings and they generally operate at higher speeds. Ball bearings can control thrust movement of an axle shaft because the balls ride in grooves on the inner and outer races. The groove walls resist lateral movement of the wheel on the spindle. The front hub bearings of front wheel drive (FWD) and four wheel drive (4WD) vehicles with front hub assemblies. Many front-wheel-drive vehicles use sealed double-row ball bearings as a complete sealed unit and are nonserviceable except as an assembly. ● **SEE FIGURE 98–3.**

ROLLER BEARINGS **Roller bearings** use rollers between the inner and outer race to reduce friction. A roller bearing having a greater (longer) contact area can support heavier loads than a ball bearing. ● **SEE FIGURE 98–4.**

FIGURE 98–1 Rolling contact bearings include (left to right) ball, roller, needle, and tapered roller.

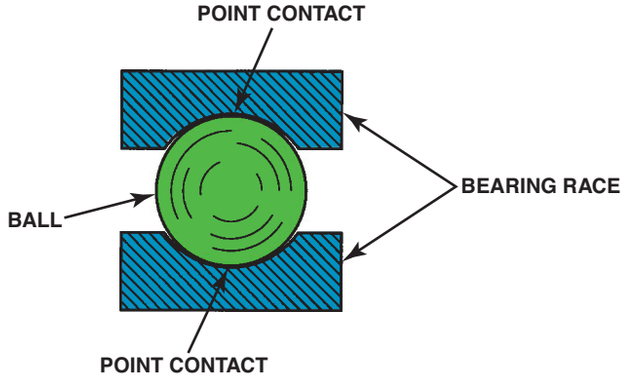

FIGURE 98–2 Ball bearing point contact.

A needle bearing is a type of roller bearing that uses smaller rollers called **needle rollers.** The clearance between the diameter of the straight roller is manufactured into the bearing to provide the proper *radial clearance* and is *not adjustable.*

TAPERED ROLLER BEARINGS The most commonly used automotive wheel bearing is the **tapered roller bearing.** Not only is the bearing itself tapered, but the rollers are also tapered. By design, this type of bearing can withstand **radial loads** (up and down) as well as **axial loads** (thrust) in one direction. ● **SEE FIGURE 98–5.**

Many non-drive-wheel bearings use tapered roller bearings. The taper allows more weight to be handled by the friction-reducing bearings because the weight is directed over the entire length of each roller rather than concentrated on a small spot, as with ball bearings. The rollers are held in place by a **cage** between the inner race (also called the **inner ring** or **cone** assembly) and the outer race (also called the **outer ring** or **cup**). Tapered roller bearings must be loose in the cage to allow for heat expansion. Tapered roller bearings should always be adjusted for a certain amount of free play to allow for heat expansion. On non-drive-axle vehicle wheels, the cup is tightly fitted to the wheel hub and the cone is loosely fitted to the

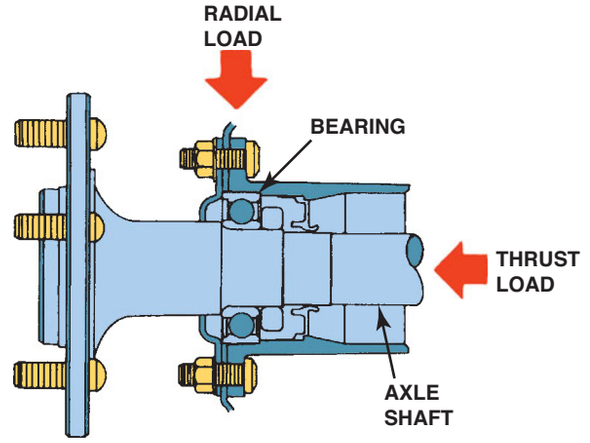

FIGURE 98–3 Radial load is the vehicle weight pressing on the wheels. The thrust load occurs as the chassis components exert a side force during cornering.

wheel spindle. New bearings come packaged with the rollers, cage, and inner race assembled together with the outer race wrapped with moisture-resistant paper. ● **SEE FIGURE 98–6.**

INNER AND OUTER WHEEL BEARINGS

Many rear-wheel-drive vehicles use an inner and an outer wheel bearing on the front wheels. The inner wheel bearing is always the larger bearing because it is designed to carry most of the vehicle weight and transmit the weight to the suspension through to the spindle. Between the inner wheel bearing and the spindle, there is a grease seal, which prevents grease from getting onto the braking surface and prevents dirt and moisture from entering the bearing. ● **SEE FIGURE 98–7.**

STANDARD BEARING SIZES

Bearings use standard dimensions for inside diameter, width, and outside diameter. The standardization of bearing sizes helps interchangeability. The dimensions that are standardized include bearing bore size (inside diameter),

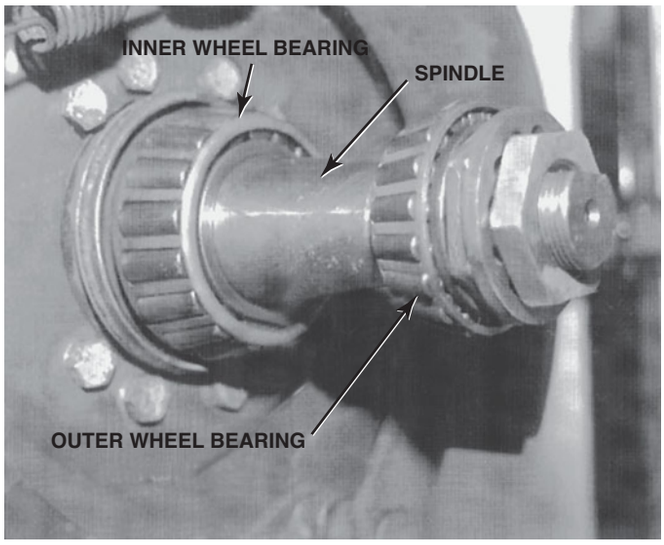

FIGURE 98–7 Non-drive-wheel hub with inner and outer tapered roller bearings. By angling the inner and outer in opposite directions, axial (thrust) loads are supported in both directions.

bearing series (light to heavy usage), and external dimensions. When replacing a wheel bearing, note the original bearing brand name and number. Replacement bearing catalogs usually have cross-over charts from one brand to another. The bearing number is usually the same because of the interchangeability and standardization within the wheel bearing industry.

SEALED FRONT-WHEEL-DRIVE BEARINGS

Most front-wheel-drive (FWD) vehicles use a sealed nonadjustable front wheel bearing. This type of bearing can include either two preloaded tapered roller bearings or a double-row ball bearing. This type of sealed bearing is also used on the rear of many front-wheel-drive vehicles and are usually called *hub assemblies*.

Double-row ball bearings are often used because of their reduced friction and greater seize resistance. ● **SEE FIGURES 98–8 AND 98–9.**

BEARING GREASES

DEFINITION OF GREASE

Vehicle manufacturers specify the type and consistency of grease for each application. The technician should know what these specifications mean. **Grease** is oil with a thickening agent to allow it to be installed in places where a liquid lubricant would not stay. Greases are named for their thickening agent, such as aluminum, barium, calcium, lithium, or sodium.

GREASE ADDITIVES

Commonly used additives in grease include the following:

- Antioxidants
- Antiwear agents
- Rust inhibitors
- Extreme pressure (EP) additives such as sulfurized fatty oil or chlorine

Grease also contains a dye to not only provide product identification but also to give the grease a consistent color.

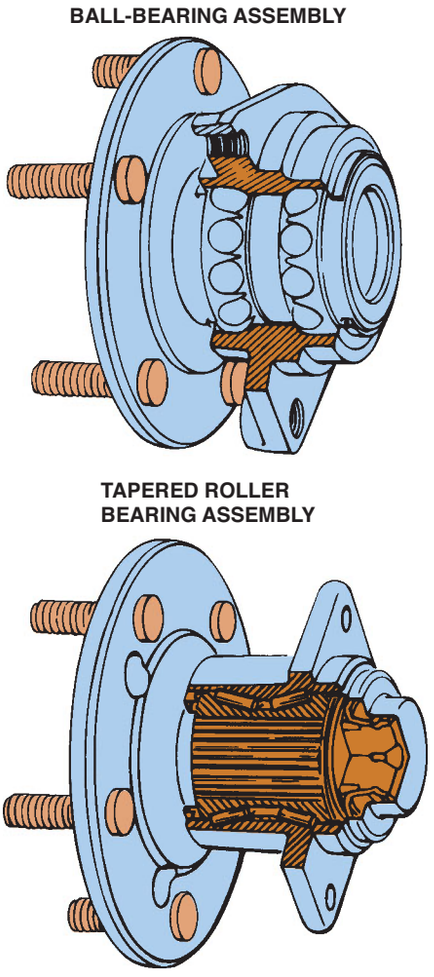

FIGURE 98–8 Sealed bearing and hub assemblies are used on the front and rear wheels of many vehicles.

The grease contains a solid such as graphite or molybdenum disulfide (moly), which acts as an antiseize additive.

NLGI CLASSIFICATION The **National Lubricating Grease Institute (NLGI)** uses the penetration test as a guide to assign the grease a number. Low numbers are very fluid and higher numbers are more firm or hard. Number 2 grease is the most commonly used. See the chart.

NATIONAL LUBRICATING GREASE INSTITUTE (NLGI) NUMBERS

NLGI NUMBER	RELATIVE CONSISTENCY
000	Very fluid
00	Fluid
0	Semi-fluid
1	Very soft
2	Soft (typically used for wheel bearings)
3	Semi-firm
4	Firm
5	Very firm
6	Hard

FREQUENTLY ASKED QUESTION

What Do Different Grease Colors Mean?

Nothing. According to grease manufacturers, grease is colored for identification, marketing, and for consistency of color reasons.

- **Identification.** The color is often used to distinguish one type of grease from another within the same company. The blue grease from one company may be totally different from the blue grease produced or marketed by another company.
- **Marketing.** According to grease manufacturers, customers tend to be attracted to a particular color of grease and associate that color with quality.
- **Consistency of color.** All greases are produced in batches, and the color of the finished product often varies in color from one batch to another. By adding color to the grease, the color can be made consistent.

Always use the grease recommended for the service being performed.

Grease is also classified according to quality. Wheel bearing classifications include the following:

- GA—mild duty
- GB—moderate duty
- GC—severe duty, high temperature (frequent stop-and-go service)

GC indicates the highest quality. Chassis grease, such as is used to lubricate steering and suspension components, includes the following classifications:

- LA—mild duty (frequent relubrication)
- LB—high loads (infrequent relubrication)

LB indicates the highest quality. Most multipurpose greases are labeled with both wheel bearing and chassis grease classifications such as **GC-LB.**

FIGURE 98–10 Typical lip seal with a garter spring.

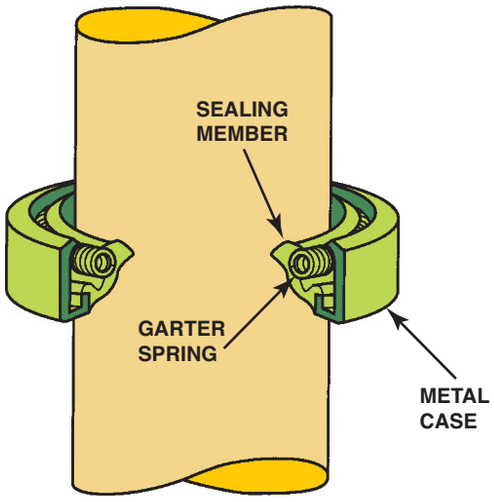

FIGURE 98–11 A garter spring helps hold the sharp lip edge of the seal tight against the shaft.

SAFETY TIP

Smoking Can Kill You

Some greases contain polymers such as Teflon® that turn to a deadly gas when burned. Always wash your hands thoroughly after handling grease that contains these ingredients before smoking. If some of the grease is on the cigarette paper and is burned, these polymers turn into nitrofluoric acid—a deadly toxin.

More rolling bearings are destroyed by overlubrication than by underlubrication because the heat generated in the bearings cannot be transferred easily to the air through the excessive grease. Bearings should never be filled beyond one-third to one-half of their grease capacity by volume.

SEALS

PURPOSE AND FUNCTION

Seals are used in all vehicles to keep lubricant, such as grease, from leaking out and to prevent dirt, dust, or water from getting into the bearing or lubricant.

TYPES OF SEALS

Two general applications of seals are static and dynamic.

- **Static seals** are used between two surfaces that do not move.
- **Dynamic seals** are used to seal between two surfaces where one or both is moving.

Wheel bearing seals are dynamic-type seals that must seal between rotating axle hubs and the stationary spindles or axle housing. Most dynamic seals use a synthetic rubber lip seal encased in metal. The lip is often held in contact with the moving part with the aid of a **garter spring,** as seen in ● **FIGURE 98–10.** The sealing lip should be installed toward the grease or fluid being contained. ● **SEE FIGURE 98–11.**

BEARING DIAGNOSIS

SYMPTOMS OF A DEFECTIVE BEARING

Wheel bearings control the positioning and reduce the rolling resistance of vehicle wheels. Whenever a bearing fails, the wheel may not be kept in position and noise is usually heard. Symptoms of defective wheel bearings include the following:

1. A hum, rumbling, or growling noise that increases with vehicle speed
2. Roughness felt in the steering wheel that changes with the vehicle speed or cornering
3. Looseness or excessive play in the steering wheel especially while driving over rough road surfaces
4. A loud grinding noise in severe cases, indicating a defective front wheel bearing
5. Pulling during braking

DETERMINING BEARING NOISE FROM TIRE NOISE

A defective wheel bearing is often difficult to diagnose because the noise is similar to a noisy winter tire or a severely cupped tire. Customers often request that tires be replaced as a result of the noise when the real problem is a bad wheel bearing. To help determine if the noise is caused by a wheel bearing or a tire, try these tests:

TEST 1 Drive the vehicle over a variety of road surfaces. If the noise changes with a change in road surface, then the noise is caused by a tire(s). If the noise remains the same, then the cause is a defective wheel bearing.

TEST 2 Try temporarily overinflating the tires. If the noise changes, then the tires are the cause. If the noise is the same, then defective wheel bearings are the cause.

TEST 3 A defective wheel bearing will change in noise level when turning. For example a defective left front wheel bearing will usually make more noise when the vehicle is turning toward the right which places more of the vehicle weight onto the left front wheel bearing.

TESTING A WHEEL BEARING

With the vehicle off the ground, rotate the wheel by hand, listening and feeling carefully for bearing roughness. Grasp the wheel at the top and bottom and wiggle it back and forth, checking for bearing looseness.

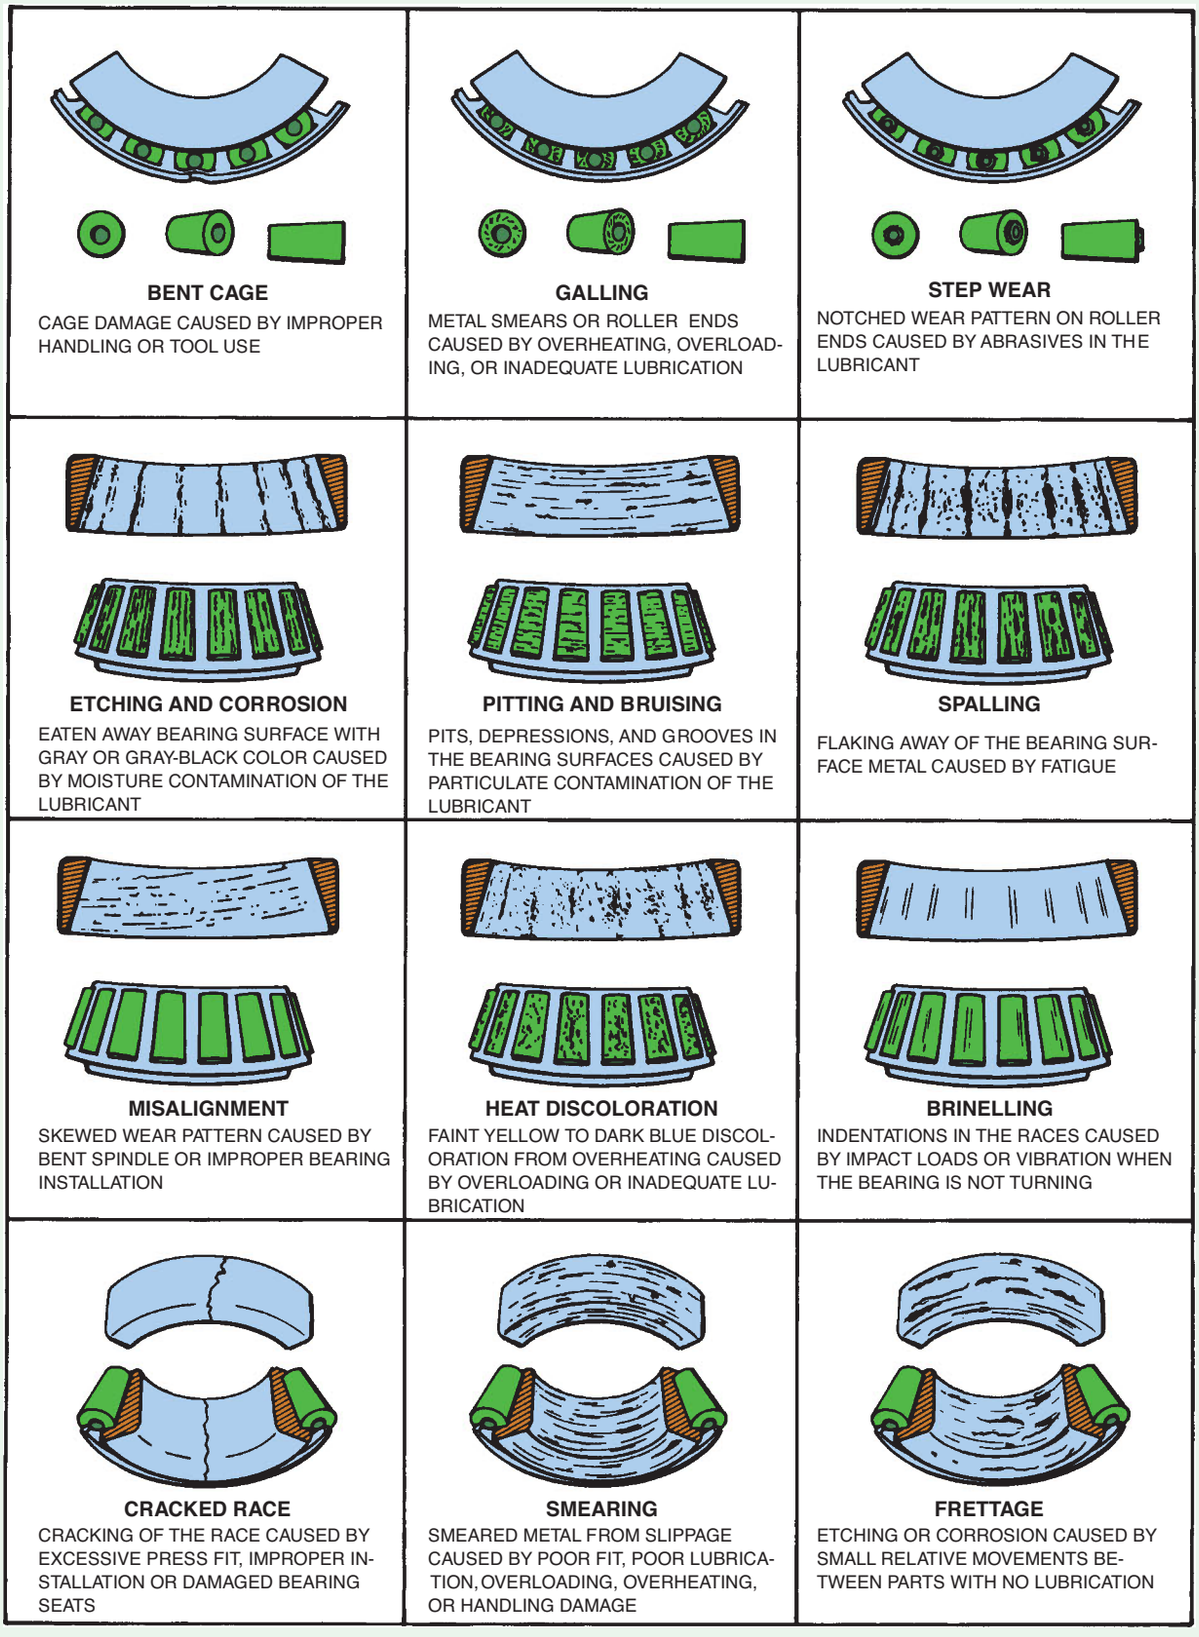
TECH TIP

Easy Wheel Bearing Looseness Test

Looseness in a front wheel bearing can allow the rotor to move whenever the front wheel hits a bump, forcing the caliper piston in, which causes the brake pedal to kick back and creates the feeling that the brakes are locking up. Loose wheel bearings are easily diagnosed by removing the cover of the master cylinder reservoir and watching the brake fluid as the front wheels are turned left and right with the steering wheel. If the brake fluid moves while the front wheels are being turned, caliper piston(s) are moving in and out, caused by loose wheel bearing(s). If everything is OK, the brake fluid should not move. Loose wheel bearings can also cause the brake pedal to sink due to movement of the rotor, causing the caliper piston to move. This sinking brake pedal is usually caused by a defective master cylinder. Before replacing a master cylinder, check the wheel bearings.

WHEEL BEARING SERVICE



The steps in a non-drive-wheel bearing inspection include the following:

1. Hoist the vehicle safely.
2. Remove the wheel.
3. Remove the brake caliper assembly and support it with a coat hanger or other suitable hook to avoid allowing the caliper to hang by the brake hose.
4. Remove the grease cap (dust cap). ● **SEE FIGURE 98–12.**
5. Remove the old cotter key and discard.

NOTE: The term *cotter,* as in cotter key or cotter pin, is derived from the Old English verb meaning "to close or fasten."

6. Remove the spindle nut (castle nut).
7. Remove the washer and the outer wheel bearing. ● **SEE FIGURE 98–13.** Remove the bearing hub from the spindle. The inner bearing will remain in the hub and may be removed (simply lifted out) after the grease seal is pried out.
8. Most vehicle and bearing manufacturers recommend cleaning the bearing thoroughly in solvent or acetone. ● **SEE FIGURE 98–14.** If there is no acetone, clean the solvent off the bearings with denatured alcohol or brake cleaner to make certain that the thin solvent layer is completely washed off and dry. *All solvent must be removed or allowed to dry from the bearing because the new grease will not stick to a layer of solvent.*
9. Carefully inspect the bearings and the races for the following:
   a. The outer race for lines, scratches, or pits.
   b. The cage should be round. If the round cage has straight sections, this is an indication of an overtightened adjustment or a dropped cage. ● **SEE CHART 98–1.**

If either of the above is observed, then the bearing, including the outer race, must be replaced. Failure to replace the outer race (which is included when purchasing a bearing) could lead to rapid failure of the new bearing. ● **SEE FIGURES 98–15 AND 98–16.** Pack the cleaned or new bearing thoroughly with

clean, new, approved wheel bearing grease. Always clean out all of the old grease before applying the recommended type of new grease. *Because of compatibility problems, it is not recommended that greases be mixed.* There are several different ways to pack wheel bearings including:

- **By hand.** Place some grease in the palm of the hand and then force the grease through the bearing until grease can be seen out the other side. ● **SEE FIGURE 98–17.**
- **By hand-operated bearing packer.** A hand-operated bearing packer is faster to use and produces excellent results. ● **SEE FIGURE 98–18.**
- **Grease gun-type bearing packer.** This type of bearing packer uses a grease gun to fill the bearing with grease. The grease gun can be hand-operated or powered by electric or air. ● **SEE FIGURE 98–19.**

10. Place a thin layer of grease on the outer race.

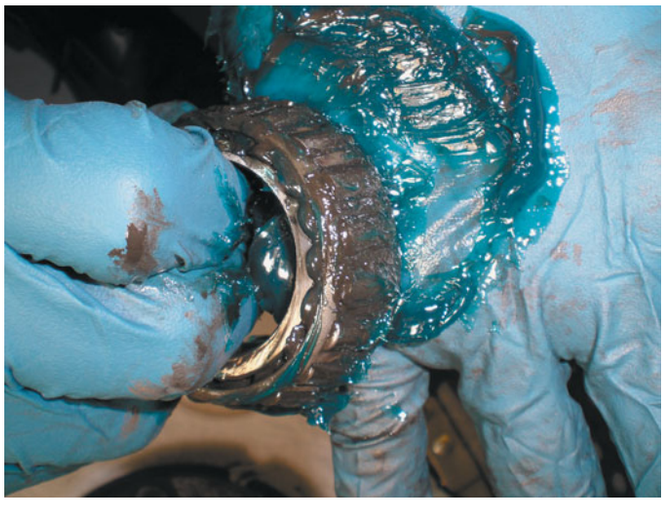

FIGURE 98–17 Notice the new blue grease has been forced through the bearing.

FIGURE 98–18 A commonly used hand-operated bearing packer.

FIGURE 98–19 The wheel bearing is placed between two nylon cones and then a grease gun is used to inject grease into the center of the bearing.

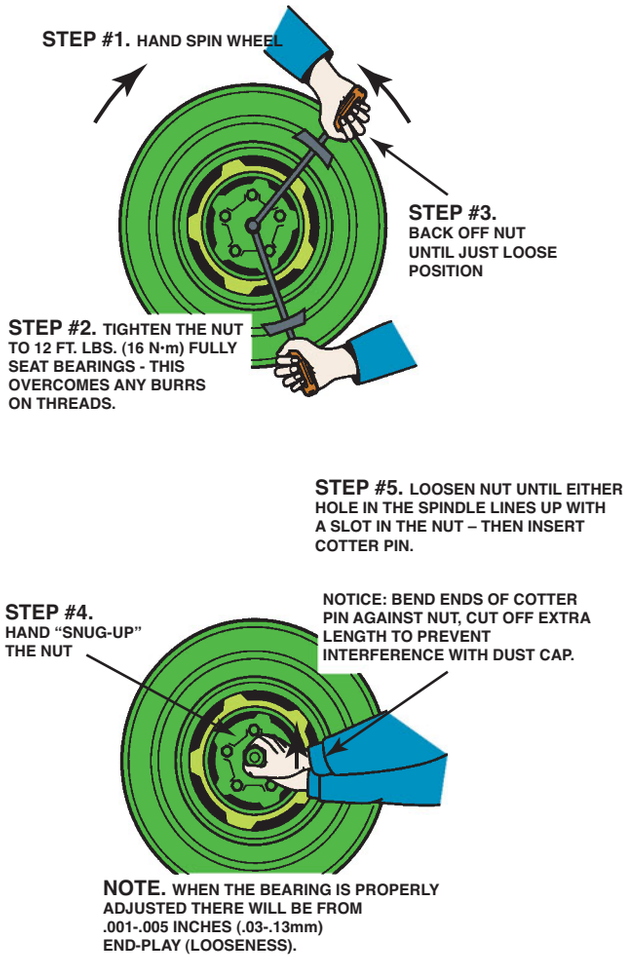

FIGURE 98–20 The wheel bearing adjustment procedure as specified for rear-wheel-drive vehicles. Always check service information for the exact specified procedure for the vehicle being serviced.

11. Apply a thin layer of grease to the spindle, being sure to cover the outer bearing seat, inner bearing seat, and shoulder at the grease seal seat.
12. Install a new **grease seal** (also called a *grease retainer*) flush with the hub using a seal driver.
13. Place approximately 3 tablespoons of grease into the grease cavity of the wheel hub. Excessive grease could cause the inner grease seal to fail, with the possibility of grease getting on the brakes. Place the rotor with the inner bearing and seal in place over the spindle until the grease seal rests on the grease seal shoulder.
14. Install the outer bearing and the bearing washer.
15. Install the spindle nut and, while rotating the tire assembly, tighten to about 12 to 30 lb-ft with a wrench to "seat" the bearing correctly in the race (cup) and on the spindle. ● **SEE FIGURE 98–20.**
16. While still rotating the tire assembly, loosen the nut approximately one-half turn and then *hand tighten only* (about 5 lb-in.).

    NOTE: If the wheel bearing is properly adjusted, the wheel will still have about 0.001 to 0.005 in. (0.03 to 0.13 mm) end play. This looseness is necessary to allow the tapered roller bearing to expand when hot and not bind or cause the wheel to lock up.

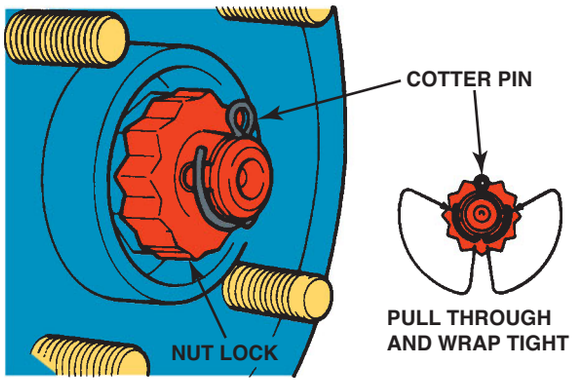

FIGURE 98–21 A properly secured wheel bearing adjustment nut.

17. Install a new cotter key. (An old cotter key could break a part off where it was bent and lodge in the bearing, causing major damage.)

    NOTE: Most vehicles use a cotter key that is 1/8 in. in diameter by 1 1/2 in. long.
18. If the cotter key does not line up with the hole in the spindle, loosen slightly (no more than 1/16 in. of a turn) until the hole lines up. Never tighten more than hand tight.
19. Bend the cotter key ends up and around the nut, not over the end of the spindle where the end of the cotter key could rub on the grease cap, causing noise. ● **SEE FIGURE 98–21.**
20. Install the grease cap (dust cap) with a rubber mallet or soft-faced hammer to help prevent denting or distorting the grease cap. Install the wheel cover or hub cap.
21. Clean grease off the disc brake rotors or drums after servicing the wheel bearings. Use a brake cleaner and a shop cloth. Even a slight amount of grease on the friction surfaces of the brakes can harm the friction lining and/or cause brake noise.

SEALED BEARING REPLACEMENT

Diagnosing a defective front bearing on a front-wheel-drive vehicle is sometimes confusing. A defective wheel bearing is usually noisy while driving straight, and the noise increases with vehicle speed (wheel speed). A drive axle shaft U-joint (CV joint) can also be the cause of noise on a front-wheel-drive vehicle, but usually makes *more noise* while turning and accelerating. Most front-wheel-drive vehicles use a sealed bearing assembly that is bolted to the steering knuckle and supports the drive axle or the rear, as shown in ● **FIGURE 98–22.**

Many front-wheel-drive vehicles use a bearing that must be pressed off the steering knuckle. Special aftermarket tools are also available to remove many of the bearings without removing the knuckle from the vehicle. Check the service information for the exact procedures to follow for the vehicle being serviced. ● **SEE FIGURES 98–23 AND 98–24.**

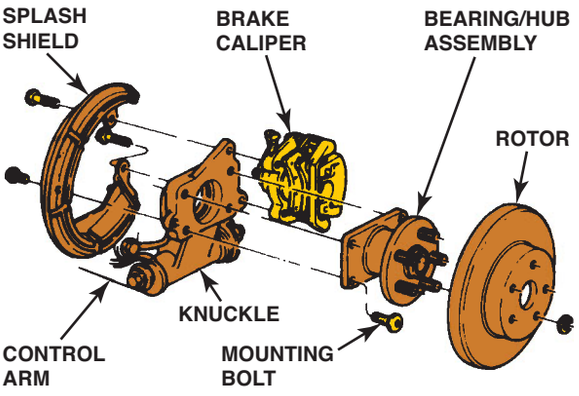

FIGURE 98–22 A rear wheel sealed bearing hub assembly.

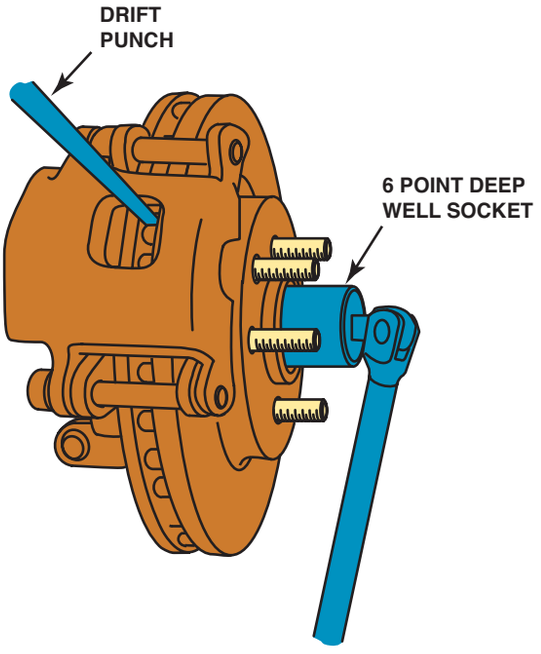

FIGURE 98–23 Removing the drive axle shaft hub nut. This nut is usually very tight and the drift (tapered) punch wedged into the cooling fins of the brake rotor keeps the hub from revolving when the nut is loosened. Never use an impact to remove or install a drive axle shaft hub nut because the hammering action can damage the bearing.

REAR DRIVE AXLE CLASSIFICATIONS

There are three rear drive axle classifications:

- Full-floating
- Three-quarter-floating
- Semi-floating

These classifications indicate whether the axle shafts or the axle housing supports the wheel. The category of a rear drive axle is determined by how the wheel and wheel bearing mount to the axle or housing.

FULL-FLOATING AXLE On a full-floating axle, the bearings are mounted and retained in the hub of the brake drum or rotor. The hub and bearing mount onto the axle housing, and are held in place by a bearing retainer or adjustment nuts and safety locks. The flanged end of the drive axle is attached to the hub by bolts or nuts. The inner end of the axle splines into the differential side gears.

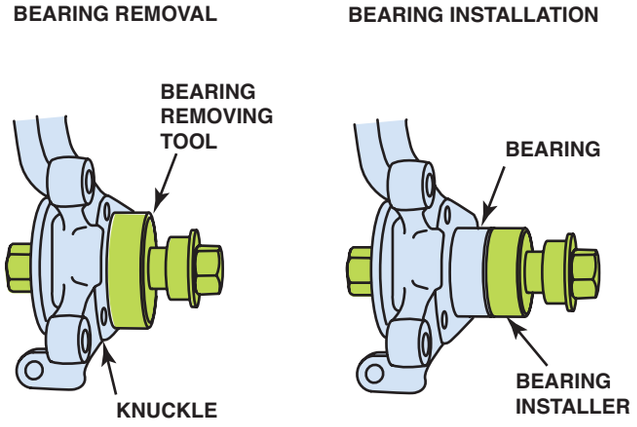

FIGURE 98–24 A special puller makes the job of removing the hub bearing from the knuckle easy without damaging any component.
